The patient is given a sedative the night before and on the morning of the injection also 1/100 grain of atropine is administered hypodermically to exclude vagovagal reflexes The patient is injected in his own bed while lying on the side opposite that to be injected His knees are drawn up and his head bent forward and supported by a pillow as for a spinal tap The highest prominent vertebral spine is the seventh cervical vertebra This and the spinous processes below down to the fifth thoracic, are the bony landmarks Each of these spinous processes is at the same horizontal level as the transverse process and angle of the rib below The injections are made from 3 5 to 4 cm lateral to the spinous process on the side of the pain at the levels of the seventh cervical and upper four dorsal spines

By means of a fine hypodermic needle intracutaneous wheals are made at the sites of injection Then needles 10 cm long are inserted through these wheals perpendicular to the surface of the back and at a depth of 3 to 3 5 cm until they touch the upper four transverse processes or the articulating portion of the ribs These needles should be made of rustless flexible steel thin lumbar puncture needles or special Labat needles may be used Markers of narrow rubber tubing are placed on the needles in order to measure the depth to which the needles are inserted Having been inserted to the point mentioned the needles are then inclined slightly caudally so as to touch the lower border of the transverse process or angle of the rib The depth marker is then pulled up so as to be 3 cm from the skin The needle is directed medially at an angle of 20 and inserted 3 cm until it is felt in contact with the lateral surface of the body of the vertebra If contact is made at a lesser depth the needle should be directed less medially The total depth of insertion through the skin varies from 5 to

6 cm in thin persons to [illegible] to 10 cm in patients with a thick chest wall

After insertion of the needles aspiration is performed to exclude the possibility that the needle may have entered a blood vessel or the subarachnoid space If this occurs the needle is withdrawn and its direction altered When the needles are properly placed [illegible] cc of 2 per cent procain is injected through each Within ten minutes anesthesia should be effected in the axilla the inner surface of the arm and over the third and fourth ribs anteriorly and posteriorly A Horner s syndrome and anhydrosis of the arm and side of the head and neck usually appear with proper anesthesia The hand and usually the neck and face feel hot and dry When this preliminary anesthesia has been accomplished an additional 3 cc of 1 per cent procain is injected at each site to prevent pain from the subsequent injection of alcohol Finally 5 cc of 95 per cent alcohol is injected slowly through each needle withdrawing the plunger of the injecting syringe each 0 5 cc in order to be certain that the needle has not slipped into a blood vessel or subarachnoid space The patient is kept quiet for one hour lying on his side with his back supported by pillows He is usually out of bed the following day if hospitalized for the procedure he may leave in 72 hours

SURGICAL TREATMENT OF ANGINA PECTORIS

The various surgical procedures advocated for the treatment of angina pectoris were designed either (a) to interrupt painful impulses by cutting sensory fibers in the sympathetics or their attachments to the spinal cord (b) to diminish the work of the heart by total thyroidectomy or (c) to promote the development of a collateral circulation to the heart

Resection of Pain Fibers

Earlier operations on the cervical sympathetic chain or ganglia or stellate ganglia gave inconsistent results because they only partially interrupted the sensory pain fibers from the heart Based on the knowledge that all painful impulses from the heart eventually pass through the upper four or five thoracic ganglia their rami communicantes and the corresponding thoracic posterior spinal nerve roots successful results in relieving angina pectoris have been obtained either by (a) surgical excision of the upper four or five thoracic sympathetic ganglia or (b) section of the upper four or five dorsal roots (posterior rhizotomy)

White and Bland[117] reported satisfactory relief with the former procedure in 8 cases with one death Landgren and Olivecrona[63] reported a series of 71 patients in whom stellate ganglionectomy and the removal of the upper three or four thoracic ganglia was performed for angina pectoris with complete relief in 44 per cent substantial relief in an additional 41 per cent unsatisfactory result in 7 per cent and 6 deaths within one month of the operation Pain in the neck or jaw was not relieved Occasionally there was a postoperative pain in the arm ("traumatic neuritis") which usually was mild but in one case required a posterior root section for relief Evans and Poppen[9] reported satisfactory results in 13 of 16 patients with angina pectoris following *bilateral* resection of the first to fourth dorsal ganglia Among the side effects of the operation are a Horner s syndrome swelling of the nasal mucosa and occasional postural hypotension

In cases with bilateral pain a posterior rhizotomy may be preferable because the dorsal posterior roots on both sides can be sectioned at a single operation This is a more formidable operation than ganglionectomy because an extensive laminectomy must be performed Both types of operations are rarely indicated

Total Thyroidectomy

The operation of total thyroidectomy was designed to ameliorate angina pectoris by diminishing the work of the heart and for other theoretical reasons and some satisfactory results were reported However it has virtually been abandoned When considered desirable myxedema may be induced more simply by the administration of radioiodine (p 483)

Production of a Collateral Blood Supply to the Heart

Several procedures have been used

(1) Grafts of intercostal muscle[6] of omentum[78] of lung[23] or of jejunum[57] have been sutured to the heart in the hope that extracardiac vessels in these structures would form functioning collateral channels to the heart These procedures are ineffective and either have been abandoned or have not gained acceptance

(2) *Cardiopericardiopexy* Pericardial adhesions have been produced by irritants to the epicardium[67] or by talc (powdered silica) instilled into the pericardial cavity (Thompson[109]) These procedures are designed to create a sterile granulomatous pericarditis and thus to promote pericardial vascular anastomoses with the coronary arteries Thus it is claimed that attacks of angina pectoris are prevented or diminished in frequency

and exercise tolerance enhanced Autopsies on patients who died ten years or more after the procedures were reported to show that the granulomas provoked by the silica powder remained vascular [77] However it is highly improbable that the fine vascular channels were of any functional importance

A small anterior incision is made over the left fifth costal cartilage, which is excised the pericardial sac is opened and all the pericardial fluid is removed The surface of the heart is completely covered by magnesium silicate powder (using 2 to 6 teaspoonfuls by volume or 4 to 12 gm by weight) Scarification or scraping of the epicardium is unnecessary

In the so called *Beck I operation*[6, 66] there is a combination of (a) abrasion of the epicardium and lining of the parietal pericardium (b) application of an irritant, 0 2 gm of powdered asbestos, to these surfaces, (c) partial occlusion of the coronary sinus where it enters the right atrium and (d) grafting of the parietal pericardium and mediastinal fat to the surface of the heart

De epicardialization is a related surgical procedure designed to relieve angina pectoris by promoting a collateral circulation [45] The application of 95 per cent phenol to the dog's epicardium was found to permit the development of anastomoses between the pericardial and coronary vessels which were large enough to carry the Schlesinger lead agar injection mass, i e, vessels 40 micra or more in diameter In 18 patients with intractable angina pectoris, an operation consisting of phenolization, instillation of talc and pneumopexy has resulted in complete relief of pain in 14 without any operative deaths

The operative mortality in the Thompson procedure is 12 per cent, but this includes operations on very sick, completely incapacitated individuals [108, 77] Pericardial effusion pleural effusion, pneumonitis and atelectasis are common postoperative occurrences Fever persists one or two weeks According to criteria set up by Thompson and Plachta,[108] there was a 50 per cent improvement in 90 per cent and a 75 per cent improvement in 40 per cent of the operated patients In this latter group the patients required no medication and no restriction of physical activity after recovery from the operative procedure In another group of 36 patients subjected to talc cardiopericardiopexy the results were interpreted as excellent in 14, good in 12 [1] The immediate operative mortality was 5 5 per cent (2 patients) and another two patients died of non cardiac causes in the follow up period The average hospital stay was 10 to 14 days Of 33 patients who had the Beck I operation there was no anginal pain in 36 3 per cent and less pain in 48 5 per cent, for a total of 84 8 per cent 27 2 per cent were better able to work without limitations and 51 4 per cent with some limitations, for a total of 78 6 per cent [6, 14] The immediate postoperative mortality rate of about 7 per cent has decreased considerably with experience

(3) Ligation of the great cardiac vein with or without pericoronary neurectomy[30, 31] has been performed This was based on observations that preliminary ligation of the coronary sinus in dogs greatly diminishes the incidence of death or myocardial infarction after subsequent experimental ligation of a coronary artery [29] This procedure has given way to the other operations discussed in this section

(4) *Beck Operation II* [6, 31, 14] In the first stage operation a vein graft is placed between the aorta and coronary sinus for the purpose of shunting arterial blood After an interval of two or three weeks, at the second stage procedure, the coronary sinus is partially occluded in order to raise the pressure in that vessel This is designed to cause the arterialized blood entering the sinus from the aorta to flow retrograde, back to the coronary capillaries Experimental observations in dogs indicated that this operation was effective, when a major coronary occlusion was later induced in reducing fatalities in preventing myocardial infarction or in diminishing the size of an infarct However, subsequent studies[26, 2] indicate that retroperfusion of the capillary bed persists only for about five weeks, after which the vein becomes occluded and loses functional contact with the capillary bed In view of this finding the beneficial effect of the operation is now attributed to the early development and persistence of functioning intercoronary collaterals which may have been produced by myocardial anoxia caused by the operation [65] The Beck II operation is being performed less frequently because of the special skill and training required the need for two operations the relatively high operative mortality (26%) and the

occasional development of congestive heart failure due to the fistula

(5) *Implantation of Internal Mammary Artery into Myocardium*[112] Vineberg implanted the internal mammary artery with an open freely bleeding intercostal branch directly into the left ventricular myocardium the artery being pulled into a myocardial tunnel after blunt dissection between the muscle bundles Pericardial fat pads used as grafts were applied to the surface of the left ventricle to supplement internal mammary artery implantation It was claimed that the implanted artery sent out large branches to the ventricular myocardium in over 70 per cent of experimental animals and that these branches were large enough to carry a supply of arterial blood into the heart at a rate as high as 51 cc per minute The presence of patent anastomoses between the implanted artery and the coronary arterial branches was confirmed by Glenn et al [36] but the new vessels were small resembling granulation tissue and tended to disappear at the end of eight weeks After four years experience with this operative procedure in the treatment of 29 patients with coronary artery insufficiency Vineberg et al [11] reported that about 70 per cent of the patients were greatly improved and returned to work The mortality rate was 4 3 per cent among patients with angina pectoris at rest

Evaluation of Surgical Revascularization of the Heart

Despite the claims made for the various operative procedures their value for the treatment of angina pectoris or other forms of coronary heart disease has not been established The results improve according to (or because of) the degree of enthusiasm of the surgeon or the medical collaborator Nevertheless many patients claim to have experienced considerable improvement after these operations and it is sometimes necessary to subject patients to them For the present I consent to trial of the coronary operations only for patients with intractable angina pectoris and only after all forms of medical therapy have been exhausted It has not been recommended as a protection against further myocardial infarction in patients with more than one coronary occlusion Heart failure is regarded as a contraindication It has seemed to me that among the patients who have reported benefit the anginal or associated pain and disability were often or usually atypical in many respects and that emotional factors were especially important The Thompson the Beck I and the Vineberg procedures are the ones most frequently performed currently

It has not been satisfactorily demonstrated that these current surgical procedures actually increase the blood supply to the heart by the collateral circulation which the operations are designed to create Direct observations on hearts so operated fail to show that the induced pericardial vessels the venous graft or the implanted mammary artery are of significant size or persist long enough to be of functional importance The cardiopericardial vessels induced by silica powder are puny and do not even compare with the substantial intercoronary vessels already present in the heart with significant coronary heart disease The vessels formed after internal mammary implantation are both unimpressive in size and usually insignificant or occluded after eight weeks The Beck I procedure accomplishes little if anything more than the Thompson silica operation In the Beck II operation the graft does not remain patent or does not maintain contact with the coronary bed after about five weeks

Thus any benefit that may accrue from these operations is due to better preoperative or postoperative medical care to the psychic influence of an operative procedure and the promise and enthusiasm accompanying it or to some factor in the operation which is not understood but not directly due to the new collateral circulation That the operative procedure may result in myocardial anoxia sufficient to induce intercoronary anastomoses [6] similar to those which follow coronary occlusion[13 14] has been mentioned The possibility that the interruption of nerve pathways may be concerned in the mechanism of chest pain must also be considered

In the absence of direct demonstration that functionally significant collateral vessels are produced by these operations the evidence purported to show their beneficial influence in patients with coronary insufficiency is unconvincing Experiments have been reported which were said to demonstrate that the prophylactic performance of one of these operations reduced the mortality

rate and prevented myocardial infarction or diminished the size of the infarct following a subsequently induced coronary occlusion in dogs These observations are difficult to evaluate because the results have been variable and contradictory and depend in large measure on the exact site of coronary occlusion and on the relatively frequent presence of large anastomoses between the major coronary arteries in the dog Burchell[18] demonstrated that all the coronary arteries in the dog could be gradually occluded without the development of myocardial infarction even though no protective operation had been performed previously to increase the coronary blood flow Other experimental evidence of the benefit of these operations consists in the demonstration of a backflow from the cannulated distal end of a ligated and cut coronary artery[illegible] Such evidence has been likewise contradictory and not directly applicable to the possible value of these operations in human coronary heart disease In humans with severe angina pectoris, coronary occlusions with intercoronary anastomoses are already present[18] and the value of the added operation is questionable Finally in humans *evidence of benefit is indirect and consists of* reported relief or diminution of pain and increased functional capacity Because of the psychic and subjective factors involved in these criteria, they are notably subject to error and bias Evidence of increased survival after the operations is even more difficult to evaluate because of our incomplete knowledge and the variable nature of the course of angina pectoris

Selective Vagotomy

Because neurogenic factors appear to be concerned in the occurrence of angina pectoris, Scherlis and Cowley[44] studied the advisability of eliminating vagal coronary vasoconstrictive impulses In anesthetized open chest dogs, stimulation of cardiac branches of the left thoracic vagus nerve produced electrocardiographic changes resembling those of acute "through-and through" myocardial infarction, whereas stimulation of the stellate ganglion caused S-T depressions suggestive of subendocardial myocardial ischemia In 4 patients with severe angina pectoris not relieved by accepted medical therapy section of the vagal cardiac branches resulted in great improvement in three and slight improvement in the fourth patient

MANAGEMENT OF ACUTE ANGINA PECTORIS STATUS ANGINOSUS ANGINA DECUBITUS INTRACTABLE ANGINA PECTORIS

In many patients the status of angina pectoris remains fairly stabilized, variations in the frequency and severity of the attacks of pain depending on similar variations in environmental and physiologic factors, such as the degree of physical activity, climatic conditions, intake of food, emotional states and the like One may then regard the organic factors (coronary disease aortic valvular disease, and so on) which are responsible for the diminished coronary reserve as fairly stable, whereas the physiologic disturbances which strain the cardiac reserve vary in frequency and degree, but are usually transient From time to time there is an acute "coronary" disturbance during which the character of the anginal syndrome is altered The attack of pain may be more prolonged and more severe, it may occur at rest and without obvious cause whereas previously there was an apparent precipitating factor, it may occur particularly when the patient is recumbent with more or less relief on sitting or standing (angina decubitus), it may occur more frequently and with less and less provocation, rest and/or nitroglycerin may afford little or no relief or the relief may be of minimal duration (status anginosus intractable angina)

Under these varied circumstances a search must be made carefully for some physiologic or emotional change that could possibly account for the altered clinical state As a rule however the cause is an organic factor which further diminishes or eliminates the coronary reserve or rarely an organic stress such as hyperthyroidism which cannot be handled by the preexisting subnormal coronary reserve A common but usually easily recognized organic factor which further reduces the coronary reserve and alters the status of angina pectoris, is an acute coronary occlusion with myocardial infarction Its treatment is discussed in Chapter 21

Greater diagnostic difficulty is afforded when the organic factor is an acute coronary thrombosis or an intimal hemorrhage with extreme reduction in size or occlusion of the coronary lumen but without myocardial infarction Although viability of muscle is maintained by collateral circulation the coronary reserve is minimized or eliminated and anginal pain occurs at rest or with minimal

stress Under such circumstances the patient should be inactivated chiefly by rest in bed for about two weeks to permit the development of intercoronary anastomoses and to prevent the development of myocardial necrosis during the unstable period When collaterals are developing anticoagulants may be as desirable as if one were treating a patient with coronary occlusion and myocardial infarction Nitroglycerin should be administered as often as necessary to relieve pain or prophylactically to minimize the frequency of attacks

The appearance of angina decubitus without objective signs of myocardial infarction also suggests an acute coronary occlusion without infarction It is presumed that *coronary reserve is now minimal* but usually adequate when the patient is upright With recumbency the increased venous return and work of the heart cannot be handled by an appropriate increase in coronary blood flow as occurs normally *An element of left heart failure may be concerned in this mechanism* Treatment should consist of elevation of the head of the bed multiple pillows special beds to permit sleep with the chest and head elevated nitroglycerin before retiring and as needed to relieve pain a two-week rest period to permit stabilization of a collateral circulation anticoagulant therapy if feasible as well as a therapeutic trial of measures to control left-sided heart failure (Chap 11)

When a patient is first seen within a *few days* after his first attack of angina pectoris it is probable that an acute coronary occlusion has also occurred (p 457) even when there is no myocardial infarct and he is treated as above with modified bed rest and so on in the hope of avoiding myocardial infarction and permitting the development of a collateral circulation This does not apply to the patient who already has stabilized chronic angina pectoris when first observed

Occasionally the organic factor which suddenly reduces the coronary reserve is not a coronary occlusion but a non-cardiac disease such as anemia due to gastrointestinal bleeding or a hemolytic anemia pulmonary embolism or other condition producing shock with or without coronary constriction Under these circumstances the causative factor should be treated and corrected if possible Loss of coronary reserve and intensification of anginal symptoms in calcific aortic stenosis or syphilitic coronary ostial narrowing may represent the last stage of a progressive disease and the outlook is poor but they may also be due to a complicating coronary atherosclerotic occlusion to which the heart may adjust or to a remediable non-coronary factor

Finally the intensification of angina pectoris may not be followed after a variable period by readjustment and clinical improvement Under such circumstances the frequency and severity of attacks of pain their occurrence with minimal or no apparent provocation and the enforced limitation of activity render the patient both miserable and an invalid When these symptoms persist for at least six months despite every *effort to eliminate or alleviate any possible* contributory factor and despite the frequent use of nitroglycerin and other drugs which sometimes appear helpful the angina pectoris may then be labeled intractable The *psychic factors which are apparent in many* patients often present great difficulty in evaluation of the angina pectoris Psychotherapy should always be employed in patients with intractable angina Recently I have observed a dramatic response to what was termed intractable angina pectoris for two years following the administration of chlorpromazine (Thorazine) I have a series of patients with persistent anginal pain weakness and other symptoms following myocardial infarction who have had a good clinical response after electric shock or electronarcosis therapy However when there is no clear indication for such procedures in a patient with intractable angina pectoris I usually recommend the induction of myxedema with radioactive iodine (I^{131}) If this is not accepted or is ineffective I consent to the *performance of the Thompson (p 485) or* Beck I operation (p 486) It is important that the patient with intractable angina pectoris should not be rendered an addict to opiates while the physician is deciding to await the effect of simple medical therapy

Chapter 19

ACUTE CORONARY OCCLUSION AND MYOCARDIAL INFARCTION

Etiology, Pathologic Physiology and Pathology

Definitions

Coronary thrombosis refers to the disease associated with an acute thrombotic occlusion of a major coronary artery The thrombosis is almost always a complication of coronary atherosclerosis and is an intrinsic stage of the atherosclerotic process Acute *coronary occlusion* is a more inclusive term denoting the sudden obstruction of a coronary artery either by the development of a thrombus or by an intimal hemorrhage with swelling of the arterial wall or by an embolus

Myocardial infarction signifies the necrosis or death of a portion of heart muscle because of an interruption or curtailment of its blood supply While it is usually the result of an acute coronary occlusion, infarction of the myocardium may also occur without mechanical obturation of a coronary artery, following a sharp reduction in the volume or oxygen content of the coronary blood due to circulatory or hematologic disturbances *Cardiac infarction* may be a more accurate designation than myocardial infarction in many instances in which the pericardium and endocardium as well as the heart muscle are affected by the coronary occlusion

Coronary thrombosis is associated with a distinctive clinical picture characterized usually by pain in the chest, similar in location and radiation to that of angina pectoris but differing in its greater severity and duration, in its usual independence of exertion and especially in its frequent association with evidences of shock and of acute left ventricular failure, fever leukocytosis and persistent and progressive electrocardiographic changes Actually these clinical features are due to myocardial infarction and not to the coronary occlusion as such Prolonged clinical usage and the usual concomitance of coronary occlusion and myocardial infarction have justified the interchangeable use of these terms when referring to the above clinical syndrome But for clarity in the interpretation of the clinical and laboratory phenomena it is essential to understand that they issue from the infarcted heart muscle and not from the coronary occlusion per se

This distinction is important, for acute coronary occlusion and myocardial infarction are not invariably associated It is now recognized that coronary occlusion may and frequently does occur without ensuing infarction,[8] and conversely that myocardial infarction may develop in the absence of an acute coronary occlusion [27] The same clinical picture is associated with myocardial infarction whether or not the latter is due to an acute coronary occlusion, on the other hand the above mentioned characteristic pain, fever leukocytosis and typical electrocardiographic changes do not follow the occlusion unless myocardial infarction ensues

Frequency and Importance of Acute Coronary Thrombosis

As heart disease is now the acknowledged greatest single cause of death in this country so coronary thrombosis is the most important cause of heart disease The cardiac mortality rate in 1940 was 292 5 per 100 000 population and 25 per cent of this was attributed to disease of the coronary arteries most of the latter undoubtedly represented coronary thrombosis and its consequences Another 46 per cent of the cardiac mortality was attributed to chronic myocarditis and myocardial degeneration, which surely includes a large

though undefined percentage of cases of acute and chronic coronary thrombosis In 1950 the crude death rate from all forms of heart disease was 354 2 per 100 000 145 4 representing that due to diseases of the coronary arteries [64]

The Increased Incidence of Coronary Thrombosis

There has been a progressive increase in the reported incidence of coronary occlusion and this rising curve of mortality has not yet levelled off The crude death rate from coronary disease had risen from 7 9 per 100 000 in 1930 to 23 1 in 1935 subsequently this increased to 71 4 in 1940 and to 226 1 in 1952 That the increase is real not merely due to improved diagnosis or more complete reports was indicated by the studies of Morris [65] In part the increased incidence is due to the reduction in childhood and other infections and to other advances in medical knowledge In consequence a larger proportion of the population reaches the age groups in which death from atherosclerotic coronary thrombosis is frequent

ETIOLOGY OF ACUTE CORONARY OCCLUSION

UNDERLYING CAUSES

Atherosclerosis of the Coronary Arteries

This is responsible for at least 95 per cent of the cases of acute coronary occlusion The etiology of atherosclerosis itself has been discussed in Chapter 16 p 417 This chapter is concerned essentially with acute coronary occlusion due to atherosclerosis Very rarely an acute occlusion is due to other causes including syphilitic occlusion of the ostia of the coronary arteries (p 894) and coronary embolism (p 440) and very rarely periarteritis nodosa dissecting aneurysm of the aorta (p 556) neoplasms or tuberculosis and possibly rheumatic fever and thromboangiitis obliterans Myocardial infarction due to granulomatous giant-cell arteritis of the type causing temporal arteritis has been reported [67] A case of myocardial infarction due to dystrophic calcification of the coronary arteries associated with calcification of the adrenal and thyroid glands was reported in an 8 week old infant [68]

CONTRIBUTORY AND PREDISPOSING FACTORS

The contributory and predisposing factors in acute coronary thrombosis and myocardial infarction are those which are concerned with the underlying coronary atherosclerosis and have been discussed (p 416) See also p 1034

Hypertension and Diabetes

Hypertension [4, 49, 29] and diabetes [33, 71, 72, 70, 1] are particularly important but not essential to the occurrence of coronary thrombosis The relative infrequency of coronary thrombosis in females in the absence of hypertension or diabetes is still worthy of note [43, 5, 4]

Familial Hypercholesterolemia (p 425)

Myxedema (pp 1017 1020)

Polycythemia (p 1051)

Disease of the Biliary Tract

A possible association of disease of the biliary tract and coronary heart disease including coronary thrombosis was discussed under angina pectoris

Age

At least 90 per cent of the cases of acute coronary thrombosis and myocardial infarction occur in persons between the ages of 40 and 70 My own experience corresponds with those studies which have revealed a somewhat higher incidence between the ages of 50 and 60 than in any other decade [61] but others have found the peak between 60 and 70 [42, 44, 45] As the ability to diagnose acute coronary thrombosis has improved and become widely disseminated this disease has been recognized with increasing frequency in subjects below the age of 50 and even before the age of 40 Furthermore it is highly probable that there has been a real increase in the incidence of coronary thrombosis with acute myocardial infarction before the age of 40 The occurrence of this condition in young persons previously reported as occasional has been emphasized by reports of large series of cases among soldiers between the ages of 18 and 40 [4, 51, 52, 53, 54, 24, 19] Most of these cases were fatal as a rule death occurred suddenly and unexpectedly Probably 5 per cent of first attacks of acute coronary thrombosis occur before the age of 40 Rarely proven cases have even been observed in childhood and infancy Thus although acute coronary thrombosis with myocardial infarction is essentially a disease of middle life and thereafter it may occur at any age and youth is no contraindication to its diagnosis when the history and findings are characteristic

Sex

There is a notable preponderance of males among patients suffering from acute coronary thrombosis Reported series of cases indicate a

ratio of males to females varying between 2 to 1 and 6 to 1[4, 49, 4, 51, 52] The ratio of 3 to 1, based on studies of cases at autopsy, is probably more accurate than the higher ratios reported in clinical series The preponderance of males is most striking in those cases of coronary occlusion in which there is neither hypertension nor diabetes mellitus Several explanations have been offered for the lesser susceptibility of women to coronary atherosclerosis and thrombosis,[38] notably the difference in lipid metabolism and the effect of estrogens (Chap 16)

On the other hand there was a recent report of an unexpectedly high incidence of myocardial infarction in the Negro female[3,9] In addition myocardial infarction was found to be associated much less frequently with angina pectoris and was associated with a higher fatality rate than that in the white race and in the Negro male

Occupation

There are insufficient data to permit a definite conclusion as to the etiologic relationship between occupation and the occurrence of coronary thrombosis[48, 57] It is improbable that occupation is an important predisposing factor The statistical and epidemiologic surveys of Morris et al[58] indicated that men in physically active jobs have a lower incidence of coronary heart disease and less severe disease than men whose work requires less physical activity

Heredity

Hereditary susceptibility appears to be a more fundamental etiologic factor in the occurrence of coronary atherosclerosis and occlusion than most of those already mentioned Every physician who has obtained a careful and accurate family history in his patients with coronary artery disease must have been impressed by the frequency with which angina pectoris, sudden death or proven attacks of acute coronary thrombosis occur in several members of the same family I have found this family tendency to be most striking in patients who suffered their acute coronary occlusion at an early age One of my patients died of his first coronary occlusion at the age of 35 and his only brother of the same cause at 39 Their father had died suddenly at 40 and their paternal grandfather had also died suddenly in his early forties, both presumably of a heart attack Hypertension cerebral hemorrhage or thrombosis and diabetes mellitus appear to occur with more than average frequency in the same families[4] The hereditary factor in familial hypercholesterolemia and xanthomatosis and its relation to coronary occlusion has been noted (p 425)

Body Build (p 416)

Temperament

The rising incidence of acute coronary thrombosis has sometimes been attributed to the increased strain of modern living Many patients with this disease disclose a history of recent or prolonged psychic conflict and emotional stress For this reason, coronary thrombosis, like hypertension, peptic ulcer and hyperthyroidism has been interpreted by some as primarily a psychosomatic disease occurring in specific susceptible personality types[1] Many of the patients with advanced coronary disease may be described as aggressive ambitious individuals with an intense physical and emotional drive, who have no hobbies and have not learned to play, and who have concentrated all their thoughts and energy in the narrow groove of their career However it need hardly be mentioned that there are also patients with coronary occlusion who do not fit this description The interpretation of this condition as primarily a psychosomatic disease has little scientific support at the present time However, the possible importance of psychic factors in the etiology of coronary artery disease is worthy of careful investigation

Tobacco (pp 416 451)

PRECIPITATING FACTORS

We have seen that attacks of angina pectoris occur promptly after certain precipitating factors such as effort, exposure to cold the intake of food and emotional excitement Although an acute coronary occlusion also appears to develop suddenly, its precipitating factors are still unknown and the causes responsible for attacks of angina pectoris do not usually initiate a coronary occlusion Analyses of the events immediately preceding episodes of acute coronary occlusion have not usually demonstrated a causal relationship between specific activities and the occlusion

Physical Exertion

In a study of patients' activities immediately prior to an acute coronary occlusion in 437 cases, Phipps[63] noted physical exercise in only 13 per cent and moderate or usual exertion in 18 per cent while in 51 per cent of

the cases the patient was at rest and in 8 per cent asleep Surgical procedures had been performed in 6 per cent In 19 per cent of the cases the occlusion had occurred during moderate exertion after a heavy meal and in 12 per cent after a meal but with the patient at rest Similar investigations by Master Dack and Jaffe[43] revealed that among 1108 attacks of acute coronary thrombosis 52 per cent occurred while the patient was asleep or resting 21 per cent during mild routine activity 16 per cent while the patient was walking and 9 per cent during moderate activity In only 2 per cent was there a history of unusual physical exertion This analysis led the authors to conclude that the percentage of attacks which occurred during sleep rest or mild moderate or intense activity coincided with the proportion of the day spent in these states and that physical exertion which is an important precipitating factor of angina pectoris is not concerned in the initiation of acute coronary occlusion

Unfortunately such studies may be invalidated by the difficulty of obtaining an accurate and complete history and especially by the nature of the pathology of coronary occlusion Although the characteristic symptoms of acute coronary occlusion usually develop suddenly the underlying pathologic process and functional disturbances associated with the occlusion may commence hours or days before distinctive symptoms appear Sometimes there are premonitory symptoms during this period which are forgotten by the patient in the throes of the more intense symptoms of the full blown attack Not infrequently the patient denies any unusual effort prior to the occlusion but questioning of a relative friend or business associate discloses some extraordinary or dramatic activity which might have been causal Since the actual occlusion precedes the striking symptoms of the attack by hours or days the factors responsible for the occlusion may have acted hours days or even weeks before the appearance of symptoms Therefore efforts to discover the precipitating cause by recording the events or activities immediately preceding the first major symptom of an acute coronary occlusion may be misleading

While the observations of Phipps[52] and of Master et al [43] indicate that physical exertion is not a precipitating cause of acute coronary occlusion other authors have reported cases in which there is strong circumstantial evidence for such a causal relationship Among 100 cases of acute coronary occlusion Fitzhugh and Hamilton[24] noted that the occlusion had occurred 24 times during or promptly following some unusual and violent physical exertion and 33 times after an unusual exertion which was not necessarily violent Boas[10] reviewed reported cases of cardiac infarction following unusual effort and described briefly 13 out of 25 cases which had come under his personal observation Cooksey[14] found that 17 out of 100 private cases of acute coronary occlusion had developed within 24 hours of definitely unusual and frequently extreme physical exertions Smith and associates[73] found that physical exertion was associated with the attack in 32 of 53 cases of coronary occlusion Yater and associates[9] reported that the proportion of attacks among young soldiers occurring during strenuous activity was more than twice as great as the proportion of time spent in such activity French and Dock[26] found that 26 or 3› per cent of 80 fatal attacks of coronary disease occurred within one to several hours after vigorous exercise The exertions reported as unusual or severe by the various authors included cranking a car in cold weather lifting a heavy trunk pushing a stalled auto rowing long hikes uphill etc all of which had never been performed previously by the patient in question or had not been done for many years Fitzhugh and Hamilton[24] emphasized that the effort had often been performed when the subject was suffering from undue fatigue inadequate sleep and excessive emotional strain In conclusion while the evidence adduced by Master and his associates[43] might indicate that physical exertion is not an essential or even important precipitating cause in most cases of acute coronary thrombosis it does not exclude the possibility that it induces at least some of the instances of coronary thrombosis

Several suggestions have been offered to explain a possible causal relationship between physical exertion and acute coronary occlusion and myocardial infarction The mechanism which often initiates the actual occlusion is probably a capillary hemorrhage within an atherosclerotic plaque in the intima [5, 50] ■ Paterson[5] suggested that a ■ e in arterial blood pressure associated with physical exertion and emotion may be responsible for the

rupture of intimal capillaries and a subsequent thrombosis Physical exertion may also be indirectly related to the development of a myocardial infarct after an acute coronary occlusion has already occurred Because of a collateral circulation the occlusion itself may not produce sufficient myocardial anoxia to result in infarction Severe physical effort at this time by augmenting the work of the heart, may enhance the degree of anoxia and cause necrosis of myocardial tissue This suggestion is supported by the finding of Yater and associates[3] that only 11 per cent of those patients with coronary artery thrombosis who died in bed had old or organizing thrombi while 38 per cent of those engaged in strenuous activity had such thrombi Similarly the observation of French and Dock[26] that a fatal attack during exertion was often associated with severe coronary artery narrowing but no occlusion may indicate that the exertion intensified a potential or relative coronary insufficiency to the point of causing fatal myocardial anoxia

Emotional Strain

Emotional strain even more than physical exertion is difficult to evaluate as a factor in the occurrence of an acute coronary occlusion The purported increase in the incidence of this condition has been loosely attributed to the stress of modern living Clinical histories upon which such conclusions are based are usually incomplete or unreliable for they are deficient in the necessary psychiatric detail They often fail to include possible causative emotional disturbances which have occurred days or even weeks before the attack The duration as well as the intensity of the emotional disturbance may be of etiologic importance Emotional strains are varied in character and must be interpreted in terms of their effect on the individual and his reaction to them In eliciting a history of emotional disturbance one must be certain that a similar history could not be obtained from numerous persons without a coronary occlusion or even from the patient himself during many previous years when he was perfectly well But despite these difficulties and uncertainties I do not wish to dismiss the possible relation of emotion to the precipitation of acute coronary occlusion without comment I have so often noted the occurrence of this condition in persons who had been under an unusually severe and protracted emotional strain that I believe this possible relationship is worthy of serious study Its implications in prophylaxis and therapy are obvious

Coronary thrombosis has been observed after an acute emotional experience as well as after prolonged emotional stress Boas[11] has reported some historical as well as personal cases of this type

Trauma[39, 43]

Trauma may produce a pericardial and myocardial contusion with hemorrhage into and destruction of the muscle tissue of the heart (Chapter 44) The resulting clinical picture may resemble that of myocardial infarction Or the injury may involve a large coronary artery and induce a coronary thrombosis with true myocardial infarction[41] The injury may be of the penetrating variety, such as a stab or gunshot wound, but similar consequences may result from nonpenetrating blows to the chest wall (p 1063)

These cases of traumatic myocardial contusion or of direct injury and thrombosis of a coronary artery must be distinguished from cases of atherosclerotic coronary occlusion in which unusual physical exertion appears to be a possible precipitating factor In the former, the essential causative role of the trauma may be supported by the finding at necropsy of a myocardial hemorrhage or an injured and thrombosed artery in a heart whose vessels are otherwise relatively normal In the latter cases the occlusion is found in a markedly atherosclerotic vessel

Operations

Attacks of acute myocardial infarction soon after operation have been observed with sufficient frequency to suggest that there is a significant causal relationship between the operation and the acute infarction[8] In most instances of acute myocardial infarction postoperatively the infarction is secondary to an acute coronary occlusion on an atherosclerotic basis In other cases however the infarction occurs without associated coronary occlusion The occurrence of shock with its associated fall in blood pressure could reduce the coronary blood flow and result in sufficiently severe myocardial anoxia to cause necrosis of muscle even though the coronary vessels were not occluded (p 505) This mechanism could be intensified by hemorrhage, dehydration and tachycardia The possibility of a coronary occlusion after an operation often poses a problem in the diagnosis of

postoperative complications since the classic pain associated with myocardial infarction may be absent or overshadowed by other symptoms in these cases and since postoperative myocardial infarction may closely resemble surgical shock and pulmonary embolism.

Among other factors[11] which have been reported as occasional precipitating or contributing causes of acute myocardial infarction are infections of the respiratory tract, insulin hypoglycemia,[29] artificial hyperpyrexia, high altitude, drinking of ice water, injections of antitoxin,[80] serum sickness[72] and so called vascular allergy.

A history of angina pectoris has been noted in one third to two thirds of cases of acute myocardial infarction. This merely denotes that clinical evidence of advanced coronary atherosclerosis or previous coronary occlusion often precedes a fresh coronary thrombus and cardiac infarct.

PATHOLOGIC PHYSIOLOGY

THE EFFECT OF EXPERIMENTAL ACUTE CORONARY ARTERY LIGATION

Mortality and Occurrence of Infarction

The early experimental attempts at acute ligation of a large coronary artery in animals usually resulted in rapid arrest of the heart and led to the conclusion that the coronary arteries were end arteries.[17] Porter[64] observed that the frequency of cardiac arrest following experimental acute coronary occlusion in dogs was dependent in part on the type of anesthetic used. More recent observers have demonstrated that acute coronary occlusion in animals is *not* invariably fatal and is compatible with long periods of survival and well being.[73]

However, if one of the three major coronary arteries is completely ligated close to its origin, a large infarct of the corresponding area of myocardium almost invariably develops.[74, 30] This corresponds in general with the usual consequence of a similar acute coronary occlusion in humans and suggests that functionally at least these vessels may act as end arteries, even though anatomic anastomoses are present and establish a *functioning* collateral circulation. On the other hand, the acute experimental occlusion of a secondary branch or the acute occlusion of a major branch in its distal portion usually causes no infarct and no significant circulatory disturbance because under such circumstances the collateral circulation is capable of maintaining an adequate blood supply to the affected area of myocardium.

Blumgart and his associates[7a] found that no structural damage to the heart muscle occurred following acute coronary artery ligation if the normal blood supply was reestablished after 5 to 20 minutes by removal of the occluding ligature; occlusion for more than 20 minutes produced focal areas of necrosis and fibrosis or massive infarction. These observations suggest that extreme myocardial anoxia results in irreversible muscular disturbance and necrosis only if prolonged beyond a minimum interval. Similarly, in human cases of cardiac pain which represent myocardial anoxia, persistence of pain for 20 minutes or more probably denotes that anatomic damage has occurred. Blumgart and associates[8] also noted that survival usually occurs if a major coronary artery is narrowed to not less than 15 to 19 per cent of its original cross section. Following such extreme narrowing it required at least 12 days for a rich collateral anastomosis, more than 40 micra in diameter, to develop.

Mechanical, Thermic, Chemical and Electrocardiographic Changes

Following experimental acute coronary artery ligation a variety of disturbances occur including (1) prompt cyanosis and weakness or loss of contraction of the muscle which loses its blood supply;[66] (2) a fall in local temperature[4] and an increase in lactic acid and muscle glycogen;[36] (3) serial changes in T waves, S-T segments and initial deflection,[73, 83] or the so-called ischemia injury pattern[2] characterized by a primary T wave inversion (ischemia) followed by R-T elevation (injury); (4) disturbances in rhythm including ectopic beats and frequently ventricular tachycardia followed by fatal ventricular fibrillation; (5) a diminished stroke output and a delay in circulation time.[3] These abnormalities can usually be reversed if the clamp occluding the coronary artery is released in 20 minutes.

Anatomic Changes

In contrast with the prompt electrical, thermal and chemical changes following experimental acute coronary artery occlusion, no histologic changes were observed by Tennant et al.[87] until 8 hours after the liga

tion After this interval, edema of the interstitial tissue and the deposition of fat droplets were noted, after 28 hours necrosis and increased fatty deposits in the muscle fibers, and an infiltration of polymorphonuclear leukocytes and red blood cells in the interstitial tissue were observed, after 48 hours fibroblasts appeared Healing became prominent after four days, and after four weeks the infarcted zone was replaced by a dense fibrous tissue scar These alterations developed only if the ligature was maintained for 2 to 8 hours, if the ligature was released after an interval of 30 minutes or less there were no demonstrable histologic changes Viability and healing of tissue are dependent on immediate retrograde flow into the ligated coronary artery from other coronary arteries and a more gradual development of an extensive interarterial collateral circulation after two to four weeks[9, 33]

Histochemical studies of myocardial tissue indicate that there is a reduction in enzyme activity such as that of succinic dehydrogenase in the early hours after experimental coronary occlusion even before any changes are demonstrable by routine staining techniques [illegible]

Mallory, White and Salcedo-Salgar[48] noted that the conversion of a small infarct into a scar occurred in two weeks while large infarcts required five weeks for this healing process Cardiac rupture occurred occasionally usually in the second week after the experimental occlusion These observations correspond in a general way with the pathologic changes in human coronary occlusion and form an experimental support for the clinical practice of keeping patients in bed for at least three weeks and preferably six weeks after the occurrence of an acute coronary occlusion

EXPERIMENTAL CHRONIC CORONARY ARTERY LIGATION

Although experimental acute coronary occlusion is followed by changes which resemble those in human cases human acute coronary occlusion differs in that it is usually preceded by a more or less prolonged period of progressive coronary narrowing during which there is an opportunity for the development of a collateral circulation Therefore, in order to simulate more closely conditions in the human disease attempts have been made to produce a gradual coronary occlusion in animals

Beck and Tichy[5] effected a gradual obturation of a large coronary artery by repeated pinching with metal clips Robertson[69] occluded the major coronary arteries in succession by serial ligation during a period of months Blum, Schauer and Calef[7] gradually narrowed a major coronary artery near its origin by progressive tightening of a modified Goldblatt clamp for a period of five weeks until there was complete occlusion The latter experimenters noted that in a control series of 25 dogs which had survived an acute coronary occlusion, a large infarct developed in 24 animals and a small infarct in the remaining one On the other hand extensive myocardial necrosis was observed in only 4 out of 14 dogs in which they had occluded the same coronary artery gradually They concluded that the collateral circulation developing during gradual coronary artery occlusion sufficed to prevent a large part of the myocardial damage which resulted when the same vessel was occluded suddenly In similar experiments Burchell[14] produced chronic coronary occlusion in the three main coronary arteries by first constricting them with metal clips for three weeks to three months and then ligating the vessels He also noted that the complete closure of a large coronary artery did not necessarily result in myocardial infarction if the occlusion was produced gradually

These experimental observations correspond to the findings in cases of human coronary occlusion in which myocardial infarction is a frequent but not an invariable consequence They indicate that with gradual coronary narrowing anastomotic vessels may provide a collateral circulation sufficient to prevent infarction even when the actual occlusion is complete and sudden On the other hand the frequency with which infarcts appear even after gradual coronary occlusion attests to the imperfection of the collateral circulation in most instances

FACTORS DETERMINING THE OCCURRENCE OF INFARCTS AFTER ACUTE CORONARY OCCLUSION

A number of factors determine whether or not a myocardial infarct will result from an acute coronary occlusion which occurs after a period of gradual narrowing as in human cases of this condition

1 **The Size of the Occluded Artery** Occlusion of any one of the major coronary arteries the left anterior descending the left circumflex or the right coronary is usually followed by a myocardial infarct occlusion of any of the smaller branches rarely causes significant myocardial necrosis

2 **The Site of Occlusion** The probability of myocardial infarction increases the nearer the site of occlusion is to the origin of a major coronary artery The more distal the occlusion the more vessels are available proximal to the occlusion to provide a collateral circulation

3 **The Speed of Occlusion.** Sudden complete occlusion in a normal large coronary artery is almost always followed by an infarct because an adequate collateral circulation has not been established However coronary embolism usually causes a prompt fatality before an infarct can develop With progressive narrowing prior to occlusion as in coronary atherosclerosis the changes in pressure gradients in anastomotic vessels permit a gradual progressive increase in the relative blood flow through these collateral channels When complete obstruction occurs the myocardium affected may be receiving its major blood supply from these enlarged collateral vessels and the occlusion of the original supplying vessel may not be of serious consequence

4 **The Condition of the Other Major Coronary Arteries** Myocardial infarction is less likely to follow an acute coronary occlusion if the other two major vessels are normal than if one or both are already occluded or extremely narrowed Under the latter circumstances the possibility that the remaining vessels will provide an adequate collateral circulation is less than if they were normal In fact the first coronary artery occlusion often causes no infarction because an adjacent major artery provides sufficient blood to the affected area This occlusion may however result in relative myocardial anoxia when the work of the heart is increased and may be manifested clinically by angina pectoris on effort However if the second major artery which provided the collateral circulation is then occluded a myocardial infarct usually results because the first major artery supplying the area of myocardium is already closed

5 **The Anatomic Pattern of the Coronary Arteries** The distribution of the coronary arteries varies in different hearts particularly with regard to the proportion of cardiac muscle supplied by the left or right coronary arteries respectively Schlesinger[75] observed myocardial infarcts with the least frequency in the hearts with a balanced coronary circulation next in those with a right coronary artery predominance and most frequently in those hearts in which there was a preponderant blood supply from the left coronary artery Furthermore in the left coronary preponderant group the first infarct was most likely to be fatal whereas multiple infarcts (fresh and healed) were most common in the right preponderant group

6 **The Effect of Cardiac Hypertrophy and Other Factors.** The deleterious effect of an acute coronary occlusion on the corresponding myocardial area may be intensified by associated diseases of the heart and circulation If the heart is hypertrophied because of hypertension rheumatic cardiovalvular disease or syphilitic aortic insufficiency there is a potential myocardial anoxia because of the increased need for blood due to the greater muscle mass and the augmented cardiac work The slightly increased blood flow in hypertrophied hearts is relatively much less than the increased requirement The acute obstruction of a major coronary artery is therefore more apt to produce myocardial infarction than in a normal sized heart In the presence of anemia the probability of myocardial infarction following acute coronary occlusion may be similarly enhanced

PATHOLOGY OF ATHEROSCLEROTIC CORONARY ARTERY OCCLUSION AND CARDIAC INFARCTION

MECHANISM OF ATHEROSCLEROTIC CORONARY OCCLUSION

The pathology of coronary atherosclerosis has been described (p 429) Briefly the process consists of thickening of the intima by cellular hyperplasia and fibrosis associated with the deposition of lipids Newly formed capillaries appear in the thickened intimal plaque Degenerative changes result in hyalinization and areas of softening (atheroma or atheromatous abscess) containing a gruel like detritus of cells and lipoid material Calcification of the atherosclerotic intimal plaque occurs commonly and occasionally spicules of bone are formed The atheromatous abscess may break into the lumen forming the atheromatous ulcer the surface of which may

be covered by thrombus The artery becomes irregularly thickened and may be transformed into a more or less rigid tube The thickening occurs at the expense of the arterial lumen which may become extremely stenosed

It was formerly believed that occlusion of an atherosclerotic coronary artery was due almost exclusively to obturation of the lumen by a thrombus deposited on an athero sclerotic plaque or atheromatous ulcer But it has been demonstrated that atherosclerotic coronary occlusion may occur without thrombosis and that capillary hemor rhages into the atherosclerotic intima are frequently important in the production of occlusion with or without thrombosis[6, 90, 94] In a study of 100 autopsied cases of acute athero sclerotic coronary artery occlusion Horn and Finkelstein[37] observed that the closure was due to intramural hemorrhage in 62 5 per cent and to formation of a thrombus on an atherosclerotic plaque in 37 5 per cent of the cases

One or more of the following mechanisms are now believed to be concerned in the occlusion of an atherosclerotic coronary artery

1 **Intimal Hemorrhage with Rupture into the Lumen and Secondary Thrombosis** Owing to the degenerative necrotic changes in the atherosclerotic intima the perivascular tissue no longer provides adequate support against the intracapillary pressure Consequently the intimal capillaries often rupture and produce an intramural hemorrhage According to Paterson[6] changes in coronary arterial blood pressure (e g due to hypertension, physical and emotional stresses) may predispose to or precipitate intimal hemorrhage Such hemor rhages may occur frequently, as part of the atherosclerotic process without necessarily leading to coronary occlusion When there is extensive intimal degeneration associated with atheromatous abscess, even a small intimal capillary hemorrhage may rupture the arterial endothelium A thrombus forms at the site of the endothelial tear and leads to occlusion of the arterial lumen Occasion ally the capillary hemorrhage does not itself rupture the arterial endothelium, but may by exaggerating the already extensive intimal degeneration initiate subendothelial and endo thelial necrosis and consequent thrombosis

2 **Intimal Hemorrhage with Occlusion by Intramural Hematoma** Sometimes the athero sclerotic process causes such thickening of the arterial wall that only a very small lumen remains Rupture of an intimal capillary may result in an intramural hematoma The swell ing thus induced may be sufficient to occlude completely the already narrowed arterial lumen, even without the occurrence of thrombosis[96]

3 **Coronary Thrombosis on an Atherosclerotic Intimal Plaque** In most cases of atherosclerotic coronary thrombosis, the occlusion is not precipitated by intimal capillary hemor rhages The intima may disclose merely dense fibrous thickening and lipoid infiltration or extensive necrosis and atheromatous ulcer It is probable that the thrombosis is precipitated by arterial endothelial damage by direct im pingement of the atheromatous abscess or by rupture of the abscess into the lumen or by other subendothelial degenerative changes Leary[40] has emphasized the occurrence of coronary artery thrombosis at the site of atheromatous ulcers, and Saphir and his associates[74] noted that in their 32 cases of cor onary thrombosis the thrombi were located on atheromatous ulcers In general the throm bosis occurs in the region of the most extensive arteriosclerotic change and at the point of greatest narrowing

PATHOLOGY OF CORONARY THROMBI

Multiple coronary thrombi are found more often than a single thrombus Many thrombi are overlooked because of failure to examine carefully all of the important branches of the coronary arteries throughout their entire extent Occasionally a thrombus is expelled by the dissecting scissors By making serial cross sections of the various coronary arteries with the scalpel at intervals of 3 to 5 mm Gross and I[31] observed multiple fresh and old coronary occlusions in about 85 per cent and a single coronary occlusion in only 15 per cent of 120 hearts with coronary occlusion Saphir and his associates[74] noted more than one oc clusion or extreme narrowing in every one of 34 hearts which they examined Blumgart Schlesinger and Davis,[8] in a study of hearts by a combined injection and dissection method, also found that more than one oc clusion was usually present in the hearts showing advanced coronary atherosclerosis, thrombosis or myocardial infarction

Fresh and old coronary occlusions are usually found in the same heart Fresh thrombi appear red and are soft and friable

They are loosely adherent to the arterial wall and easily dislodged The thrombi undergo organization early After 24 hours fibroblasts and capillaries appear[6] Within a few days the red blood cells degenerate and are gradually absorbed and the fibrin is re placed by collagen The thrombus during this period appears brownish and is more firmly attached Eventually it undergoes complete fibrous replacement and the pigment dis appears The thrombus becomes firm and gray and is securely attached to the wall of the artery Recanalization of the lumen occurs commonly and may lead to a partial but in adequate reestablishment of the circulation Frequently it is impossible to determine with certainty whether we are dealing with an old recanalized thrombotic occlusion or with ex treme atherosclerotic narrowing or oblitera tion of the lumen for vascular channel forma tion in an atherosclerotic plaque may closely simulate recanalization of an old healed thrombus

LOCALIZATION OF CORONARY ARTERY OCCLUSIONS

It was formerly believed that occlusion occurred predominantly in the anterior de scending branch of the left coronary artery Levine and Brown[4] noted occlusion of the left anterior descending branch 39 times and of the right coronary artery only twice in their 46 cases of fatal coronary thrombosis More recent studies have disclosed that coronary occlusion occurs with almost equal frequency in the left anterior descending and the right coronary arteries while occlusion of the left circumflex coronary artery develops somewhat less often In addition occlusions are found not infrequently in somewhat smaller branches such as the ramus primus of the left anterior descending and in the branch to the obtuse margin of the heart which arises from the left circumflex In 100 autopsied cases of acute coronary artery occlusion Horn and Finkelstein[17] observed 61 occlusions of the right coronary artery (right circumflex) 56 in the left anterior descending 27 in the left circumflex 15 in the ramus primus and 7 in the branch to the obtuse margin

In my experience occlusions are found most commonly in the proximal portions of the affected vessels but rarely in the first two centimeters The former belief that the region from 2 to 3 cm from the origin of the left anterior descending artery was a site of special predilection for coronary thrombosis has not been substantiated by more recent careful studies Blumgart and his associates[3] described a great variety of localization of the occlusions within each of the major arteries The relative freedom from occlusion of the proximal 2 cm of the vessels is of particular importance because it permits a free circula tion through the first branch or two proximal to the occlusion by means of which a col lateral circulation may be maintained This explains the possibility of survival of humans and experimental animals even after multiple occlusions involving both coronary arteries

OCCURRENCE AND LOCATION OF CARDIAC INFARCTION

The occlusion of one major coronary artery may not be followed by cardiac infarction either because death ensues too rapidly i e within a period of minutes or a few hours or because the flow of blood through collateral channels maintains the viability of the af fected myocardium The former circumstance is noted chiefly in cases studied by coroners Thus Benson[6] observed 54 instances of recent coronary thrombosis without infarction among 1750 autopsies in the Portland morgue Usually myocardial infarction follows the recent occlusion of two major coronary ar teries or it results from one recent occlusion in the presence of at least one old occlusion or the extreme narrowing of one or more large branches However myocardial infarction may follow the first acute coronary thrombo sis provided death does not result within the first few hours thereafter

In most cases the infarct lies within the area of myocardium supplied by the recently oc cluded vessel The extent of the infarct varies considerably from laminar patches 1 to 2 cm in diameter to widespread areas of necrosis which extend through and through from the endocardium to the pericardium *Occlusion of the left anterior descending artery* often causes infarction of the anterior wall of the left ventricle near the apex but more extensive areas of the anterior wall of the left ventricle of the papillary muscles and of the anterior portion of the septum may be involved *Occlu sion of the left circumflex artery* usually pro duces infarction of some portion of the lateral wall of the left ventricle or of the posterior wall near the base *Occlusion of the right circumflex*

artery usually results in an infarct of the posterior wall of the left ventricle near the base, and it may include a variable portion of the posterior half of the interventricular septum. The septum has such a rich anastomotic circulation that it is rarely infarcted to any great extent unless both major vessels are occluded or unless one is severely narrowed and the other occluded. Infarction of the region of the atrioventricular node usually is due to occlusion of the right coronary artery close to its origin.

The location and extent of the infarct depend not only on the size and location of the vessel recently occluded but also on the presence or absence of other occlusions, recent or old, on the degree of narrowing of unoccluded vessels, on the volume of the collateral circulation in adjacent vessels, on the anatomic pattern of the coronary vessels, as well as on other factors. These variables account for the frequent lack of correspondence between the site of infarction and the area normally supplied by the occluded artery. Thus an initial occlusion of the obtuse marginal branch of the left circumflex artery may produce *no infarct* of the posterolateral wall of the left ventricle which it supplies, because this region may continue to receive an adequate blood supply from collateral branches of the right circumflex. A subsequent acute occlusion of the right circumflex, by eliminating this collateral circulation, may produce infarction of the area formerly supplied by the now occluded left circumflex branch, whereas the posterior wall of the left ventricle supplied by the right circumflex maintains its viability through collaterals from the main left circumflex. A collateral circulation is frequently provided by branches of the occluded artery, arising proximal to the occlusion.

In a detailed study of both the coronary arteries and the myocardium in 25 hearts from patients with clinical coronary heart disease, Snow et al.[8] observed that almost all coronary occlusions gave rise to myocardial infarcts, even when the occlusion occurred in a previously narrowed vessel. This finding did not support the concept that gradual narrowing of a coronary artery leads to the development of collateral vessels which are capable of preventing infarction when the vessel is occluded. Furthermore, these observers discovered that not only did major occlusions almost invariably cause infarction, but in addition a single occlusion frequently resulted in more than one infarct. They found that for a period of three to eight weeks after acute myocardial infarction, a period which corresponded with the time required for collateral vascularization of the ischemic area, there was frequently an extension of the initial infarct into adjacent ischemic zones.

Cardiac infarction is confined almost exclusively to some portion of the left ventricle or the interventricular septum. The right ventricle is involved rarely; Saphir and his associates[74] observed one instance of right ventricular infarction in their 34 cases of myocardial infarction, and Wartman and Hellerstein[93] 4 in 160 cases. Whether this is due to a richer coronary anastomosis,[66] to the relatively smaller myocardial mass of the right ventricle or to other factors is unknown. Occasionally infarction of the atria results from atherosclerotic coronary artery occlusion simultaneously with ventricular infarction.[7] Atrial infarcts, usually involving the right atrial appendage, were reported in 17 per cent of cases of ventricular infarction.[45] I have also seen atrial infarction in a case of periarteritis nodosa with coronary thrombosis. Within the wall of the left ventricle the site most frequently and most severely affected is the subendocardium. The papillary muscles are also frequently involved. The intermuscular branches of the coronary arteries extend perpendicularly from the main superficial vessels in the epicardium and terminate in the subendocardium. The latter represents the periphery of the coronary circulation and therefore suffers most intensely from a reduction in the coronary blood flow. The endocardium itself is adequately nourished by the blood within the cardiac lumen. In cases of patchy necrosis or infarction due to coronary insufficiency without coronary occlusion, the lesions are confined to the subendocardium and papillary muscles.

The localization of myocardial infarction according to muscle bundles has been described by Robb and Robb.[65]

MACROSCOPIC AND MICROSCOPIC PATHOLOGY OF CARDIAC INFARCTS

The earliest changes of infarction of the myocardium are those of ischemic or coagulation necrosis. The affected heart muscle appears pale, yellowish or gray. Its consistency becomes firmer and drier than that of the surrounding muscle. The periphery of the infarct

is often delineated by a more or less regular reddish zone of hyperemia. *Microscopically* at this early stage the muscle fibers are seen to have lost their nuclear structure while the nuclei of the connective tissue and blood vessels are still apparent. But soon, especially in large infarcts, the cells of the connective tissue and blood vessel walls also undergo necrosis. At an early stage the muscle cells show evidences of hyaline and granular degeneration and loss of myostriation. These changes are associated with an uneven staining of the muscle fibers resulting in the appearance of deeper and lighter eosinophilic bands.

Somewhat later there is complete necrosis of the cells of the connective tissue and blood vessels as well as of the muscle fibers. The muscle fibers become completely vacuolized and eventually there is complete homogenization or disappearance of many muscle fibers. Hyperemia of the surrounding vessels and the accumulation of *polymorphonuclear leukocytes*, lymphocytes and mesenchymal cells are evidences of reaction to the necrotic cardiac muscle. The polymorphonuclear leukocytes may invade the necrotic muscle and produce an appearance somewhat similar to that of an acute suppurative inflammation. Between the central zone of necrosis and the peripheral zone of hyperemia there may be a yellowish band of fatty infiltration due to partial anoxia. Often there is an extravasation of red blood cells from the congested vessels and the entire area of infarction may appear hemorrhagic. The infarct appears yellowish green or gray, often mottled or streaked with hemorrhage depending on the predominance of one or the other of these changes.

The infarcted muscle undergoes various degrees of friability or softening (*myomalacia*) due to the transudation of fluid from the neighboring vessels into the degenerated muscle tissue. If the degree of softening is extreme, the infarcted muscle may become the site of a small irregular tear resulting in *cardiac rupture* (p. 542). Complete rupture, usually in the anterior wall near the apex or the posterior wall at the base of the left ventricle, is followed by hemorrhage into the pericardiac sac (*hemopericardium*) and a fatal issue. Occasionally extreme softening of an infarct produces a *rupture of the interventricular septum* which may be diagnosed intra vitam and which is usually but not always fatal (p. 543). Rupture of a papillary muscle is also a rare complication of myocardial infarction (p. 543). Cardiac rupture may be incomplete and the seepage of blood through the tear produces a dissecting aneurysm of the heart which may appear as an hemispherical bulge of the cardiac surface. A considerable interval may elapse between the development of an incomplete cardiac tear and dissecting aneurysm and the occurrence of a complete rupture.

Organization of a myocardial infarct begins within a week. The necrotic material is resorbed and the infarcted area is invaded by a granulation tissue rich in blood vessels and fibroblasts. Remnants of necrotic muscle are still visible within the granulation tissue. Pigment granules giving a positive iron reaction are seen within and outside macrophages and are residua of old hemorrhage. At this stage of early organization the hemorrhagic infarct is converted into a grayish red area of healing. Eventually the granulation tissue is replaced by a dense collagenous tissue rich in elastic fibers which is converted into an avascular scar. Grossly this appears as a pearly white tendon like cicatrix of varying extent. Occasionally the healed infarct becomes more or less calcified[76] and rarely bone may be formed.[14] Fresh and old infarcts are often observed in the same heart.

Cardiac aneurysms are not infrequently associated with both fresh and old infarcts (p. 543). An aneurysm at the site of a fresh myocardial infarct is often overlooked unless the affected ventricle is distended with fluid under pressure. Where an infarct heals, the damaged myocardium may become thinned and stretched into an aneurysm. At postmortem examination the aneurysm may appear as a pale depressed area or as a localized bulge. The aneurysm may become calcified.[12]

ENDOCARDIAL AND PERICARDIAL LESIONS IN CARDIAC INFARCTS

Cardiac infarcts frequently damage or rupture the endocardial endothelium either by direct involvement of the entire endocardial thickness or by an hemorrhagic extravasation which produces a dissecting aneurysm extending to the cardiac lumen. An endocardial thrombus very often overlies fresh or healed infarcts. Mural thrombi were found at autopsy in 44 per cent of 924 cases of acute myocardial infarction reported by various observers.[24] These mural thrombi are almost al

ways situated in the left ventricle, especially at the apex. But when there is extensive infarction of the interventricular septum, mural thrombi may develop on both sides of the septum. Occasionally large semispherical masses of thrombi fill the cavity of a bulging aneurysm at the apex of the left ventricle. Although these thrombi are quite adherent to the endocardial surface superficial portions may become detached and cause embolization of the brain, the viscera or the extremities.[73] However, pulmonary emboli, which commonly complicate acute coronary occlusion, arise usually from thrombi in the veins of the lower extremities and only occasionally from mural thrombi in the right ventricle.

Cardiac infarcts extend frequently also to the pericardial surface and produce a localized or occasionally an extensive fibrinous pericarditis.[84] With recent infarcts there is a dull fibrinous exudate overlying the area of necrosis; healed infarcts are covered with a gray or white adherent patch of scar tissue. Pericarditis was observed at autopsy in 28 per cent of 111 cases of myocardial infarction analyzed by Wartman and Hellerstein.[91] Effusions develop occasionally when a wide area of pericardium is involved.[77, 89]

SIZE OF THE HEART AFTER CARDIAC INFARCTION

Cardiac enlargement or hypertrophy occurs in at least two thirds of the cases of cardiac infarction due to coronary artery occlusion. Palmer[60] observed cardiac enlargement, as determined roentgenologically, in 128 (64 per cent) of 200 clinical cases of coronary thrombosis, and Bartels and Smith[2] noted cardiac hypertrophy in 37 (88 per cent) of 42 infarcted hearts examined postmortem.

However, it is uncertain whether or how frequently cardiac hypertrophy is the direct consequence of the cardiac infarct or whether it is always due to associated conditions or to complications of the infarct. Hypertension is present in the majority of patients with coronary artery occlusion and may represent the commonest cause of cardiac hypertrophy in such cases. The etiologic role of hypertension may be overlooked because the blood pressure often falls to within the normal range after an attack of coronary artery occlusion. In other cases an associated rheumatic cardiovalvular disease or syphilitic aortic insufficiency may account for the enlargement of the heart.

But cardiac hypertrophy undoubtedly occurs in cases of coronary artery occlusion in the absence of these associated conditions. In such cases the hypertrophy has been interpreted as a direct consequence of the ischemia due to the coronary artery occlusion. This conclusion is based on evidence that cardiac hypertrophy may follow experimentally induced anemia and that it occurs in various clinical forms of anemia (p. 1049) and in cases of an anomalous coronary artery arising from a pulmonary artery and supplying the heart with relatively unoxygenated blood (p. 791). More direct evidence was adduced by Smith, Miller and Graber,[80] who observed the development of cardiac hypertrophy in dogs following experimental coronary artery ligation. Unlike these observers, Sutton and Davis[84] saw no change in the size of the heart in dogs following coronary artery ligation.

My own observations have led me to believe that when cardiac hypertrophy follows coronary occlusion it is due either to present or preexistent hypertension, to associated cardiovalvular disease or to congestive heart failure caused by severe extensive myocardial damage. Solival and I[8] studied the hearts at autopsy of 100 cases of acute coronary occlusion to determine the relationship of this condition to cardiac hypertrophy. Hearts with associated cardiac disease had been excluded. The cases with and without hypertension were segregated. Evidence of previous hypertension in patients with normal blood pressure during their final illness was sought in the records of previous hospital admissions or from their family physicians. Preexistent hypertension was also assumed to have been present if the examination of the fundus had disclosed severe arteriosclerosis and if postmortem examination disclosed advanced renal arteriolosclerosis of the interlobular arteries or arteriolosclerosis. The presence or absence of cardiac hypertrophy was based on the relationship of the heart weight to normal body weight and comparison of this figure with the normal figures of Smith.[81] This study disclosed that cardiac hypertrophy was absent in every case of acute coronary occlusion without evidence of hypertension or associated cardiovalvular disease, unless there were distinct clinical or pathologic signs of congestive heart failure. In the presence of congestive heart failure marked cardiac hypertrophy was noted whether or not there was associated

hypertension Within the hypertensive group cardiac hypertrophy was much more prominent when the hypertension was associated with failure than in the absence of failure Hypertension per se was accompanied by lesser degrees of hypertrophy than heart failure without hypertension

Davis and Blumgart[6] also noted the relationship of congestive heart failure to the occurrence of cardiac hypertrophy in a study of cases of heart failure not due to hypertension valvular disease or other accepted causes of hypertrophy In 14 of 15 cases of congestive heart failure associated with advanced coronary atherosclerosis the heart weights were above 400 gm and in 11 of these above 500 gm and in 5 above 600 gm On the other hand in 31 cases of advanced coronary heart disease without associated heart failure only 6 hearts weighed more than 400 gm and no heart weight exceeded 440 gm Davis and Blumgart concluded that the failure was the cause and not the result of the cardiac hypertrophy since otherwise they would have found some markedly hypertrophied hearts which had not yet failed

Although cardiac hypertrophy is seen pathologically and cardiac enlargement is observed clinically in many cases of coronary occlusion it is important to emphasize that the heart is often of normal size in this condition Horine and Weiss[36] reported 20 cases of acute coronary thrombosis followed roentgenologically for periods between five months and ten years in all of which the size of the heart was normal during the entire period of observation Miller and Weiss[51] studied 19 necropsied hearts with old cardiac infarcts none of which disclosed cardiac hypertrophy In a roentgenographic study of 200 patients with acute coronary thrombosis followed for an average period of three years Palmer[60] found 72 (36 per cent) to be of normal size Of those which were enlarged only 4 (2 per cent of the total series) were not associated with hypertension or other conditions which are accepted as causes of cardiac enlargement No mention was made of the possible role of congestive heart failure in these cases In a somewhat similar roentgenologic study of the hearts of 16 patients with acute coronary thrombosis Massie and Miller[47] noted no change whatever in the size or shape of the heart in 8 cases In the first two weeks following the acute attack an increase in heart size was observed in only 2 cases The absence of cardiac enlargement should therefore not depreciate a clinical diagnosis of acute coronary occlusion The presence of cardiac enlargement should merely suggest associated or complicating conditions

RECENT MYOCARDIAL INFARCTION WITHOUT ACUTE CORONARY OCCLUSION

Experimental and pathologic observations have revealed that coronary artery occlusion is not invariably followed by cardiac infarction because of the presence or development of collateral circulation It is less well known that areas of acute myocardial necrosis or infarction occur frequently in the absence of a recent occlusion of a coronary artery Isolated observations of this kind were noted by Libman Saphir et al[74] Buchner et al among others Friedberg and Horn[27] found that in a series of 1000 consecutive autopsies 31 per cent of the cases of acute myocardial infarction were not associated with a recent coronary artery occlusion All the coronary vessels were meticulously examined by transverse sections of the arteries at intervals of 3 mm and microscopic examinations were made of all extremely narrowed portions of the vessels In 37 such cases of acute myocardial infarction without recent coronary occlusion pulmonary embolism was associated in 12 calcific aortic valvular stenosis in 8 severe coronary and old occlusions with congestive heart failure in 6 an operative procedure in 4 a severe acute anemia in 3 malignant hypertension and a cerebral complication in 3 and occlusion of the superior mesenteric artery in 1

It is probable that myocardial infarction may occur whenever there is prolonged severe myocardial anoxia whether this be due to a mechanical occlusion or to other disturbances in circulatory dynamics which result in coronary insufficiency In the above cases of myocardial necrosis or infarction without recent coronary occlusion there were many factors which could result in a sharp inadequacy of the coronary blood supply for the needs of the myocardium Shock following operation or mesenteric thrombosis the fall in aortic and therefore in coronary blood pressure after a massive pulmonary embolism or acute hemorrhage could precipitate such a coronary insufficiency[21] In cases of calcific aortic

stenosis there is a progressive increase in intraventricular pressure with a diminished cardiac output and a deficient filling of the coronary capillaries (p 701) At the same time there is a greatly augmented need for blood because of cardiac hypertrophy and the increased work of the heart with this valvular lesion In most of the cases a severe narrowing of the coronary arteries or an old occlusion had already impaired the coronary circulatory reserve

Chapter 20

ACUTE CORONARY OCCLUSION AND MYOCARDIAL INFARCTION

Clinical Features

SYMPTOMATOLOGY

PREMONITORY SYMPTOMS

Acute myocardial infarction presents itself usually as a sudden catastrophic incident, and its definitive clinical picture develops without warning prodromata. But numerous studies[18, 4, 181] disclose that preliminary chest pain may represent an harbinger of acute coronary occlusion in 10 to 50 per cent of the cases. Such premonitory pain usually develops within 24 hours prior to the occlusion, but it may precede the attack by several days or even weeks. Occasionally palpitation, weakness or dizziness may represent the premonitory symptoms, with or without associated pain.

The premonitory pain is usually identical with that of angina pectoris in character and location and in being often precipitated by exertion or emotional excitement. Of course such pain can be considered definitely a premonitory symptom only if the patient has not been subject to regular attacks of angina pectoris for many months or years, and if it is followed by the more definitive clinical picture of acute cardiac infarction within a few days or at most a few weeks. The absence of characteristic electrocardiographic changes and other objective evidence of myocardial infarction during the interval substantiates the concept that the pain is actually a preliminary symptom and not due to the infarction itself. In my own experience the most striking instances of premonitory pain have been observed in patients with previous myocardial infarcts and usually with angina pectoris on effort. In these patients a fresh coronary occlusion and cardiac infarct were often signalized by *increasing frequency and severity of* the episodes of angina pectoris which appeared with less and less exertion and even at rest or only in recumbency.

The pathologic basis for the premonitory pain may be a sudden narrowing of a coronary artery due to the rupture of intramural capillaries in an atherosclerotic plaque. The interval preceding the actual infarction represents the time required for the formation of a thrombus or hematoma sufficient to occlude the artery completely. It is more likely that the sudden appearance of premonitory angina pectoris actually corresponds to a coronary occlusion but that infarction of the heart muscle is delayed until exertion or some other factor, by enhancing the oxygen requirement of the *ischemic area* of heart muscle intensifies the myocardial anoxia and produces necrosis. Or else the occluding thrombus extends proximally to involve additional branches of the vessel which had been serving to maintain viability of the affected myocardium.

Recognition of these premonitory symptoms has been stressed because an early diagnosis of impending coronary occlusion may prompt immediate institution of rest in bed and other therapeutic measures. Whether such measures would actually diminish the mortality rate or the frequency of complications is unknown. However, since myocardial infarction does not invariably follow coronary occlusion immediately rest in bed by diminishing the work and oxygen requirement of the heart muscle might occasionally inhibit the development of myocardial infarction despite

the coronary occlusion and the administration of anticoagulants might inhibit extension of the coronary arterial thrombus

Desirable as these theoretical benefits might be in practice it is difficult to evaluate this preliminary pain except in retrospect after the full picture of myocardial infarction has unfolded Quite frequently identical pain and associated symptoms are later found to represent episodes of angina pectoris which are not followed by myocardial infarction On the other hand it is important to recognize that many episodes of anginal pain or so called premonitory pain actually represent attacks of myocardial infarction even when the classic symptoms of the latter are absent Such symptoms may be properly interpreted only when careful studies are made of the temperature white blood count sedimentation time and electrocardiograms

CLINICAL PICTURE OF ACUTE MYOCARDIAL INFARCTION

For purposes of presentation the clinical picture of acute myocardial infarction may be classified according to the following distinctive features

1 Cases dominated by pain
2 Cases dominated by shock
3 Cases dominated by pulmonary edema or other evidence of acute left ventricular failure
4 Cases characterized by the more gradual development or aggravation of congestive heart failure
5 Cases dominated by complications

Emphatically I do not intend to pose these groups as distinct entities most cases are characterized by a combination of the symptoms and signs listed under the various headings However one group of symptoms or the other often dominates the clinical picture and recognition of acute myocardial infarction will be facilitated by a knowledge of these varied and sometimes sharply different clinical forms that the disease may assume

1 Cases Dominated by Pain

In its most characteristic form the clinical picture of acute coronary occlusion with myocardial infarction is dominated by severe and prolonged pain in the region of the sternum the precordium or the upper abdomen [70, 87, 93] The victim is stricken while at rest or at work when awake or asleep with or without the dubious benefit of premonitory pain The pain may either begin as a relatively mild but persistent discomfort which becomes increasingly severe or it may strike with sudden terrifying intensity Often the subject has previously experienced paroxysms of angina pectoris But despite certain similarities of the pain of myocardial infarction to that of angina pectoris he often knows that this is a new and different pain The pain may appear distinctive because for the first time it attacks while he is asleep or at rest and without apparent cause Or if it arises during walking or other exertion it fails to subside promptly with rest If the patient follows his custom of taking nitroglycerin to dispel his anginal pain he discovers with alarm that this pain is not similarly alleviated

Character of the Pain The pain of acute myocardial infarction has the same quality of constriction oppression or compression which characterizes angina pectoris and it may be no more severe But often it is more crushing in intensity and becomes intolerable because of its prolonged duration Usually the pain is characterized as squeezing constricting choking vise-like or like a heavy weight but it has also been described as expanding stabbing knife-like dull and boring or burning in quality

Location and Radiation Almost always the pain is located in the retrosternal area Often it spreads to both sides of the anterior chest especially to the left A prominent component of the pain may affect the epigastrium or upper abdomen This accounts in part for the resemblance of myocardial infarction to acute surgical or chronic diseases of the abdominal viscera and for the frequency with which such cases were formerly diagnosed as acute indigestion

Like the pain of angina pectoris that of acute myocardial infarction radiates frequently to the shoulders and both upper extremities to the neck and jaw and to the interscapular region Radiation of the pain to the neck is often described as causing a clutching or choking sensation The pain in the upper extremities more often in the left may either extend continuously from the shoulder to the fingers or reach only to the arms or skip directly to the forearms or wrist There may be only a dull ache weakness or numbness of the wrists associated with severe substernal and precordial pain

Duration of Pain The pain persists in vary

ing degree for many hours, occasionally for several days

The duration of the pain is abbreviated frequently by the administration of morphine or some other opiate, but even opiates may hardly diminish the pain or at best leave a persistent dull ache or pressure With or without morphine the pain may not be constant even though prolonged After an hour or two of severe pain, the pain may lessen perceptibly or subside entirely only to recur for hours or days in irregular rhythm

In some cases there is intense pain for thirty minutes to one or two hours, thereafter the pain disappears completely and the patient may feel and appear perfectly well Only electrocardiographic studies may disclose that the pain was due to an acute myocardial infarction When a pericardial rub discloses the existence of an acute fibrinous pericarditis there may be no distinct change in the pain occasionally however a recurrence or intensification of pain suggests a relationship to the pericardial lesion or the precordial pain becomes intensified by deep respiration Sometimes there are two distinct types of pain a constant retrosternal pain characteristic of the myocardial infarction and a pericardial (pleuropericardial) sharp pain related to deep respiration

After the pain due to the myocardial infarct subsides the patient may become subject to paroxysms of angina pectoris whether or not he suffered angina pectoris prior to the acute attack These may occur while he is still in bed, as a result of slight *activity, meals or emotional states* More often angina pectoris develops only during convalescence, upon the resumption of activities out of bed On the other hand, patients previously plagued by frequent attacks of angina pectoris may be completely relieved of their pain after they recover from the acute myocardial infarction

Pathogenesis of the Pain of Myocardial Infarction The essential similarities in quality, location and radiation support the theory that the pain of myocardial infarction like that of angina pectoris is due to myocardial anoxia (p 457) In angina pectoris the pain is brief and paroxysmal because the myocardial anoxia is provoked only by certain activities or emotional states which are themselves transient The pain subsides with the cessation of the causative factor or after administration of a vasodilator like nitroglycerin, because the myocardial anoxia is reversible and there is no significant permanent anatomic change In cases of myocardial infarction the pain is prolonged because myocardial anoxia is usually due to mechanical occlusion of a coronary artery which is not transient or reversible, the artery is not capable of dilatation by nitrite In cases of myocardial infarction without coronary artery occlusion the causative factors produce a severe and prolonged myocardial anoxia sufficient to cause permanent myocardial damage

The greater severity of pain of myocardial infarction as compared to that of angina pectoris is probably an expression of more extensive or more intense myocardial anoxia, and of the longer duration The severity and persistence of the pain of myocardial infarction may be simulated during a paroxysm of angina pectoris caused by rapid walking if the patient forces continuation of his activity despite the pain The extension of the pain of myocardial infarction to the upper abdomen may represent an overflow of pain impulses to a wider area of neighboring segments of the spinal cord due to the severity and extent of the cardiac lesion However, occasionally this localization may be due to an associated acute pericarditis or perhaps occasionally to hepatic engorgement Aside from these considerations individual differences in pain sensitivity and in the pathways of conduction of pain from the heart (p 459) probably account for some of the variations in the severity, location and radiation of the pain of *myocardial infarction*

The eventual course of the pain is determined by the pathologic and physiologic changes in the ischemic area A variable central portion of the affected muscle undergoes complete necrosis and is no longer capable of causing pain, for the pain stems from anoxic but viable tissue The peripheral rim of ischemic muscle remaining viable may receive a completely adequate collateral blood supply from anastomotic vessels In that circumstance there may be no pain at all after the acute infarction even with exertion If the collateral supply is merely adequate to maintain viability but provides no reserve, this portion of the ischemic myocardium may become anoxic with effort or under other conditions which temporarily increase the oxygen need of the myocardium or diminish its blood

supply Then paroxysms of angina pectoris may follow recovery from the acute infarction

Myocardial Infarction without pain has been documented in a number of cases[44, 84, 111] In Bean's series[17] of 125 cases of acute myocardial infarction pain was noted in only 75 per cent but pain was absent in only 4 4 per cent of 974 cases of acute myocardial infarction and 226 cases of coronary insufficiency studied by Sigler[172] In an additional 2 9 per cent the pain was very mild and in 8 3 per cent the pain was elsewhere than the anterior chest Cases without pain have been described as silent or atypical[186] But usually these are characterized by the sudden development of pulmonary edema congestive heart failure shock or weakness features now recognized as intrinsic elements in the symptomatology of acute myocardial infarction Pain is said to be uncommon with acute myocardial infarction occurring in Negroes in whom dyspnea is the usual clinical manifestation[72] In a study of 70 cases of myocardial infarction without pain Evans and Sutton[68] found that preexistent heart failure or myocardial infarction as well as atrial fibrillation and hypertension increased the likelihood that pain would be absent in myocardial infarction These authors suggested that slowness of myocardial infarction rather than the size of the infarct determined the absence of pain

In many purported instances of acute myocardial infarction without pain I have been able to elicit a history of typical pain on requestioning the patient Often pain was not reported by the patient because it was overshadowed by dyspnea weakness or other symptoms Some patients who deny the presence of pain will admit that they experienced a clutching or gripping sensation a sense of strangulation or a feeling of a massive weight on their chests Pain may also be overlooked when it is relatively mild and of brief duration or forgotten if the diagnosis is made long afterward by electrocardiographic examination If those instances are omitted in which pain is overshadowed by other symptoms misinterpreted or forgotten only a small percentage of cases of acute myocardial infarction remain which were unaccompanied by cardiac pain Reports indicate that pain is absent in not more than 3 to 4 per cent of cases of acute myocardial infarction[28] and Babey[11] could find only one case without pain in a series of 116 In some of these painless cases coronary occlusion may have been followed by such prompt and complete ischemia of a portion of the myocardium that no pain could arise This is apt to occur when a previous occlusion has produced myocardial anoxia without infarction and the fresh occlusion leaves this portion of anoxic myocardium without any collateral blood supply Extreme shock following myocardial infarction may completely benumb the cerebral centers to the awareness of pain Finally hyposensitive individuals may experience no pain at all atypical radiation of pain or substitution symptoms instead of pain The latter include weakness dizziness syncope sweating or vomiting instead of the usual and characteristic pain[17] As most of these substitution symptoms are manifestations of shock there may be some question whether pain is absent because of the hyposensitivity of the patient or because it is overshadowed by manifestations of shock

2 Cases Dominated by Evidence of Shock

While some evidence of shock is often observed in the previous group of cases characterized by intense substernal pain there is a group in which the manifestations of acute cardiac infarction are *primarily* those of shock The patient suddenly experiences weakness which slowly or rapidly may develop into intense prostration or collapse He may unexpectedly slump in his chair if sitting or fall to the ground if standing or walking He may lose consciousness for a brief period probably because of cerebral ischemia due to the low cardiac output Syncope marked the onset of acute cardiac infarction in 10 of 200 cases studied by Cookson[44] In extreme cases shock may be followed by sudden death

In milder cases the patient may complain only of feeling weak dizzy faint or nauseated or less specifically of feeling sick These symptoms may be very transient and associated with a cold sweat Sometimes there is a terrifying inexplicable fear of impending doom angor animi out of proportion to the symptoms Vomiting is not uncommon and rarely diarrhea occurs The patient may complain of thirst

In instances of profound shock the subjective symptoms are associated with cold clammy extremities and tip of the nose a rapid weak or thready pulse pallor or grayish cyanosis and a low blood pressure (below 80

mm Hg) and low pulse pressure In attacks beginning with syncope there is often a bradycardia, but there may be a tachycardia [33] Respiration may be rapid and shallow, especially if there is some associated left ventricular (congestive) failure and sometimes there is frequent sighing The facial expression is often drawn and anxious The patient's intellect may be clear but often he is mentally befogged and apathetic The oral temperature may be subnormal, while the rectal temperature is elevated There may be a notable diminution in the urinary output and rarely complete anuria for 24 hours [148]

The advent of therapeutic agents which give promise of usefulness in the treatment of shock in acute myocardial infarction has pointed up the disagreement regarding the criteria of shock and consequent differences in the mortality rate in such cases of shock (p 564) For purposes of uniformity it appears desirable to formulate as minimal criteria for shock associated with myocardial infarction (1) a systolic blood pressure less than 80 mm Hg regardless of the previous pressure, (2) clinical manifestations secondary to diminished cardiac output and sympathetic vasoconstriction e g cold clammy skin, rapid thready pulse etc (p 302)

When shock occurs it usually evolves soon after the onset of myocardial infarction and lasts a few hours to one or two days In fatal cases it may persist longer and until the patient succumbs Often in such cases shock is accompanied by pulmonary edema If the patient recovers from the shock state, some *degree of weakness often persists The patient* may first become aware of other symptoms hitherto obscured He may complain of a pressure pain over the sternum or precordium, pain or weakness in the arms or forearms or numbness in the wrist or fingers Epigastric fullness gaseous eructations and other symptoms of indigestion may become annoying Sometimes subsidence of shock may be followed gradually by the emergence of signs of congestive heart failure In some cases shock may persist for one or two weeks especially when there is extensive or progressive myocardial infarction, or when complications such as embolization, arrhythmias or bronchopneumonia ensue

Pathogenesis of Shock in Acute Myocardial Infarction Most probably the symptoms of shock are due to the sharp and sudden reduction of the cardiac output resulting from myocardial injury [55 176 80] Observations that experimental shock occurred only after occlusion of coronary vessels of certain critical sizes were interpreted to indicate that some mechanism, probably neurogenic prevented a compensatory rise in peripheral resistance, with consequent fall in blood pressure [9] Shock due to cardiac infarction may sometimes be distinguished from that due to peripheral vascular failure by the frequent presence in the former of dyspnea and orthopnea and distention of the peripheral veins The degree of shock does not always correspond to the size of the infarct, for the extent of the infarct is not necessarily an accurate measure of the severity of the chemical and physiologic disturbances in the heart muscle Moreover, some nervous mechanism may be concerned the behavior of which varies in different persons

3 Cases Dominated by Acute Left Ventricular Failure

A sudden attack of pulmonary edema is often the first and may be the dominant manifestation of acute myocardial infarction The attack may appear suddenly and without warning causing thoracic oppression and intense, suffocating dyspnea and orthopnea Sometimes however, it follows hours or days after premonitory substernal pain or recovery from the earlier stage of shock

The respirations become noisy and asthmatic or bubbling in character A copious white or pinkish foam may be coughed up or merely wells up from the bronchopulmonary *passage and out of the oral cavity and nasal* passages Retrosternal pain may be absent or slight or if moderately intense it is usually overshadowed by the profound dyspnea and sense of suffocation Patients in this group may be deeply cyanotic or may present a pale or ashen cyanosis due to the combination of pulmonary edema with shock Particularly in elderly persons and in the presence of both shock and left ventricular failure or after opiates, there may be *Cheyne Stokes respiration*

Lesser grades of pulmonary congestion due to acute left ventricular failure are also common The onset may be characterized by episodes of paroxysmal nocturnal dyspnea The wheezing respiration and cough associated with diffuse bronchial rhonchi and distention of the chest may provoke a diagnosis of

bronchial asthma More commonly such episodes of cardiac asthma are associated with the characteristic pain of acute myocardial infarction or they appear after pain and evidences of shock have subsided *If myocardial* infarction begins with massive pulmonary edema the patient may succumb rapidly or if he recovers he may become subject to less severe left ventricular failure characterized by recurrent cardiac asthma orthopnea or dyspnea on slight exertion Cough with or without expectoration and hemoptysis may also be present Moist râles are usually audible at the base of the lungs and the second pulmonic sound may be accentuated

Since myocardial infarction affects the left ventricle almost exclusively it is not surprising that manifestations of left ventricular failure are common Sudden inability to expel the venous return results concomitantly in pulmonary congestion and in deficient cardiac output and shock Some evidence of pulmonary congestion as denoted by râles at the base of the lungs is very frequent whether the dominant manifestation is pain or shock or congestive heart failure

4 Cases Dominated by Manifestations of Right Sided Heart Failure

Although evidences of left sided heart failure usually combined with varying degrees of pain and shock are common even *with* the first acute myocardial infarction right sided heart failure develops rarely during the first attack and then only after the acute symptoms have subsided However with the second or subsequent infarction evidences of right sided congestive heart failure appear with increasing frequency and occasionally dominate the clinical picture The peripheral veins become engorged and the venous pressure elevated [171] Usually the liver becomes enlarged and it may be tender Peripheral edema may be present but usually ■ a late development Right sided heart failure after myocardial infarction is always associated with *left sided failure Dyspnea orthopnea and at*tacks of cardiac asthma usually persist but they are often at least partly alleviated with the development of right sided failure Basal râles are usually audible and the circulation time remains prolonged The symptoms and signs of right sided heart failure may emerge during the first week after myocardial infarction but usually they develop after many weeks as the patient ■ convalescing and resuming some degree of physical activity Sometimes rapid enlargement of the liver and peripheral venous engorgement may appear *within a few hours after the occurrence of* chest pain

There is in addition a group of cases in which a first attack of myocardial infarction is followed within a period of weeks or months by progressive and advanced right-sided heart failure with minimal or no apparent evidence of left sided heart failure The pathogenesis has been explained on the basis of ventricular septal infarction and a so called Bernheim ■ syndrome This explanation is *dubious*

Occasionally the development or intensification of right sided heart failure is the major or sole feature of an attack of acute myocardial infarction In most of these cases the patient is one who has had a previous attack of myocardial infarction following which he has continued to experience angina pectoris or paroxysmal and exertional dyspnea Then without characteristic symptoms of acute myocardial infarction the signs and symptoms of right-sided heart failure develop more or less rapidly over a period of days or weeks

Less frequently patients of middle or advanced age without previous cardiac symp*toms or evident cardiac disease* experience progressive dyspnea and display signs of left and right-sided congestive heart failure That these clinical manifestations are the result of a fresh myocardial infarct is demonstrated either by definite electrocardiographic changes or by pathologic findings at autopsy The occurrence of right sided heart failure after coronary occlusion is dependent on widespread myocardial damage which implies the existence of multiple or large infarcts fresh or old

5 Cases Dominated by Complications

Occasionally none of the above mentioned striking symptoms are present or they appear in such mild form that they are overlooked *The first conspicuous symptom* of acute myocardial infarction may be that of a complication whose relation to the cardiac infarct may or may not be recognized These complications which are discussed in detail below (p 510) include cerebral or other embolization and arrhythmias

Sometimes coronary occlusion results in prompt and *sudden death* in patients who may

or may not have suffered from angina pectoris or other evidences of coronary disease

ASSOCIATED AND MINOR SYMPTOMS

The clinical features of acute myocardial infarction have been depicted as distinct integral groups, but I reemphasize that the main symptoms of pain, shock and heart failure are usually associated in the same patient, although one or the other may predominate at different stages of the disease It should also be reaffirmed that quite frequently these symptoms do not appear in the striking form in which they have been described and that they are often mild in intensity and brief in duration Indeed it is probable that instances of myocardial infarction with mild symptoms of brief duration are more frequent than is generally recognized, for postmortem studies indicate that there are many more coronary occlusions than are or could be recognized clinically Many patients do not suffer severely enough to warrant the summons of a physician

There are many less specific accessory symptoms which accompany but are overshadowed by the major clinical features enumerated Sometimes when cardiac pain is relatively mild and evanescent and there are no distinctive symptoms of shock or congestive heart failure, these accessory or minor symptoms may dominate the clinical picture

Gastrointestinal Disturbances and Abdominal Pain

Symptoms classified loosely as "*indigestion*" occur so frequently that cardiac infarction was formerly often mistaken for an attack of acute indigestion Nausea and vomiting are common especially when pain is severe When the pain extends to the upper abdomen and is associated with vomiting the clinical picture may resemble that of cholelithiasis, acute cholecystitis, peptic ulcer or urolithiasis When there are also evidences of shock it may simulate a perforated ulcer or acute pancreatitis In other cases the pain is so obscured by the nausea and vomiting that the whole episode is attributed to a gastrointestinal disturbance It is probable that the nausea and vomiting are due to a vagovagal reflex from the region of the infarcted myocardium to the gastrointestinal tract Often it is uncertain whether vomiting which occurs only after the administration of an opiate is due to the opiate or to the disease itself

Diarrhea with or without vomiting is occasionally experienced at the onset of acute cardiac infarction probably also as the result of a vagovagal reflex More often *constipation* results from the diminished intake of food the administration of morphine or its derivatives and the stay in bed

Abdominal distention and a sense of epigastric fullness are common If the pain is not severe, they may dominate the clinical picture from the outset, but more often they become conspicuous after the pain has subsided Self medication with bicarbonate of soda or other alkalis or carminatives in an unsuccessful effort to relieve these digestive symptoms often precedes the patient's summons of a physician In some instances abdominal distention and constipation are intensified later in the course of the attack by gastrointestinal and hepatic engorgement due to the development of right sided heart failure

Jaundice has been noted rarely In at least one patient whom I observed the jaundice was due to a coincident obstruction of the common bile duct by a calculus

Other Symptoms

The occurrence of intense prostration or collapse due to shock has been mentioned but often only a moderate sense of *weakness* accompanied by cold perspiration and perhaps slight dizziness represents the total or dominant symptomatology of an attack Weakness is a common and conspicuous feature which persists long after most or all of the acute symptoms of cardiac infarction have disappeared It is especially common in patients who develop distinct signs of congestive heart failure, but it may represent the only or the chief residual symptom

Palpitation is a common complaint, especially after the more conspicuous symptoms have subsided It may become particularly annoying when it is associated with extreme tachycardia or other arrhythmia or when there is a sinking or fluttering sensation of irregular, premature or dropped beats

Urinary symptoms are rarely prominent but there may be a reduction or more rarely an almost complete suppression of the urinary output (p 520)

Cerebral symptoms are relatively uncommon except for the mental torpor or collapse as-

sociated with severe cardiac shock at the onset of the disease But occasionally they are the most impressive features of the disease while the coronary occlusion is unsuspected[19, 21] Mental torpor or confusion dizziness or vertigo loss of memory stupor or coma is likely to occur in elderly patients with cerebral atherosclerosis in whom the blood flow to the brain is further diminished by the sudden drop in blood pressure Hemiplegia and aphasia may result early from cerebral vascular thrombosis with encephalomalacia or hemorrhage or from cerebral embolization arising in ventricular mural thrombi Occasionally there are epileptic convulsions or delirium Attacks of convulsions and faintness or syncope (Adams-Stokes syndrome) may be due to complete heart block or episodes of ventricular fibrillation with resulting intervals of asystole and cerebral ischemia (p 390) Cheyne-Stokes respirations may appear especially in elderly persons with cerebral atherosclerosis or when intense cerebral ischemia results from extreme cardiac shock (for pathogenesis see p 198) The administration of opiates and the advent of left ventricular failure with consequent overventilation and acapnia may be important contributing or precipitating factors Coma may be due to a complicating diabetic acidosis

Other symptoms occur rarely *Hoarseness* due to the paralysis of the left recurrent laryngeal nerve may result from compression of that nerve by the engorged left pulmonary artery in left ventricular failure[11]

Hiccup has been noted occasionally[114] and has been attributed to associated diaphragmatic pericarditis with irritation of the phrenic nerve or to associated pneumonitis with diaphragmatic pleurisy

OBJECTIVE MANIFESTATIONS OF ACUTE MYOCARDIAL INFARCTION

GENERAL APPEARANCE AND BEHAVIOR

In the classic case characterized by severe pain the patient presents a striking contrast to the person suffering from a paroxysm of angina pectoris Although the pain is similar in quality and location the patient with angina pectoris usually remains utterly quiet fearful of every motion having discovered that rest relieves and activity kindles or intensifies the pain With the onset of pain from an acute myocardial infarction he may at first also try to remain motionless But with persistence and increasing intensity in the pain he becomes extremely restless Sometimes his futile efforts to relieve the pain lead to bizarre forms of behavior He may tear or clutch at his chest as if to remove a weight or release a vise-like band or he may massage it vigorously as one does a cramp in a leg He may thrash from side to side in an effort to find a comfortable position in bed or he may alternately get up and sit down or pace the floor as he moans with pain I have seen patients on the floor crouching on their knees as some do when suffering from a biliary or renal colic Occasionally a patient with acute cardiac infarction purchases some relief by extending his arms upward as if to enlarge the capacity of the chest He may be found lying in bed with his hands above his head clutching the head of the bedstead On one occasion I found a patient suspended by his hands from the top of a door As a rule however when the physician arrives the patient is found in bed where he is squirming restlessly holding his chest and complaining of pain

When shock is the predominant feature the patient s appearance is characterized by listlessness or prostration as he lies quietly in bed Although he may acknowledge the presence of pain he does not complain of it spontaneously His vocal responses in general are low and brief as if every word is an exhausting effort Occasionally he is somewhat confused and disoriented or he may appear dazed His countenance is of ashen pallor and his lips and fingertips faintly cyanotic His hands and feet and the tip of his nose are cold and moist There may be a bluish red mottling of the skin (cutis marmorata) On one occasion I have seen striking acrocyanosis of the fingers and toes From the beginning or as the shock clears after the first few days the patient s appearance is gradually modified by the intrusion into the picture of a variable degree of left-sided heart failure

A somewhat different appearance is presented by the patient whose attack of myocardial infarction is evinced predominantly by acute pulmonary edema He is found propped up high on several pillows gasping for breath his neck veins often engorged and his lips and skin distinctly cyanotic Between gasps he may complain of a massive oppression over the chest This may be described as a pain

but more often as a sense of suffocation He may express a fear of impending death He may cough occasionally, the sputum produced may be blood tinged In extreme cases there is a copious foamy pink stained fluid exuding from his mouth and sometimes even from his nostrils Frequently, moderate or severe shock is associated, then the cyanosis has an ashen hue, the extremities are cold and the peripheral veins in the extremities may be collapsed although those in the neck are tense The appearance described above may be observed only if the patient is seen soon after the inception of his symptoms Pulmonary edema often clears with remarkable speed either spontaneously or after an opiate, the morning after the attack the patient may appear quite comfortable or only moderately dyspneic and orthopneic In the more ominous cases however, pulmonary edema may persist for several days until the fatal end or disappear and recur several times until the patient succumbs

These, the most dramatic and most severe clinical pictures usually represent only the onset or first few days of the attack Some patients, appearing perfectly well, walk into the physician's office to report a pain that has already disappeared or dyspnea which disturbs them only at night or recently developed symptoms of indigestion Many others are sufficiently alarmed to go to bed and call a physician, but present no striking abnormalities in appearance or behavior as they complain of persistent chest pain and perhaps also weakness, perspiration nausea or abdominal distention or breathlessness

THE HEART

Physical examination of the heart often reveals surprisingly little in view of the extent and severity of the cardiac damage When percussion of the cardiac borders and palpation of the apical impulse are satisfactory, there is often no evidence of cardiac enlargement However, in the presence of congestive heart failure the heart may be so enlarged that this is readily determined by percussion and palpation

Auscultation of the heart may be more revealing although frequently this also discloses no significant abnormality In many cases the heart sounds are faint in volume and muffled in quality The first sound in particular is usually faint and low pitched It may be indistinguishable from the second sound, with a consequent tic tac rhythm A soft blowing murmur at the apex, probably due to a functional mitral insufficiency, is most often heard in instances of second or multiple infarction in which there is some degree of left ventricular dilatation An aortic systolic murmur may also be noted, its pathogenesis is uncertain but it is usually attributed to atherosclerotic changes in the ascending aorta near the aortic ring When hypertension persists despite the myocardial infarction, the second aortic sound may be accentuated or even reduplicated Often in cases characterized by left ventricular failure with pulmonary hypertension the second pulmonic sound is accentuated and may be louder than the second aortic sound, even when there is systemic hypertension

Gallop rhythm and pericardial rub have a more specific diagnostic value I have heard a gallop rhythm in one quarter of the patients whom I have been able to observe within the first few days after the onset of the attack Shillito et al [171] noted it in 8 of their 50 cases The gallop rhythm is usually best heard at or slightly medial to the apex of the heart, but it may be most clearly audible in the fourth interspace near the left sternal border Occasionally the gallop can be detected over a wide area of the precordium It is protodiastolic or presystolic in time, more frequently the latter if the ventricular rate is rapid

In their study of the heart sounds in 80 cases of cardiac infarction, Master and Friedman[107] noted an atrial sound in 83 per cent which was sufficiently accented in 33 per cent to produce an audible presystolic gallop In 47 per cent there was a third heart sound early in diastole, in 8 per cent this sound was accented and audible as a protodiastolic gallop In 6 per cent there was a superimposition of the atrial and third heart sound causing an audible summation gallop Thus there was an audible gallop in almost one half of their cases

Since gallop rhythm is probably associated with left ventricular dilatation (p 69), it is usually encountered in cases in which heart failure is significant Gallop rhythm most frequently appears in the first day or two after the infarction and disappears as cardiac function is adjusted But if conspicuous heart failure continues, gallop rhythm may

also persist Sometimes in cases with severe shock at the onset of the attack there is no audible gallop during the first few days But as shock subsides and left ventricular failure becomes more prominent gallop rhythm may become manifest

A *pericardial rub* has been noted in about one fifth of the cases in several reported series [22, 17] Undoubtedly it would be heard more often if it were deliberately sought and if patients were examined frequently soon after the onset of the attack For the rub appears intermittently persisting briefly at each appearance It may first be audible a few hours after the attack but most commonly on the second or third day thereafter it recurs usually only for a few days Occasionally with large infarcts or progressive myocardial infarction a pericardial rub persists continuously for many days

The pericardial rub is usually heard best just inside the apical impulse or along the left border of the sternum but it may be audible over a large part of the precordium or localized over the lower portion of the sternum A pericardial rub is not indicative of anterior infarction as is commonly believed it may be heard also following posterior ventricular infarction [184] It is much more likely to appear when there is a generalized acute fibrinous pericarditis than with a localized pericarditis and generalized pericardial inflammation may follow posterior as well as anterior wall infarction *In 3 out of 5 cases of generalized* pericarditis associated with an audible rub Stewart and Turner[186] found the infarcted area limited to the posterior wall

A pericardial effusion following myocardial *infarction has been reported rarely* [175] *It is* probably overlooked in most cases in which it occurs Nichol[1 5] reported a pericardial effusion sufficiently large to necessitate a paracentesis A pericardial rub may be audible even when the effusion develops A distinction should be made between pericarditis with effusion and a non inflammatory hydropericardium representing a serous transudate due to advanced congestive heart failure The pericardial effusion may consist of pure blood (hemopericardium) a consequence of cardiac rupture (For hemopericardium see p 604)

THE PULSE

There is usually an acceleration in the pulse rate to between 100 and 110 per minute especially during the febrile stage At the very onset the pulse rate may be rapid in the presence of shock or heart failure even when the temperature is normal In the absence of noticeable heart failure shock or fever the pulse rate is usually normal Occasionally there is a sinus bradycardia with a pulse rate of 60 per minute and rarely complete heart block with a pulse rate below 40 The rhythm of the pulse is usually regular but premature beats occur commonly and occasionally other arrhythmias may produce irregularity or a striking quickening of the pulse

THE BLOOD PRESSURE

As a rule cardiac infarction is followed by a fall in the blood pressure [188] But initially there may be a transient rise even when there are other clinical evidences of shock [184] The blood pressure usually falls further in patients with hypertension than in those with a normal pressure prior to the attack The eventual pressure may decline to 90 mm Hg or lower regardless of the blood pressure before cardiac infarction But patients with previous hypertension usually have higher pressure after infarction than those with previously normal pressure The diastolic as well as the systolic pressure is reduced but not to the same degree In consequence the pulse pressure is usually significantly diminished In contrast with these usual findings Yater et al [207] reported that the blood pressure remained *normal or returned to normal in 70 per cent of* soldiers between the ages of 18 and 39 who had survived an attack of acute coronary thrombosis

The fall in blood pressure usually occurs *rapidly sometimes after several hours* but more often on the second day of the attack Occasionally there is a gradual progressive decline and rarely it is delayed for a week [25] In early fatal cases often associated with blood pressures below 90 or 80 mm Hg there may be little or no rise in pressure up to the end But in most cases a low point is reached some time in the first week or more often in the second or third week [108] After one to three weeks at this level there is a gradual progressive rise However the blood pressure seldom returns quite to its initial level until after convalescence About two thirds of the patients with previous hypertension eventually regain their hypertension In some of these hypertension reappears within several

weeks or months after moderate activity is resumed but in others one to three years may elapse before the previous levels of high blood pressure are attained.[131] Occasionally I have observed the blood pressure dive precipitously on the first day after an acute coronary occlusion and rise sharply on the following day, almost but not quite to its initial level. In fatal cases the blood pressure may remain at its lowest hypotensive level until the patient succumbs.

The fall in blood pressure after acute myocardial infarction is probably related chiefly to the reduction in cardiac output although these two do not follow a uniformly parallel course. Compensatory vasoconstriction is an important modifying factor. This and the later recovery in cardiac output account in most cases for the subsequent rise in blood pressure and restoration to the original level. But in about one third of the patients with previous hypertension the blood pressure, after cardiac infarction, remains within a normal range for at least many months, even though there is no longer any evidence of a diminished cardiac output, and cardiac function appears well compensated. In these patients it must be assumed that the persistent diminution in blood pressure is due to a permanent relaxation in the peripheral arterial resistance.

FEVER

Usually within 24 to 48 hours, and occasionally as early as 4 to 8 hours after the onset of acute cardiac infarction, there is a moderate rise in temperature to 100 to 102 F. But fever up to 104° or 105° has been observed not infrequently. Shillito et al[171] noted fever at some time in all of their 50 cases of uncomplicated myocardial infarctions. The temperatures must be taken rectally and at regular intervals to discover slightly abnormal elevations.

The temperature usually reaches its peak on the third or fourth day and persists altogether for two to four days but occasionally longer. As a rule, the temperature returns to normal by the seventh or eighth day. However, progressive myocardial infarction or the development of complications may prolong the duration of the fever, or may cause a recrudescence if the temperature has already returned to normal.

LEUKOCYTOSIS

An increase in the white blood cell count occurs almost invariably and early, occasionally within two hours after the onset of the attack. Most frequently the leukocytosis is detected on the second or third day, but Slapak[173] found that the leukocytosis appeared on the first day, reached its maximum on the eighth day, and then fell rapidly. As a rule the white blood count varies between 12 000 and 15 000 but counts between 15 000 and 20 000 are not rare. There is an associated polynucleosis of 75 to 90 per cent and there may be a slight shift to the left, that is, the percentage of young (nonsegmented) forms is increased.

The leukocytosis recedes after a few days and usually disappears by the end of a week. Persistence of the leukocytosis thereafter or the presence of extremely high white blood counts suggests the development of a complication such as pulmonary or other embolism, bronchopneumonia or progressive myocardial infarction.[99] However, Levy[95] has observed a which they reported and Shillito et al[171] in 49 cated case of acute myocardial infarction.

The presence of a leukocytosis may be a valuable diagnostic aid in dubious cases of myocardial infarction. The white blood count is often a more sensitive index of cardiac infarction than the temperature because there may be a definite leukocytosis when the presence of fever is uncertain as in cases with a temperature around 100° F.[96] Furthermore, the leukocytosis usually develops before fever.

INCREASED SEDIMENTATION RATE

The rate of sedimentation of the erythrocytes is almost always increased following an acute myocardial infarction.[149, 141] Rabinowitz et al[146] noted this in all of the 29 cases which they reported and Shillito et al[171] in 49 of 50 uncomplicated cases of cardiac infarction. The increased sedimentation rate is attributed to a change in the composition of the plasma due to the absorption of products of the necrotic heart muscle.

Usually the increased sedimentation rate is first noted on the second or third day of the attack and persists for several weeks until the infarct is healed. The accelerated rate may begin within a few hours after the acute myocardial infarction, attain its most rapid phase in four or five days and persist for a variable

period of weeks or months. In the classic cases of acute myocardial infarction there does not appear to be a good correlation between the degree of increase in sedimentation rate and the severity of the attack or the prognosis.

SERUM GLUTAMIC OXALACETIC TRANSAMINASE (SGO-T) AMINOPHERASE

The enzyme glutamic oxalacetic transaminase (GO T) is probably present in all human sera and also in various tissues, particularly heart muscle, skeletal muscle, brain, liver and kidney in descending order of concentration. The normal serum glutamic oxalacetic transaminase (SGO T) concentration is 8 to 40 units per milliliter. Following acute myocardial infarction, the serum transaminase (SGO T) rises to 70 to 600 units in 12 hours to six days.[illegible, 77, 109a] It is presumed that the enzyme is released from damaged myocardial cells, since the concentration of GO T in infarcted myocardium is only 2 to 10 per cent of normal heart muscle.[17, 110] Following experimental coronary occlusion and myocardial infarction in dogs, serial serum transaminase determinations show a linear correlation between the peak level of SGO T and the amount of myocardial infarction.[3] But myocardial ischemia of 45 minutes' duration in dogs did not influence SGO T if there was no myonecrosis.[17] Following myocardial infarction in humans, the peak level of transaminase is usually noted about 36 hours after onset of the pain and the concentration usually returns to normal by the fourth day. Occasionally, however, the maximum rise in SGO T does not occur until after the third day, and in other cases the rise occurs early and is transient, with return to normal within 36 hours.[29] Hence it is important to measure the SGO T early and to do serial determinations. The SGO T may be determined by the method of Karmen et al.[77]

It has been suggested that serum transaminase determinations may prove useful as a clinical aid in the diagnosis of acute myocardial infarction[illegible] and in estimating the amount of myocardium involved. It is apparent, however, that SGO T will be elevated whenever there is necrosis of any transaminase-rich tissue, i.e., in acute liver damage (hepatitis), acute skeletal muscle damage including dermatomyositis, acute renal damage (renal infarction), and in rheumatic myocarditis. However, as a rule, it should be possible to exclude these other causes of elevation of the SGO T. Differentiation of myocardial necrosis and hepatic damage may be facilitated by the simultaneous determination of the activity in the serum of the enzymes glutamic pyruvic transaminase (SGP T) and lactic dehydrogenase (S LD).[159] SGP T rises sharply after hepatic damage and insignificantly after myocardial necrosis, whereas S LD activity increases after myocardial necrosis and is relatively unaltered after hepatic damage. Since serum glutamic oxalacetic transaminase (SGO T) is not increased following uncomplicated pulmonary embolism, its determination may be helpful in the differential diagnosis of pulmonary embolism and myocardial infarction.[63] The determination of SGO T activity has also been found useful in the diagnosis of acute myocardial infarction in cases in which the diagnostic electrocardiographic changes are obscured by those of left bundle branch block.[6] On the other hand, Denney et al.[26a] reported an incidence of 4.8 per cent false negatives among 95 patients with myocardial infarction and a significant elevation of the SGO T in half of their cases of acute pulmonary embolism. But the level is not as high in the latter and the peak is reached on the third to sixth day instead of the second.[130a]

C-REACTIVE PROTEIN

This is an abnormal serum globulin which appears in the blood in response to a variety of infectious, neoplasms and other disturbances such as rheumatic fever and arthritis (p. 836). A positive serum C-reactive protein was detected regularly in cases of transmural infarction, but not during the "premonitory phase" of coronary occlusion or in patients with so-called coronary insufficiency.[14]

WELTMANN SERUM COAGULATION BAND

Delaney and Keyes[34] observed a *shortening of the Weltmann serocoagulation band* in cases of myocardial infarction, beginning on the second or third day and reaching its minimum by the fifth or the seventh day. Healing of the infarct was associated with progressive extension of the coagulation band.

OTHER LABORATORY FINDINGS

The examination of the urine usually discloses no significant abnormality. In patients with hypertension, a faint trace of albumin

and occasional hyaline casts are often found These findings are also associated with the development of right sided heart failure

Glycosuria and *hyperglycemia* have been observed not infrequently in patients with and without a previous history of diabetes [32,48] In diabetics who are especially subject to acute myocardial infarction glycosuria may reappear during the attack if previously controlled by diet or insulin Occasionally an acute myocardial infarction may precipitate diabetic acidosis and coma with obscuration of its clinical picture Patients with these complications often succumb despite prompt and adequate treatment of the metabolic disturbance

The occurrence of hyperglycemia and glycosuria in patients without a previous history of diabetes has been explained as due to adrenal stimulation in shock to circulatory disturbances in the vegetative centers of the brain or to the development of a manifest diabetes in a latent diabetic as a result of the acute cardiac infarction Goldberger et al [6] supported the latter theory and refuted the assumption that the hyperglycemia and glycosuria were insignificant and transient These observers performed glucose tolerance tests repeatedly over a period up to thirteen months on 14 patients with acute myocardial infarction none of whom had a history of diabetes They concluded that 6 presented definite evidence of diabetes 4 yielded abnormal glucose tolerance curves and 4 normal curves In several instances hyperglycemia and abnormal glucose tolerance curves were absent soon after the attack and appeared months later The tendency for the curves to become more and more abnormal over a period of months led these investigators to conclude that the hyperglycemia was not transient and that it indicated latent diabetes in these patients

Oliguria sometimes of extreme degree has been noted in association with intense shock and there may be anuria for as long as 24 hours [67, 115] In other instances acute tubular nephrosis ("lower nephron nephrosis") develops and may be fatal These disturbances result chiefly from prolonged cardiac shock and a consequent reduction in blood flow through the kidneys Sometimes urinary retention results from an associated prostatic obstruction the symptoms of which are intensified by bed rest

Hematuria may appear as a consequence of renal infarction, secondary to emboli arising from left ventricular mural thrombi Unilateral hemoglobinuria has been reported [98]

Creatinuria may result from increased catabolism following myocardial infarction [1] Urobilinuria has been noted, usually in the third day [62]

Chemical examination of the blood may disclose a hyperglycemia, which has been discussed above Although this may denote latent diabetes, it should not in itself be interpreted as an indication for the administration of insulin

Azotemia appears occasionally and rarely the blood urea nitrogen may exceed 60 mg per 100 cc [179] It is usually associated with severe shock and other factors which cause oliguria Blood lactate, pyruvate and amino acids are slightly elevated [8]

The serum alpha 2 globulin was found to be markedly increased in patients in shock due to myocardial infarction [81] The plasma fibrinogen is also elevated and the severity of the disease and prognosis have been correlated with the degree of elevation [100] Cryoglobulins have been found in the serum [73] Accelerated coagulability of the blood has been detected by means of a heparin clotting time [155]

CIRCULATORY DYNAMICS IN ACUTE MYOCARDIAL INFARCTION

The Cardiac Output

Determinations by the Wezler Boeger method[65] and by the ballistocardiograph[178] showed a tendency to a reduction in the cardiac output either in the first two or three days or after the first two weeks More recently a reduction in cardiac output following acute myocardial infarction was determined by the method of cardiac catheterization using the Fick formula [144] and by the dye dilution method [84, 174, 80] Gilbert et al [80] in a study of 20 patients with acute myocardial infarction found the cardiac index reduced, usually but not invariably in proportion to the clinical severity of the disease The degree of reduction was most marked in patients with shock The cardiac index normally 3 2 liters/min /sq m of body surface area averaged 2 6 for those without heart failure or shock 1 9 for those with heart failure, 1 0 for those in shock and 1 8 liters/

min /sq m for the entire group of 20 Except in cases with very low cardiac outputs and shock the blood pressure is well sustained even when the cardiac output is diminished denoting over all arteriolar vasoconstriction

The venous pressure is frequently normal or low but may be difficult to determine in patients with severe shock in whom the veins are collapsed Most reports now indicate that the venous pressure tends to be elevated in the shock following myocardial infarction[176] In patients with right sided congestive heart failure the veins may be engorged and the venous pressure elevated In the study of Gilbert et al [80] the venous pressure averaged 13 cm water in the group without failure or shock 16 7 in those with heart failure and 21 5 in those with shock but there was considerable variation in each group and all the patients in shock suffered some degree of heart failure also

The Circulating Blood Volume

The plasma volume determined by the Evans blue method in patients with myocardial infarction and shock was found to be somewhat low by Agress et al [4] but this was not confirmed by Smith et al [178] or by Gilbert and his colleagues [80]

The Circulation Time

This is usually prolonged only in patients with heart failure or shock According to Gilbert et al [80] the circulation time is much more prolonged in patients with shock than in those with heart failure without shock

ROENTGENOLOGIC FINDINGS IN ACUTE CARDIAC INFARCTION

The roentgenographic examination of the heart often discloses no abnormality following acute cardiac infarction or only slight alterations due to previous hypertension

Disturbances in the pulsations of the left ventricle can often be ascertained by fluoroscopic examination and by kymography or electrokymography These disturbances result from the diminution or absence of contraction of the infarcted heart muscle or from its passive expansion during systole The following fluoroscopic abnormalities may be noted

1 Localized more or less extensive *absence of pulsation* along the left lower border of the heart (left ventricular contour)

2 Local *reversal of pulsation* of the left ventricle i e there may be a systolic expansion of one part of the left ventricular contour while the remainder contracts For orientation the observer may view the aortic pulsations Distention of the aorta marks the onset of ventricular systole In addition to the above abnormalities kymography may also disclose diastolic splintering denoted as marked irregularities during diastole

Several sources of error should be considered (1) In large hearts the apical region a frequent site of infarction may disclose no pulsation or even reversal of pulsation when there is no infarction A pericardial tumor may produce reversal of pulsation (2) Accurate fluoroscopic observation of the pulsations of the heart is often difficult especially when there is a large extrapericardial triangular shadow (due to a fat pad) (3) The apical and adjacent supra apical region normally contracts slightly later than the more basal portion of the left ventricular contour Thus may be misinterpreted as a reversal of pulsation Roentgenologic diagnosis is further hampered by the fact that most patients with acute myocardial infarction are too ill to be subjected to such examination The findings of absence diminution or reversal of ventricular pulsation in cases of myocardial infarction may be observed with old as well as recent infarcts and with posterior as well as anterior infarction

Other roentgenologic abnormalities may result from complications of myocardial infarction such as pulmonary congestion due to heart failure pulmonary infarction pneumonia and ventricular aneurysm Enlargement of the heart in coronary occlusion has been discussed above (p 504)

Calcification of a myocardial infarct rarely with bone formation may be observed roentgenologically[59] However cardiac infarction is not the only cause of myocardial calcification Calcification of the coronary arteries of mural thrombi in mitral stenosis or after cardiac infarction of the pericardium of cardiac aneurysms and of the mitral or aortic valves must be differentiated[18]

ELECTROCARDIOGRAPHIC CHANGES IN ACUTE CARDIAC INFARCTION

Acute cardiac infarction usually produces alterations of the electrocardiogram which when studied early and by serial examination at brief intervals are diagnostic of the disease

The electrocardiographic changes following cardiac infarction are determined not by the causative coronary occlusion as such but by the location extent and irreversibility of the consequent myocardial anoxia and necrosis When coronary occlusion occurs without infarction there may be no significant electrocardiographic abnormality despite the occlusion, or only transient RS-T depressions or inversion of T waves associated with temporary and reversible myocardial anoxia

The process of cardiac infarction is an active and changing one, during which the absolute and relative extent of necrosis and anoxia varies until healing occurs The progressive changes are documented by corresponding electrocardiographic alterations which differ according to the interval since infarction and the degree of healing This evolutionary nature of the electrocardiographic patterns is an important diagnostic feature After the infarct has healed the electrocardiogram may continue to disclose abnormalities suggestive of the occurrence and even of the localization of previous infarction but these changes are rarely as conclusive or striking as those accompanying acute cardiac infarction

Factors Limiting Electrocardiographic Diagnosis

In most cases of acute cardiac infarction the electrocardiogram discloses changes which not only are distinctive for this disease, but also reveal accurately the location of the area of infarction [12, 54, 78] However in a variable percentage of cases the electrocardiographic changes may not be typical of acute myocardial infarction or do not disclose its location under the following circumstances [1]

1 Multiple infarcts occur commonly The electrocardiographic changes produced by the fresh infarct may be neutralized by those of previous infarcts Or the multiple infarcts may produce diffuse myocardial damage the electrocardiographic representation of which is indistinguishable from that of other varieties of diffuse myocardial disease

2 The presence of a bundle branch block may obscure the electrocardiographic pattern of acute cardiac infarction (p 533)

3 When extensive pericarditis complicates acute myocardial infarction, the electrocardiographic changes may be dominated by and diagnostic of acute pericarditis (p 534)

4 The number of electrocardiograms taken may be insufficient or the time at which these are taken in relation to the occurrence of the infarct may be improper to disclose characteristic changes

5 Previous treatment by digitalis produces RS T and T wave changes which may conceal those of myocardial infarction

6 The position of the heart in the thorax, i e a decidedly transverse or vertical heart, by its effect on the electrocardiogram may obscure the localization of the infarct

7 Electrocardiograms taken shortly before the death of the patient may fail to disclose the typical electrocardiographic changes of myocardial infarction

Typical Electrocardiographic Patterns in Standard Leads

The earliest changes affect the RS T segments[136] *and are usually observed within 24* hours rarely within a few hours after the attack [8] In some instances the ST changes appear only after two or three days or longer However according to the experimental observations of Bayley and associates [14] a primary inversion of the T wave may precede RS-T segment deviation

The first significant abnormality is an elevation of the RS T segment above the iso electric level in lead I or lead III or in precordial leads Characteristically this segment presents a "high take-off" from the descending limb of the R wave and its slope is convex upward [133] This elevation is transient lasting usually a few hours or days but it may persist for two to three weeks The upward convexity of the RS T segment often remains after it reaches the isoelectric level

Subsequent changes[136, 137, 8] produce a progressive regression of the ST segment to the isoelectric level and a concomitant lowering and eventual inversion of the T wave in the same lead (Fig 100) Simultaneously there is often a conspicuous and sometimes broad Q wave in the same lead [133]

Parkinson and Bedford [137] and Barnes and Whitten [■] observed that the changes in the ST segments and T waves fell into two common patterns which they designated as the T_1 and T_3 types Subsequent studies of the initial ventricular complex[136, 138] enlarged these patterns into the Q_1-T_1 and the Q_3-T_3 types A correlation of electrocardiographic and necropsy findings demonstrated that the Q_1-T_1 pattern was associated with an acute or healing infarction of the anterior wall and the Q_3-T_3 pattern with an acute or healing infarc

tion of the posterior or diaphragmatic wall of the left ventricle

Theoretical Basis of Electrocardiographic Changes in Acute Myocardial Infarction[11, 15, 78]

RS-T Deviations When myocardial infarction ensues after an acute coronary occlusion a central core of muscle undergoes necrosis and therefore produces no electrical phenomena This dead tissue is surrounded by a concentric shell of injured tissue which is still alive and therefore partially polarized[15] The injured tissue in turn is surrounded by ischemic tissue which may be normally polarized in diastole but which experiences a delay in repolarization during systole During the acute stage of infarction the injured tissue which is negative relative to ischemic or normal tissue gives rise to a persistent current of injury Normally during the transition from depolarization to repolarization i e during the RS T interval there is electrical neutrality and the RS T segment is on the base line (i e the isoelectric line) In myocardial infarction the current of injury directed toward the endocardium causes a negative or depressed ST segment in electrodes overlying the injured area But in standardizing the electrocardiogram we introduce a positive compensating current from the control battery to bring the string up to the base line by neutralizing the current of injury during diastole[15] When all of the normal muscle is depolarized (electrically negative) and the injured area is electrically negative the positive compensating current is unbalanced and produces an elevation of the ST segment In cases of anterior wall infarction with subpericardial injured tissue the leads whose exploring electrode faces the injured tissue (left arm lead I and precordial leads) show an elevated RS T segment A posterior wall infarct is associated with RS T segment elevations in leads facing the posterior wall of the left ventricle namely aV$_F$ lead III or II and III and the esophageal lead On the other hand leads facing away from the infarcted area may show RS T depressions or no deviation In a similar manner one can explain the occurrence of ST depressions in epicardial or precordial leads when the infarcted tissue is subendocardial since the current of injury now flows toward the epicardium and the compensating current is negative

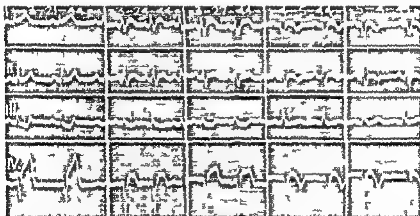

Fig 100 Acute coronary occlusion Anterior wall infarction Progressive changes R T elevations in leads I and IVF with depression in lead III Subsequent T wave inversion Absence of initial deflection (presence of Q waves) in IVF and lead I

The explanation for RS T deviations in acute myocardial infarction is uncertain and there are other explanations besides the one indicated above[111] Thus during the completely depolarized state i e the RS T interval the electrically negative injured tissue may be less negative than the depolarized normal tissue hence it conveys positive electromotive forces to the overlying electrode producing an elevated ST segment Or the injured area may actually be positive throughout systole including the S T interval when the normal muscle is isoelectric

According to vectorcardiographic theory the sum of electromotive forces in a heart with an acute infarct is not zero during the RS-T interval as it should be normally when all muscle is completely depolarized This is

owing to the persistent current of the injured muscle Hence the vector loop of the QRS does not return to its starting or zero point and the loop is open A line drawn from the zero point to the termination of the loop represents the vector of the RS T segment, indicating its direction and magnitude In infarction of the outer layers of the myocardium this vector is directed toward the epicardium Hence an elevated RS T segment is recorded in the electrode overlying the injured wall of the left ventricle

T Wave Changes *The ischemic area*, in contrast with the injured area, is believed to modify only the process of repolarization and is responsible for T wave changes including inversion[14] When the ischemic area is very large and the injured area absent or small, T wave changes may occur without ST deviations Normally T waves are upright in leads facing the epicardium if repolarization proceeds from epicardium to endocardium With myocardial infarction, negative T waves are thought to occur because repolarization proceeds from the normal subendocardium toward the injured subepicardial layer Hence in anterior wall infarcts T waves are likely to be negative (inverted) in precordial leads and leads I and aV_L In posterior wall infarcts leads aV_F (and II and III) have their exploring electrodes facing the ischemic areas and show inverted T waves but there are no T wave inversions in precordial leads In fact the absence of the normally counterbalancing electrical forces of the infarcted posterior wall *causes greater positivity of both R and T* waves in the right-sided precordial leads According to Dressler and Roesler,[4] high T waves precede inversion of the T waves or RS-T deviations The high T waves are believed to be part of the injury pattern possibly *due to the release of potassium from the* cells

Q Waves The dead infarcted tissue gives rise to no current If it extends transmurally it may be considered as a window cut out of the ventricular wall[197] Therefore the negative potential within the endocardial cavity is transmitted through this dead tissue to a superjacent precordial lead Instead of the normal positive initial deflection, the initial ventricular complex is downward, i e there is either a deep Q wave or QS in a lead placed directly over the infarct Or more commonly there is a deep or broad Q wave representing cavity negativity transmitted through the necrotic area, followed by an R or r wave representing depolarization forces of normal subepicardial tissue adjacent to the infarct

With healing of infarction, Q waves often persist in the precordial leads because a core of dead electrically inert tissue remains On the other hand, the injured tissue either dies, becomes ischemic or recovers and the RS T deviation therefore disappears The persistence of T wave changes depends on the presence of ischemic tissue of significant size, *thus causes aberrations in the repolarization process*

According to vectorcardiographic theory, the normal electromotive forces during depolarization and repolarization become unbalanced by the loss of electromotive forces of the injured infarcted tissue which was rendered electrically inert The direction and magnitude of the sum of the electromotive forces (i e, the cardiac vector) from moment to moment is therefore altered Normally, the initial and early vectors during depolarization are directed entirely toward the epicardial surface of the left ventricle or are so directed after a very brief moment away from that direction Consequently exploring electrodes facing the left ventricular epicardium show a major upward deflection (R) or a major upward deflection after an initial downward deflection of small magnitude (qR) Following subepicardial or transmural myocardial infarction the loss of electrical forces of the infarcted tissue unbalances the net sum of cardiac electromotive *forces in favor of* those directed away from the inert, injured tissue Therefore, an electrode facing the epicardial surface of the portion of the left ventricle which is injured has an early prominent negative or Q wave Thus in anterior wall *infarcts, there is a loss of anteriorly* directed electromotive forces which would normally be generated by the injured area The resultant forces are therefore directed away from the precordial electrodes and there is consequently a predominant negative or Q wave in the precordial leads

According to the theory of Prinzmetal and associates[80, 143, 147, 170] based on their studies of intramural leads the subendocardial layers are electrocardiographically inert during depolarization or are depolarized too rapidly to record on the electrocardiogram *Intramural* leads from the subendocardial layers give a

QS deflection identical with that from the cavities of the heart instead of the rS complex expected according to classic electrocardiographic theory Prinzmetal et al believe that subendocardial infarcts do not alter the QRS complex since they contributed nothing to this complex normally Their studies indicate that abnormal Q waves (coronary QR waves) occur in myocardial infarction of the outer layers of the wall when these layers contain both living and dead muscle They observed QS waves in transmural myocardial infarcts leading to a window effect[109] but also when there was through and through infarction with islands of living myocardial tissue[34]

These observers also found that the current of injury responsible for ST deviation was generated in injured tissue in the outer myocardial layers whereas injury to the inner layers produced ST segment deviations too small generally to be registered by clinical electrocardiography ST elevations diminished in amplitude from the epicardium to the endocardium and from the center to the border of the injury There is thus a gradient of positivity toward the epicardium and toward the center of the injured muscle accounting for ST depression on the wall opposite the injury They also observed a type of primary ST depression which occurs commonly at all stages of myocardial infarction and is usually noted in islands adjacent to infarcts

The changes seen in the standard or unipolar limb leads depend on the location of the infarcted injured or ischemic tissue the position of the heart and the relation of the latter to the sites of attachment of the extremities to the trunk If the injured and infarcted zone reaches the epicardium of the anterior wall there is a Q wave and an elevation of RS T in leads I and V_L which face the injured area and a depression of RS T in leads III and V_F and V_R facing the relatively normal tissue In posterior wall subepicardial infarcts Q waves and elevation of the RS T segment appear in leads III and V_F and in esophageal leads at the level of the ventricle Ex In pericarditis with universal subepicardial involvement of both walls RS T elevations occur in all standard leads since they all face the injured area But Q waves are absent since there is no transmural dead tissue In subendocardial injuries all standard leads usually face normal tissue which is interposed between them and the injured tissue therefore ST depressions may be seen in all these leads and there are no Q waves due to dead tissue

According to the electrocardiographic localization in one series of 974 cases of acute myocardial infarction the infarct was anteroseptal in 67 anteroseptal and anterolateral in 341 anterolateral in 117 posterobasal in 395 posterolateral in 21 and anterior and posterior in 33[112]

Anterior Wall Infarction (Q_1 T_1 Pattern)

The Q_1 T_1 type of electrocardiogram is characterized as follows (Figs 100 101)

1 At first there is an *elevation of the ST segment in lead I* and sometimes also in lead II with a simultaneous depression of ST in lead III (discordant ST deviations) Occasionally ST depressions only or high T waves may precede these discordant changes

2 The ST_1 elevation appears characteristically convex upward or dome-shaped with a downward slope toward the T wave

3 *The T wave in lead I subsequently becomes depressed or diphasic and eventually sharply inverted and V shaped* The limbs of the T wave may be symmetrical and the shoulders rounded upward At the same time the T wave in lead III becomes upright and sometimes exaggerated and sharply peaked (discordant T waves in leads I and III) The T wave deflection in lead II is usually similar to that in lead III but occasionally is inverted as in lead I

4 An early frequent change is the appearance of a *prominent Q wave in lead I* The Q wave may be broad It is followed usually by a low R wave with or without a subsequent S deflection This may produce an *M or W* shaped QRS in lead I There may also be a *definite Q wave in lead II* S_2 and S_3 are often conspicuous There may be a tendency to right deviation of the electrical axis

5 After two to four weeks but often in a few days the ST elevation in lead I is very slight or disappears but it may retain its upward convexity which slopes sharply downward toward an inverted T wave (coronary T wave[135] cove plane T wave[136]) The T wave may become upright in a few weeks but more often after three to six months or longer or may remain inverted

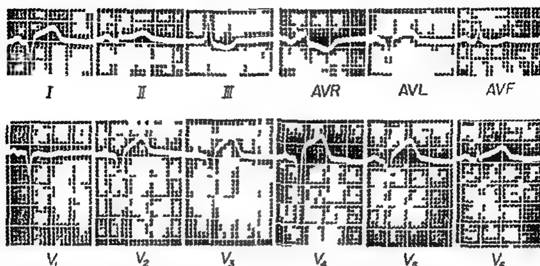

Fig 101 Acute myocardial infarction anterior wall *Q* waves and *ST* elevation in leads *I* and aVL as well as precordial leads

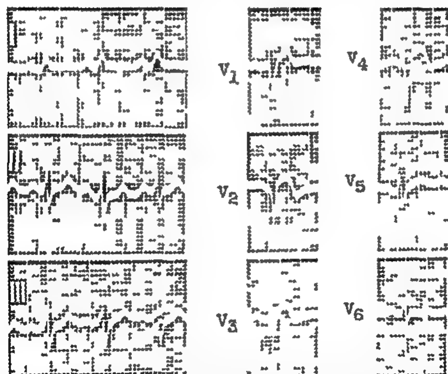

Fig 102 Acute anteroseptal infarction Characteristic changes of acute infarction absent or indefinite in standard limb leads Q waves RT segment elevations and diphasic T waves in V_{1-4} overlying anteroseptal wall with relatively normal QRST complexes in V_5 and V_6 overlying apex or anterolateral wall

Precordial leads[204, 197] may reveal characteristic changes when there is no abnormality in the standard leads or when the latter disclose only suspicious changes (Fig 102) They also localize the infarct more distinctly

1 There is an *early elevation of the ST segment* (more than 2 mm) Often the ST segment has a characteristic upward convex shape The ST elevation usually disappears in a few days but occasionally persists much longer

2 From the onset, or as the ST segment declines, there appears a *large initial negative deflection* (*Q wave*) (more than 2 mm) in lead of the normal initial upward deflection This

may be the sole deflection (QS) of the QRS group if so it is frequently slurred or notched in its descending limb Or else the deep Q may be followed by a much smaller R wave and occasionally also by a very small S wave In the latter instance the QRS may appear M or W shaped

3 As the elevated RST segment declines *the T wave becomes diphasic and then inverted* The inverted T wave is often large and sharply peaked Unlike the RS T elevations which are quite transient the T wave inversion usually persists for months and occasionally for years before reverting to normal or it may be permanent

Depending on the extent and location of the infarct these changes will be observed in one two or more of the precordial leads The presence of an abnormal Q wave may be due to either a recent or an old infarct A negative T wave in precordial leads is usually abnormal except in V_1 or V_2 and in children but it does not denote myocardial infarction unless serial electrocardiograms previously disclosed elevation of the RST segment and progressive T wave inversion The combination of an abnormal Q and a negative T is strongly suggestive of a previous or recent anterior wall infarct But in the presence of a normal R wave a negative T wave may be due to left ventricular strain or axis deviation RS T segment elevations and T wave inversions even without Q waves may denote acute myocardial infarction if there are serial changes Even then a definite diagnosis depends also on a compatible clinical history Serial changes in the T waves only may be suggestive of acute myocardial damage but then also a diagnosis of myocardial infarction is dependent chiefly on the clinical history As a rule infarcts causing only T wave changes are of small size and in unusual locations relative to the leads concerned

Subendocardial Infarction In some cases of typical clinical myocardial infarction subsequent pathologic examination discloses extensive necrosis confined to the subendocardial region and due to left or right coronary occlusion or extreme stenosis In such cases there may be no Q waves or ST segment elevations For ST segment elevations depend on subepicardial infarction and Q waves on through and through (transmural) infarction Instead there are striking ST depressions in all the standard leads and the precordial leads Thus electrocardiographic ST depression alone may signify serious or fatal cardiac infarction and should not be interpreted necessarily as denoting only reversible coronary insufficiency or coronary failure Furthermore ST depressions may be the initial electrocardiographic abnormalities before the classic findings of transmural infarction (Fig 103) Levine and Ford [*] on the basis of 6 proven cases of subendocardial infarction suggested as clues to the diagnosis ST depressions in precordial leads RS T elevation in aV_R and absence of prominent Q in aV_F

Occasionally there are *deeply inverted* T waves in one or more of the precordial leads from V_1 to V_6 and usually deepest in V_3 These findings were related frequently to subendocardial myocardial infarction in the anterior or lateral wall of the left ventricle [145] It was postulated that the T wave changes might be due to a transmural region of myocardial ischemia overlying a subendocardial zone of myocardial infarction [145] Similar T wave inversions may occur in patients with angina pectoris or with left or right ventricular hypertrophy pericarditis acute right ventricular dilatation anteroseptal ischemia or a small intramural or subepicardial infarct [116 146]

Anteroseptal Infarction An infarct localized in the anteroseptal region may be indicated by the following changes in unipolar precordial leads[1 0] (Fig 102)

1 An abnormal QR occurs in leads V_1 and V_2 or in one or more of V_2 V_3 or V_4 with a normal initial R in V_1 A Q wave may be considered abnormal if it exceeds one quarter of the height of the following R wave or it is prolonged more than 0 02 second from onset to nadir

2 There may be an elevation of the RST segment in leads V_1 or V_2

3 There are no abnormal Q waves in V_5 or V_6

Occasionally the Wilson type of right bundle branch block is the only sign of slight anteroseptal infarction [133]

Standard limb leads usually show no significant abnormalities as they are perpendicular to the direction of the advancing excitation wave and current of injury

If the entire septum is involved from anterior to posterior surface the electrocardiogram may disclose signs of anteroseptal infarction in precordial leads and of posterior

infarction in standard leads[183] Extensive septal infarction[1, 9, 183] may be suggested by (1) the occurrence of bundle branch block or severe atrioventricular block in the course of an acute myocardial infarction (2) the finding of Q waves in the right precordial leads in the presence of complete right bundle branch block, or (3) the finding of Q waves in left precordial leads in the presence of left bundle branch block

Anterolateral Infarction When small infarcts are localized to the lateral portion of the anterior wall, the presence of a Q wave and associated abnormalities in the RST segment and T wave might be limited to precordial leads taken from the fourth, fifth and sixth positions and be absent in positions further to the right

Lateral Wall Infarction (Posterolateral Apical lateral, Basal lateral, and High lateral)

Wood Wolferth and Bellet[98] described electrocardiographic changes which they believed were associated with infarction of the lateral wall of the left ventricle These consisted of depression of RS T in leads I and II absence of signs of infarction in lead III and depression of RST in lead IV Thomson and Feil[187] found 19 cases of infarction of the lateral wall (9 recent) in 106 necropsied cases of cardiac infarction In 4 of the 9

recent cases the electrocardiogram presented a pattern resembling that described by Wood et al [06]

In 6 cases of suspected infarction of the basal portion of the lateral wall of the left ventricle Rosenbaum Wilson and Johnston[154] found no unequivocal evidence of infarction in the standard precordial leads However distinctive changes were observed in unipolar leads from points on the lateral surface of the upper left thorax In another study of 105 cases showing lateral wall infarction at autopsy Myers et al [1 1] discovered electrocardiographic changes in one group like those described under anterolateral infarction In another group of cases representing a lateral

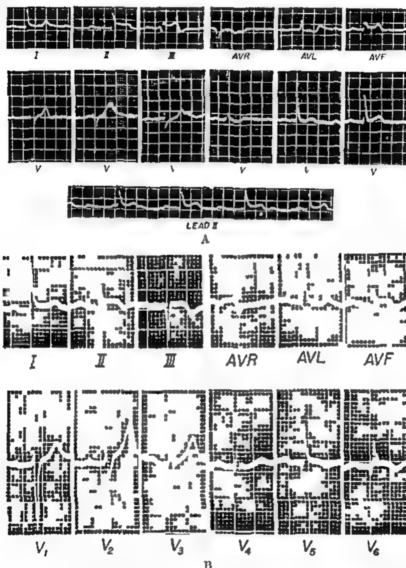

Fig 104 *A* Forty nine year old man Angina pectoris 2 years Premonitory pain 2 days Severe pain 9 hours 2 14 56 Electrocardiogram shows infarction of posterior wall of left ventricle with complete heart block T waves upright in precordial leads

B 2 15 56 Anterolateral extension of posterior wall infarct Q waves RT segment elevation and cove plane inverted T waves in V_5 and V_6

extension of a posterior infarct (posterolateral infarct) the lateral extension could be diagnosed from V_5 V_6 or V_7 and posterior infarction from V_E[119] (Fig 104*B*) The posterior portion of the infarct was most commonly undiagnosed when there was counter

clockwise rotation and a horizontal electrical axis of the heart conversely the commonest cause for failure to diagnose the lateral portion of the infarct in aV_L was clockwise rotation and a vertical electrical axis Primary lateral infarcts near the apex revealed abnormalities in V_5 V_6 and V_L, those near the base disclosed abnormalities in V_L and leads high in the left lateral thorax but uncommonly in V_5 or V_6 Q waves are most significant, while RS-T elevations or depressions depend on the subepicardial or subendocardial localizations of the infarct In high posterior infarcts ST depressions and/or tall R and T

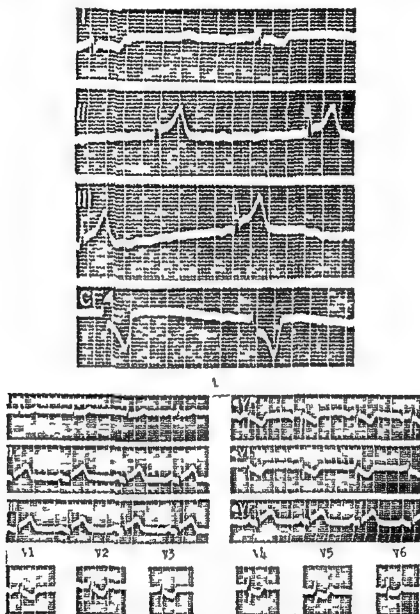

Fig 105 Posterior wall infarction A One half hour after onset R T elevations in leads II and III and R T depressions in leads I and CF_4 Tall broad T waves Atrial fibrillation
B One day after onset Same case Sinus rhythm Small Q_2 and Q_3 now present R T elevations in unipolar limb lead from left foot (aV_F)

waves in the precordial leads may be the sole changes

As a rule one should consider lateral infarction when deep Q waves and RS T elevations and T wave inversions are noted in aV_L and less regularly in V_6 or V_7 There may be a

prominent R and a shallow S wave in V_1[34] and in aV_R owing to the unbalanced electromotive forces away from the injured lateral ventricle and toward the right precordial leads Horizontal projections of the vector cardiogram in such cases show the vector loop strikingly displaced to the right.[47] In high posterolateral infarction Tulloch[188] has described findings significant of infarction in aV_L and in I, a predominant R in V_1 high upright T waves in two or more precordial leads ST depressions in V_5 and V_6 with elevations in leads V_7 to V_9

Posterior Wall (Diaphragmatic) Infarction (Q_3 T_3 Pattern)

1 There is an *early elevation of the ST segment in lead III and usually also in lead II* At the same time the ST segment in lead I is depressed (discordant ST deviation) (Figs 104 105)

2 The ST_3 elevation has a characteristic upward convexity or dome shape beginning at its high take-off from the R wave and sloping downward toward the T wave (Fig 106)

3 *The T wave in lead III and usually also in lead II becomes progressively lower diphasic and eventually sharply inverted and V shaped* The T wave in lead I is upright and often sharply pointed (Fig 106)

4 There is often an *early appearance of a conspicuous Q wave in lead III and often also a smaller Q wave in lead II* The Q wave in lead III may be the sole initial ventricular deflection or there may be a small R or small R and S waves In lead II Q R and S are often all of small amplitude producing a W or M shaped configuration A similar configuration in lead III is usually not significant There may be a tendency to left deviation of the electrical axis The presence of a Q_3 and inverted T_3 in themselves may not signify myocardial infarction for they may be produced by a transverse position of the heart The significance of a Q_3 is enhanced if S is absent in lead I[189] The presence of a deep Q wave in V_F strongly increases the probability that the Q_3 is due to posterior infarction and not to a semitransverse or transverse position of the heart[1] (Fig 105B) A Q wave in aV_F is probably indicative of posterior infarction if its voltage is 40 per cent or more of the voltage of the entire QRS in that lead (which must exceed 0 7 millivolt) and if the duration of Q is 0 04 second or more and is associated with an inverted T[110] Left ventricular hypertrophy may produce a Q wave and inversion of T in V_F

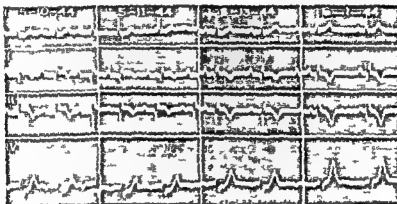

Fig 106 Posterior wall infarction Progressive changes

The *precordial leads* in cases of posterior (or diaphragmatic) wall infarction are not usually of diagnostic importance The following abnormalities may be observed (Fig 107)

1 Early and transient depression of the ST segment This is not as prominent as the elevation observed in instances of anterior infarction The ST depression is most likely to occur in true posterior wall infarcts not in farction of the diaphragmatic surface

2 An extremely *tall T wave* may appear (above 12 mm) Tall sharply pointed T waves in leads V_1-V_3 have been noted in the earliest electrocardiographic changes[190]

An esophageal lead at the level of the ventricles may disclose more striking changes including presence of a Q wave RS T elevation and T wave inversion[1 5 1 7] In posterior

basal infarcts only a unipolar lead over the xiphoid process may reveal the Q and RS-T changes of infarction. But there may be reciprocal RS-T depressions in V_1 to V_4. In high posterior (posterobasal) wall infarcts no Q waves may be inscribed in conventional leads and the electrocardiogram may appear relatively normal (see Vectorcardiogram, p. 535).

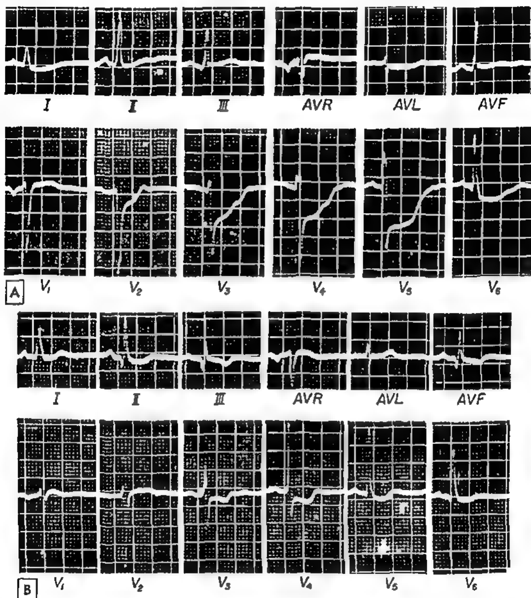

Fig 107 *A* Seventy year old man. Operated on for strangulated inguinal hernia. Angina pectoris 2 days preoperatively. Shock and pulmonary edema 4 hours postoperatively when this electrocardiogram was taken. Extreme ST depressions in all precordial leads (interpreted as "coronary insufficiency"). Slight ST depression in I and aV_L.

B After 10 days of progressive changes: Q wave, slight RT elevation and inversion of T wave in lead III and aV_F indicative of posterior wall infarction. Progressively less ST depressions in precordial leads.

Combined Anterior and Posterior Infarction

In combined infarcts of the anterior and posterior walls of the left ventricle the electrocardiogram may disclose patterns which include elements of the Q_1T_1 and of the Q_3T_3 type, or changes representing defective intraventricular conduction or bundle branch block, or nonspecific QRS and T wave changes. Occasionally one observes at the onset changes suggestive of a posterior wall infarction with subsequent development of a pattern of anterior wall infarction, or vice versa. When there is an old infarct on one surface and a

fresh infarct on the other the changes due to the recent infarct may be added to or may replace those of the previous infarctions [9] Thus Q waves in leads II and III may be residua of an old posterior infarct while RS-T *changes with subsequent inversion of* the T wave in lead I result from a recent anterior infarct The standard leads may disclose the Q_3-T_3 pattern of a posterior infarct while the precordial leads reveal the additional presence of an anterior infarct The V_F lead may be helpful [113] Often however an *acute* anterior infarct tends to conceal the electrocardiographic changes of posterior infarction [97]

ert the negative potentials of the right ventricular cavity are transmitted to the left precordial leads and Q waves appear Although Q waves are usually absent when left bundle branch block complicates anterior wall *infarction there may be a reduction in the* voltage of the R wave and elevated ST segment elevation in left precordial leads [11]

With *right bundle branch block* and a *posterior wall infarct* the characteristic electrocardiographic changes of the latter may be visible in the limb leads while the right bundle branch pattern is most distinctive in right precordial leads (Fig 108)

With *right bundle branch block* and an *an*

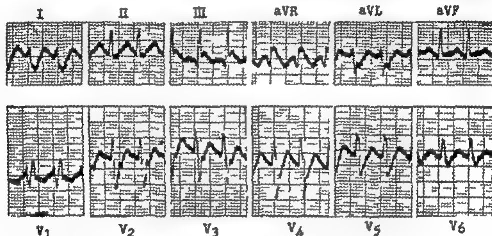

Fig 108 Posterior wall myocardial infarction with right bundle branch block in a diabetic woman 65 years old Posterior infarction indicated by Q and RT elevation in lead III Electrocardiogram per se compatible also with pulmonary embolism and acute cor pulmonale

Acute Myocardial Infarction with Bundle Branch Block [177, 13, 197]

In left bundle branch block the left ventricular cavity remains positive until the impulse from the right bundle branch crosses the septum The usual Q wave due to transmission of left cavity negativity to the exploring electrode over an infarct does not occur because of the positive left cavity potential An exception is a complete left to right infarction of the septum

With *left bundle branch block* the diagnosis of myocardial infarction is usually precluded except with extensive septal infarction [197] Owing to the left bundle branch block the left cavity potentials are positive and therefore the Q waves representing transmitted negative cavity potential in transmural infarcts are not present But if the entire septum is also infarcted and electrically in

terior wall infarct the presence of the latter may be obscured in the standard limb leads Significant Q deflections are absent but there may be an RT segment elevation with or without inversion of the T wave in lead I or I and II [11] The presence of the anterior infarct is revealed clearly in the precordial leads, which disclose the classic Q wave RS T elevation and T wave inversion (Fig 109)

Sometimes bundle branch block in the course of acute myocardial infarction is of transient duration Serial electrocardiograms may then disclose the characteristic changes of acute infarction in both the limb and precordial leads at those times when bundle branch block is not present The Wilson type of right bundle branch block may appear as a transient phenomenon in light anteroseptal infarction Occasionally, when the electro-

cardiographic changes of acute myocardial infarction are obscured by those of bundle branch block there may be sporadic interpolated premature ventricular beats which reveal characteristic changes of infarction [41]

Less Specific Electrocardiographic Changes

Dressler[40] has noted that at certain stages of acute myocardial infarction and sometimes during the period of preliminary pain an electrocardiographic pattern in which T_1

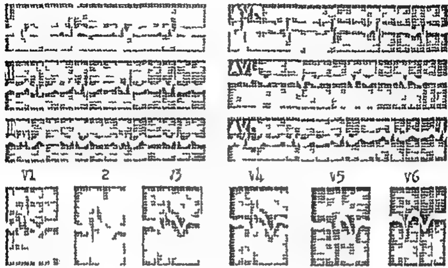

Fig 109 Anterior wall infarction with right bundle branch block Wide QRS complex with broad S in standard leads and catt n of right bundle branch block Anterior wall infarction disclosed by Q waves and RT elevations in precordial (V) leads

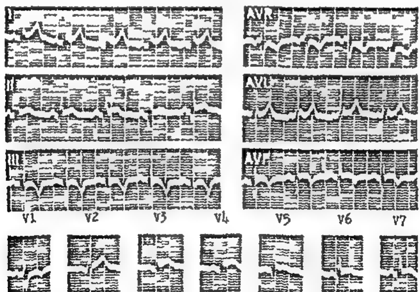

Fig 110 Acute posterior wall infarction with pericarditis RT elevation in leads II III and aVF with characteristic convexity upward Cove-plane T wave inversion and Q waves in leads III and aVF indicate posterior infarction The RT elevations with concavity upward in lead I and in precordial leads without Q waves suggest pericarditis

Myocardial Infarction and Pericarditis

In cases of acute myocardial infarction with diffuse pericarditis both the pericarditis and cardiac infarction may produce distinctive changes (Fig 110) For a differentiation between the electrocardiogram in pericarditis and acute myocardial infarction see p 598

is lower than T_3 is indicative of an anterior wall infarction This is especially significant when the patient is over 40 years of age and has been subject to attacks of angina pectoris In young persons rheumatic heart disease is more commonly responsible for this picture Normally T_1 is taller than T_3 except

when the heart has a vertical position when there is pulmonary emphysema or rarely in the presence of congenital heart disease thyrotoxicosis uremia, vitamin deficiency and trichinosis This pattern in which T_1 is smaller than T_3 is also associated with an old myocardial infarct Consequently a consideration of the clinical history is essential to determine whether this pattern signifies recent or old cardiac infarction

Characteristic elevation of the RS T segment with inversion of the T wave in lead I is strongly suggestive of anterior wall infarction even when the classic reciprocal RS-T depression in lead III is absent or inconspicuous Absence of the reciprocal ST depressions may be due to a simultaneous posterior wall infarct Similarly in cases of anterior wall infarction the RS T segment elevation in lead I may be inconspicuous or absent and T_1 may be only flattened or isoelectric but the reciprocal ST depressions and prominence of the T waves in leads III and II may be striking Sharply inverted V shaped T waves alone may appear in the standard leads after acute myocardial infarction but these findings in themselves are not diagnostic of the infarct

In some cases the significant finding is the low voltage (less than 0 5 mv or 5 mm) of the QRS complex in all leads with or without inverted T waves Often the QRS complexes are not only of low voltage but slurred and notched and they may be widened beyond the normal limit of 0 1 second These findings are associated with both fresh and old infarction as well as other conditions but in some instances with the aid of the clinical history and previous electrocardiograms it may be possible to conclude that the infarct developed recently Similar significance may be attached to an M or W shaped QRS of low voltage in leads I or II when interpreted in the light of clinical data

The P wave may be increased in amplitude and occasionally it is notched and widened Master[104] observed a P wave of 2 mm or more in at least one lead (usually lead II or leads I and II) in 40 per cent of his cases of acute coronary occlusion and attributed it to enlargement of the left atrium Bloom and Gilbert[21] observed a higher incidence of arrhythmias and conduction disturbances in those cases with large or notched P waves than in those with normal P waves The occurrence of conduction disturbances and arrhythmias in the electrocardiograms seen after acute myocardial infarction is discussed below

Although the electrocardiogram of acute myocardial infarction is usually distinctive patterns appearing in a variety of conditions (left or right ventricular hypertrophy bundle branch block potassium disturbances and myocarditis) may be mistaken for those of myocardial infarction[116 ...] See pp 462 3

VECTORCARDIOGRAM IN MYOCARDIAL INFARCTION[163 ... 6 203 195 201]

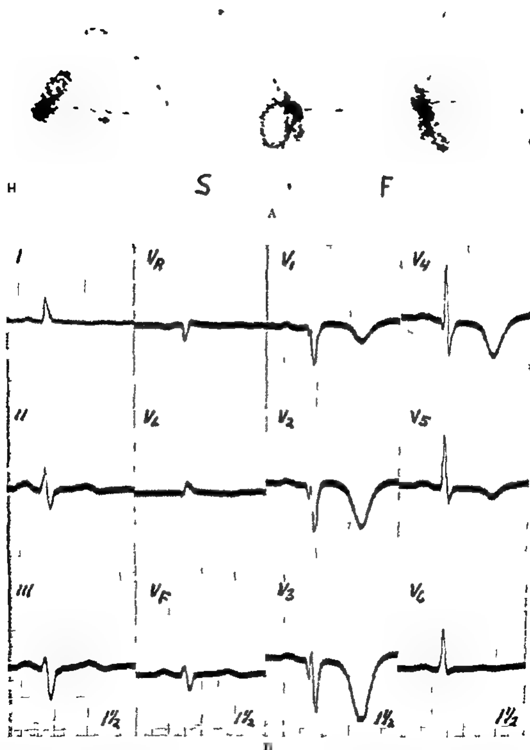
Consistent vectorcardiographic patterns delineating acute myocardial infarction cannot be presented because of persistent disagreement as to basic concepts of vectorcardiography and differences in method[162] of electrode placement Nevertheless it is claimed that myocardial infarction is one of the conditions in which vectorcardiography is diagnostically superior to electrocardiography

Myocardial infarction renders a portion of the myocardium electrically inert In consequence this muscle tissue fails to contribute its electromotive forces to the summation cardiac vector and the balance of forces is altered This disturbance affects predominantly the initial and early portions of the spatial vectorcardiographic QRS loop Abnormalities are indicated by changes both in the spatial orientation and in the direction of inscription of these initial and early forces of the QRS Such abnormalities as cannot be explained on the basis of position and rotation of the heart may be attributed to myocardial disease Changes in the initial portion of the loop are due to damage of the septum those in the very early portion of the loop to injury to the free wall of the left ventricle

Myocardial infarction during the acute phase is indicated also by failure of the loop to be closed the line drawn from the point of onset to the point of conclusion of the loop representing the ST vector Abnormalities in the T loop also occur

Septal Infarction The *initial* forces of the QRS *are oriented to the left and upward* instead of as normally to the right anteriorly and very slightly upward Usually this is combined with infarction of neighboring portions of the anterior wall (Fig 111)

Anterior Wall Infarction The early forces of the QRS are oriented posteriorly instead of anteriorly[6 ... 78a] there is clockwise inscription instead of counterclockwise in the frontal loop



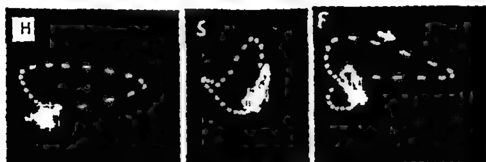


Fig 111 *A* Vectorcardiogram in anteroseptal infarction characterized by loss of initial deflection which is *normally directed anteriorly and to the right Therefore absence of R waves in right precordial leads of electro*cardiogram QRS loop inscribed sharp posteriorly and to the left in the horizontal plane
B Electrocardiogram of same patient

A

B

Fig 112 *A* Vectorcardiogram indicating infarction of diaphragmatic wall of left ventricle Normal QRS loop in horizontal plane but inscribed superiorly in frontal and sagittal planes with consequent absence of R waves in leads V_F II and III

B Electrocardiogram in same case

projection The entire loop may be oriented posteriorly

Diaphragmatic (Inferior) Wall (Fig 112) The early forces are directed upward and the major loop is displaced superiorly The inscription of the loop is usually clockwise in the frontal and counterclockwise in the sagittal projections both the reverse of normal But a horizontally lying loop which is inscribed clockwise in the frontal projection may represent ventricular hypertrophy

Posterior Wall Infarction The QRS loop is deviated anteriorly owing to loss of electromotive forces which are directed posteriorly The loop is inscribed clockwise in the frontal projection and counterclockwise in the sagittal projection both the reverse of normal Burch et al [6] using the tetrahedron reference frame, observed a characteristic upward displacement of the early portion of the QRS sÊ In high posterior infarctions which may not produce significant abnormalities in the conventional electrocardiogram the vectorcardiogram (tetrahedron or cube coordinates) shows a characteristic alteration of the loop to a rounded rather than oval form, the initial forces are markedly anterior and the rotation is clockwise instead of counterclockwise in the horizontal plane [illegible]

Lateral Wall The initial forces are normally oriented, but the early forces continue to the right because of a loss of the leftward forces of the lateral wall of the left ventricle If the posterolateral wall is involved the early forces are directed anteriorly and to the right, if there is a *high* posterolateral lesion the early forces are directed downward as well as anteriorly and to the right

In addition to the above changes in the variously located infarcts during the acute stage the QRS loop is open The previously described alterations in the QRS loop account for the presence of Q waves in various leads of the electrocardiogram the open loops for the ST deviations The direction of the vector from the zero point to the end point of the loop varies according to the location of the infarct being directed anteriorly to the left and upward in anterior wall infarcts, and posteriorly, downward and to the right in posterior wall infarcts The T loop often becomes long and narrow and is oriented opposite to the ST vector and points away from the infarcted area

When *left bundle branch block* occurs, it alters the entire vectorcardiographic QRS loop and precludes the diagnosis of associated myocardial infarction But in the presence of right bundle branch block of the Wilson type the occurrence of an infarct is indicated by changes in the initial or early portions of the QRS loop, whereas the bundle branch block is characterized by a slow inscription and abnormal orientation (to the right and anteriorly) of the terminal appendage of the loop

THE BALLISTOCARDIOGRAM[illegible]

Severe abnormalities of the ballistocardiographic pattern, graded II or worse by the criteria of Brown et al [illegible] are regularly observed during the acute stage of the disease In those who recover progressive improvement in the pattern usually occurs and may continue up to 8 months Serial ballistocardiograms were found by Mandelbaum and Mandelbaum[10] to provide a reliable index in determining myocardial functional recovery and prognosis with regard to resuming gainful activities

CARDIAC ARRHYTHMIAS IN ACUTE MYOCARDIAL INFARCTION

Premature contractions (extrasystoles), usually of ventricular origin, constitute the most frequent arrhythmia associated with acute myocardial infarction Rarely, multiple premature ventricular contractions presage the onset of ventricular tachycardia (see below)

All other arrhythmias combined appear much less often than premature contractions perhaps in about 15 to 20 per cent of cases of acute myocardial infarction They usually develop in the first three days of the attack but in occasional cases at any other time in the first two weeks Most of the arrhythmias subside spontaneously in 4 to 24 hours

Atrial fibrillation is next in frequency to premature ventricular contractions, whereas atrial flutter is observed less commonly [illegible] Atrial fibrillation often appears in the first few days and disappears spontaneously after several hours For this reason it is easily overlooked Occasionally, however, one of these paroxysms is the onset of persistent atrial fibrillation

Atrial or nodal tachycardia has been encountered in 0 5 to 2 0 per cent of cases [9] It may persist for several weeks

Ventricular tachycardia occurs rarely but may preface ventricular fibrillation and death. For this reason its prompt recognition and treatment are essential (p. 374).

Heart Block. Various grades are not infrequent (Fig. 113). The *prolongation of the P-R interval* was observed by Master et al.[106] in 16 per cent of 375 cases of acute myocardial infarction. In addition partial and complete heart block were noted in 3.2 per cent of their cases. Bean[17] observed a P-R interval of 0.2 second or longer in 30 per cent of his cases.

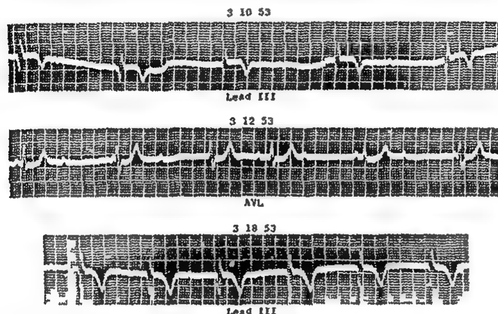

Fig. 113. Varying degrees of heart block with acute myocardial infarction, posterior wall.
3-10-53. Complete heart block; atrial rate 65, ventricular rate 34 and regular. P-R interval varies.
3-12-53. High degree of partial heart block with intermittent conducted beats. First and fifth ventricular complexes are sinus beats; second, third and sixth nodal beats; and fourth a fusion beat.
3-18-53. First degree heart block with prolongation of P-R interval to 0.48 second. Atrial rate 54, ventricular rate 54. P-R interval constant.

The prolongation of the P-R interval appears early, usually in the first week and often on the first or second day of the attack. However, occasionally it is observed only after several weeks. Decided variations in the length of the P-R interval may suggest that the process in the heart muscle is both recent and active. Bundle branch block and other intraventricular conduction disturbances are found more frequently in cases of cardiac infarction with a prolonged P-R interval than in those with a normal P-R interval. Usually the prolongation of the P-R interval persists several weeks and disappears. Occasionally it remains permanently, differing in this respect from other arrhythmias which rarely persist after myocardial infarction.

Partial heart block with Wenckebach period and dropped beats occurs occasionally. Both partial and complete heart block occur early in the attack and they may represent the first or only indication of an acute coronary occlusion. *Complete heart block* with atrioventricular dissociation has been considered very uncommon, but Schwartz[155] reported personal observation of the surprisingly large number of 15 cases. According to Kerr,[8] complete heart block occurs in only 2 to 3 per cent of cases of acute cardiac infarction and all forms of conduction disturbance in 7 to 8 per cent. As a rule heart block occurs early in the attack (Fig. 101). It is usually persistent but may disappear. The occurrence of heart block is almost always associated with occlusion of the right coronary artery, which in 90 per cent of hearts supplies the a-v node and the bundle of His through its ramus septi fibrosi. Since this branch arises almost at the origin of the right coronary artery, proximal to the usual site of thrombosis, the blood supply through this vessel to the node and bundle of His is only infrequently suppressed

But a subsidiary supply to the bundle comes from the left anterior descending coronary artery by way of its ramus limbi dextri. Because of a rich anastomosis between the left and right coronary arteries in the region of the a-v node and bundle, complete heart block is most likely to develop when both arteries have been occluded. If heart block appears after an acute anterior infarction (left coronary artery occlusion), it is probable that the right coronary artery was previously occluded. In most cases of heart block, autopsy examinations reveal multiple coronary occlusion with massive cardiac infarction, usually involving the interventricular septum. As a result, impaired intraventricular conduction (as denoted by wide and notched QRS complexes) is often associated with complete heart block.[169] Sometimes complete heart block is the result of damage and interruption of both bundle branches and not of the main bundle of His.

Adams Stokes syndrome (p. 390), This is characterized by convulsions, syncopal attacks and coma, may appear after the development of complete heart block,[169] but usually only when the ventricular rate falls below 40. Thus the incidence of the Adams-Stokes syndrome after acute myocardial infarction is much lower than that of complete heart block. Cookson[33] observed 5 cases of syncope or convulsions in the course of 200 cases of acute cardiac infarction. Two had syncope and 3 the complete Adams-Stokes syndrome including convulsions. In one instance an electrocardiogram taken during the attack showed complete heart block with the rate falling from 100 to 34. These attacks may also result from periods of ventricular tachycardia or ventricular flutter and fibrillation, which culminate in ineffectual cardiac systole and consequent cerebral ischemia (p. 377). In some instances, paroxysms of Adams-Stokes syndrome result from ventricular standstill following supraventricular or ventricular tachycardia or partial heart block. In cases with Adams-Stokes syndrome complicating cardiac infarction, other abnormal rhythms are common between attacks. Cookson[33] found posterior ventricular infarction in 4 of 5 cases of this type, in the other the site of infarction was undetermined.

Bundle branch block and other intraventricular conduction defects (p. 395) are fairly common, but only recognizable electrocardiographically.[168] These disturbances usually appear early and persist. However, I have seen bundle branch block appear with the onset of acute myocardial infarction and disappear as the more classic cardiographic features of this condition emerged. But when the bundle branch block persists, it often obscures the electrocardiographic features of myocardial infarction. Right bundle branch block may conceal a small anteroseptal infarct, both occurring simultaneously because the right bundle branch and the myocardium involved receive their blood supply from the ramus limbi dextri of the left anterior descending artery. Intraventricular and atrioventricular conduction defects may be associated.

COMPLICATIONS AND CAUSES OF DEATH

Shock and Acute Left Ventricular Failure

These occur so frequently with acute myocardial infarction that they have been discussed as intrinsic features of the disease rather than as complications. Either of these may be sufficiently severe to cause death within the first few days after the onset.

Chronic Left Ventricular Failure

This may develop gradually, weeks or months after the occurrence of acute myocardial infarction. Under these circumstances it is characterized by recurrent episodes of nocturnal dyspnea, a progressively increasing dyspnea on exertion, orthopnea, cough and the presence of rales at the bases of the lungs. Death may result from an acute attack of pulmonary edema. Often the symptoms of acute left ventricular failure subside after the first few days or weeks. In many cases chronic left ventricular failure persists for several years and the patient eventually succumbs to increasing left- and right-sided congestive heart failure or some other complication.

Right Ventricular Failure

This may appear after the acute symptoms of myocardial infarction have subsided. Patients with these symptoms may run a slow downhill course or die more or less suddenly. Together, left and right ventricular failure with or without shock constitute the chief cause of death from acute myocardial infarction.[49]

Embolization

Pulmonary, cerebral and peripheral emboli constitute the next most common cause of

death although such emboli are not always fatal Garvin[59] observed that in about 60 per cent of the cases of myocardial infarction that he studied there were one or more infarcts (presumably due to embolism) in the lungs brain *kidneys, spleen extremities and/or* intestine In a review of cases reported in the literature Hellerstein and Martin[49] found an average of 11 5 per cent of embolism or infarction In their own autopsy series of 160 cases 73 or 45 per cent were associated with embolism which was the main cause of death in 12 per cent and a contributory cause in an additional 15 per cent The frequency and importance of thromboembolic lesions in acute myocardial infarction has gained increasing significance recently because of treatment with anticoagulants

Pulmonary Embolism[15, 114] Pulmonary embolism is the most frequent of these embolic complications of acute myocardial infarction and is a commoner cause of death than is generally recognized Eppinger and Kennedy[49] found pulmonary emboli in 23 per cent of 200 cases of myocardial infarction proved at autopsy and emphasized the significance of pulmonary embolism as a cause of death Massive pulmonary emboli in accounted for 10 per cent of 577 deaths in somewhat more than 1000 cases of acute coronary occlusion studied by various observers[133, 49, 114] As a rule pulmonary emboli originate from peripheral thrombi in the veins of the lower extremities unlike the other forms of emboli which originate in mural thrombi in the left ventricle or atrium

Thus pulmonary emboli may be only in part a direct consequence of the cardiac infarction and slowing of the peripheral circulation bed rest and the associated venous stasis are probably more important causes This consideration is important in the treatment of acute myocardial infarction Although mural thrombi associated with myocardial infarction are located almost always in the left ventricle[159] they may also form in the right ventricle when there is extensive infarction of the interventricular septum In the latter circumstance the pulmonary emboli may be generated from a mural thrombus but this is a much less frequent source than the peripheral veins and the resulting emboli are less likely to be as large or as serious In still other cases in which there is *marked cardiac dilatation associated with right sided heart failure* mural thrombi may develop in the right atrium and may promote pulmonary emboli

Pulmonary embolization may *occur within the first few days after the onset of myocardial infarction but usually not until the* end of the first week or during the second week of the disease The emboli tend to recur each new embolus increasing the probability of a fatal outcome These episodes of recurrent emboli are usually misinterpreted as repeated fresh coronary thromboses Pulmonary embolization may occur while the patient is still bedridden, but frequently it develops suddenly when the patient sits up in bed strains at stool or gets out of bed for the first time

Cerebral emboli are probably the next most *serious form of embolization and like other* emboli to the systemic arteries originate in left ventricular mural thrombi Dozzi[33] in a review of 1000 consecutive necropsies found that in 12 (29 per cent) of 41 cases of coronary thrombosis there was an associated cerebral vascular accident Cerebral infarction was found in 5 to 15 per cent of various series of cases of myocardial infarction proven at autopsy[15, 49, 46] The clinical features may overshadow or obscure the more classic features of myocardial infarction Cerebral emboli usually result in encephalomalacia which may be evidenced by aphasia *hemiplegia* convulsions and psychic disturbances while the underlying myocardial infarction is unsuspected[50, 31] Occasionally such emboli are responsible for or contribute materially to the fatal outcome

Visceral emboli usually affect the kidney and spleen and occasionally the intestinal tract They may produce renal infarction with or without lumbar and ureteral pain and hematuria, *splenic* infarction usually asymptomatic but sometimes denoted by local pain on respiration and a splenic rub due to perisplenitis and rarely intestinal infarction with acute abdominal symptoms

Peripheral Emboli Embolization of the aorta at its bifurcation (saddle embolus), of the iliacs of the popliteals and of other peripheral arteries has also been noted Usually the embolus lodges at the bifurcation of a peripheral artery The most common site is the femoral at the origin of the profunda femoris and next most common are the common iliac, axillary and brachial popliteal and aorta in *that order*[1-8] Peripheral embolism is charac

terized usually by acute and excruciating pain, blanching of the affected area of skin, loss of sensation, coldness of the extremity, loss of arterial pulsation and later loss of motion of the affected muscles. Eventually these emboli may result in gangrene of the extremity but when located distally in the lower extremity or in any artery of the upper extremity, an adequate collateral circulation usually precludes the occurrence of gangrene. Gangrene has also occurred in cases in which there was no apparent evidence of embolism or thrombosis and it was attributed to spasm.[138]

Bronchopneumonia

The true incidence of this frequent complication of acute myocardial infarction is difficult to determine. On the one hand it is unrecognized when it complicates advanced pulmonary congestion associated with rales at the bases of the lungs; on the other hand it is often diagnosed clinically when the pulmonary signs and other clinical features are actually due to pulmonary embolism with infarction. Undoubtedly pulmonary congestion, pulmonary infarction and bronchopneumonia are often combined in the same person. Bronchopneumonia is commonly a terminal or terminating incident in fatal cases.

Rupture of the Heart

This is one of the commoner causes of sudden death in the first few weeks after acute myocardial infarction.[46, 57, 196, 129] Martland[103] found a rupture of the heart in 2 per cent of 2000 cases investigated by the medical examiner; these comprised about 7 per cent of the 318 cases of coronary occlusion in his series. While cardiac infarction due to coronary atherosclerosis and occlusion is by far the commonest cause of rupture of the heart, the latter may also result rarely from bacterial endocarditis, myocardial abscess due to sepsis, dissecting aneurysm of the sinus of Valsalva, gummatous (syphilitic) myocarditis, tuberculous perimyocarditis, echinococcus cyst and malignancy. Traumatic rupture of the heart is discussed in Chapter 44.

According to Fulton,[59] one eighth of the patients who succumb in the first three weeks after acute myocardial infarction die from rupture of the heart. The 44 cases of cardiac rupture reported by Nesvadba[114] represented 7 per cent of the fatal cases of myocardial infarction in his series. Krumbhaar and Crowell[85] found the cardiac rupture through the left ventricle in 225 cases and through the right in 32. The anterior surface was lacerated three times as often as the posterior surface. Infarction and rupture of the right atrium have also been reported (p. 516).

Rupture of the heart results from a through and through laceration of an infarcted area which is still soft and necrotic. The rupture occurs most frequently in the first week, sometimes in the second week, and rarely thereafter. In Fulton's series [illegible] death from cardiac rupture occurred within 17 days in all but one and the average was 9 days after cardiac infarction. It may occur in the first two or three days. Whereas softening of the myocardium is a major factor responsible for ventricular rupture, the height of the intraventricular pressure may also be important. Edmondson and Hoxie[46] found that patients who have hypertension which persists after infarction are three times more likely to develop cardiac rupture than those who have normal or subnormal blood pressures. Women are somewhat more susceptible than men. Although cardiac rupture may occur when the patient is in bed, occasionally a specific physical strain or continued normal activity after the myocardial infarction may contribute to the cardiac perforation. Thus while Friedman and White[57] encountered 10 cases of rupture of the heart (9.4 per cent) in 105 autopsied cases of myocardial infarction in a large general hospital, Jetter and White[74] found 16 instances of rupture of the heart (73 per cent) out of a total of 22 autopsied cases of acute myocardial infarction in mental institutions. The implication was that continued activity by mental patients with unrecognized myocardial infarction was an important factor in causing rupture of the heart. But although hypertension and exertion are accessory factors favoring cardiac rupture after myocardial infarction, cardiac rupture depends primarily on the site and extent of the infarct and is favored by absence of a collateral circulation and absence of fibrosis in the infarct.[196]

Rupture of the heart following cardiac infarction leads to hemopericardium, cardiac tamponade and sudden death. Occasionally the amount of blood in the pericardium may even exceed a liter, but usually about 250 cc is sufficient to cause cardiac tamponade. Death may occur within a few minutes after

the rupture but occasionally there is a survival period of a half hour or longer There has been at least a threefold rise in the prevalence of hemopericardium without rupture and a twofold increase of rupture of the myocardium in patients who received anticoagulant therapy during acute myocardial infarction in comparison with those who did not [15]

Rupture of the Interventricular Septum

Rupture of the interventricular septum after infarction of this portion of the myocardium is less common than that of the ventricular wall [65, 88] Edmondson and Hoxie[66] observed 13 instances of rupture of the interventricular septum compared with 56 of the left or right ventricle The perforation is usually a single one in the lower or central portion of the septum varying from pinpoint size to 6 cm in length occasionally there are two or three perforations

Unlike ventricular rupture rupture of the septum can be readily diagnosed antemortem [160, 110, 81, 101, 167] and may occasionally permit a period of survival of several months[114] or even up to five years [205, 16] Clinically the symptoms are those of severe myocardial infarction associated with intense dyspnea and increasing shock The symptoms and signs of right sided heart failure may develop rapidly The diagnostic feature is a loud and often roaring systolic murmur which is usually loudest in the fourth and fifth interspace near the left border of the sternum A systolic thrill is almost always present in the same region but it may be absent The prognosis is almost always extremely poor partly because the infarction in these cases is usually extensive and partly because of the added circulatory disturbance of the acute perforation itself In those who survive even for a few months there are usually symptoms and signs of left and right sided congestive failure

Rupture of a papillary muscle is a rare complication of cardiac infarction [183, 165, 1] It may be due also to bacterial endocarditis or trauma The posterior papillary muscle of the left ventricle is most often affected the anterior papillary muscle is next in frequency and rarely the papillary muscles of the right ventricle Sometimes there are no auscultatory findings but there may be a loud apical systolic murmur or a whistling to and fro murmur or a murmur and a thrill resembling those of a ruptured interventricular septum Pulmonary edema and progressive heart failure follow rapidly

Sudden Death

Sudden or unexpected death is a common termination of acute myocardial infarction It may be the only manifestation of the attack (p 513) or it may occur in any stage of the acute disease during convalescence Among its causes massive pulmonary embolism and rupture of the heart have already been mentioned It is believed that most often sudden death results from ventricular fibrillation or cardiac standstill although only rarely is it possible to demonstrate this electrocardiographically Of 16 instances of sudden death associated with coronary disease analyzed by Stroud and Feil [185] 8 were due to a sudden paroxysm of ventricular fibrillation and 8 to sudden ventricular standstill According to Brofman et al a difference in oxygenation of two adjacent areas of myocardium associated with a difference in electrical potential across the transitional zone acts as a trigger' to destroy the coordinated mechanism of the heart and thus induces ventricular fibrillation [24] In patients with complete heart block and Adams Stokes syndrome following cardiac infarction death may occur suddenly during a paroxysm of prolonged cardiac asystole It may follow the intravenous administration of various therapeutic agents such as aminophylline papaverine and quinidine A definite causal relationship between the drug and the fatality is usually difficult to establish since sudden death strikes so commonly in cases of acute myocardial infarction

Aneurysm of the Left Ventricle[184a]

Aneurysm of the left ventricle is usually due to myocardial infarction although rarely it may result from congenital defects trauma myocardial abscess and ulcerating bacterial endocarditis It is said to occur in 7 to 8 per cent of cases of cardiac infarction but it is probably much more frequent [15, 0, 151, 129] Applebaum and Nicolson[6] found ventricular aneurysm present in 57 (38 per cent) of 150 cases of coronary occlusive disease Inconspicuous aneurysms are easily overlooked at necropsy when the pouch is not distended with blood as it is during life

Following coronary occlusion the intraventricular tension stretches the noncontracting infarcted heart muscle and may a

produce a *localized bulge where the myocardium* consists only of a relatively weak thin layer of soft necrotic muscle and fibrous tissue *This bulge, known as a ventricular* aneurysm may not protrude beyond the remaining surface of the ventricle except during systole, or it may be so prominent that it resembles a tumor It may be filled with thrombus, the overlying pericardium is usually adherent Sometimes the aneurysm is partially calcified [139, 50] It may develop during the acute stage of infarction[99] and become

Fig 114 Left ventricular aneurysm due to old myocardial infarction Localized bulge above cardiac apex which showed diminished pulsations by fluoroscopy and kymography

more prominent after healing But often it is first recognized months or years after the acute infarction The wall of the aneurysm may be perforated but almost always during the acute phase only [illegible] The site of the aneurysm corresponds to the usual site of the infarcts at the apex and anterior wall of the left ventricle or at the base and posterior wall

Although there are no characteristic symptoms of ventricular aneurysm angina pectoris may be associated and symptoms of congestive heart failure are common Cerebral or other embolism may complicate endocardial thrombosis Physical examination may disclose a forceful and rather broad pulsation of the anterior chest wall at the level of the fifth rib or interspace just inside the midclavicular line *This pulsation is often distinguishable* from that of the apical impulse The heart sounds are frequently muffled and gallop rhythm is common

Roentgenologic examination[167] may disclose not only cardiac enlargement, but also a circumscribed bulge or hump in the lower left (ventricular) contour (Fig 114) or a sharp angulation or ledge which transforms this contour into oblong shape The aneurysm may be best visualized in the oblique positions Its shadow cannot be separated from the heart shadow in any position in which it is seen Occasionally its demarcation is accentuated when lime salts have been deposited in its wall [7] Fluoroscopic, roentgen kymographic, or electrokymographic[161] examination may reveal a paradoxical pulsation of the aneurysmal site, contrasting in direction with the pulsation of the remainder of the left ventricle but this may be observed also after myocardial infarction without distinct aneurysm

The electrocardiographic findings are those of old infarction of the anterior or posterior wall bundle branch block or non specific evidences of myocardial damage RS T segment elevations and cove plane inversion of the T wave ordinarily associated with acute myocardial infarction may be observed with ventricular aneurysm when cavity potentials are transmitted through a completely fibrotic aneurysmal wall[117] or may be due to potentials of the opposite hypertrophied wall [11] There may be widespread inversion of T waves in at least three precordial leads Goldberger and Schwartz[41] described electrocardiographic patterns of ventricular aneurysm in standard leads characterized by (1) small R_1 and deep S_2 and S_3 and (2) main deflection downward in the three standard leads due to unusual rotation of the heart A deep S may also be present in aV_F and a QS in lead aV_L and in one or more precordial leads

The diagnosis of ventricular aneurysm may be based on a history or definite electrocardiographic demonstration of previous myocardial infarction and the finding of a strong abnormal precordial pulsation contrasting with a weak first sound at the cardiac apex [87] The roentgenologic findings mentioned above may confirm this clinical diagnosis or suggest it independently A ventricular aneurysm must be differentiated roentgenologically from a tumor of the heart a local pericardial effusion pericardial cyst aneurysm of the sinus of Valsalva localized calcification of the pericardium gumma of the myocardium syphilitic aneurysm of the descending aorta and enlarged pulmonary conus

The outlook for patients with ventricular aneurysm is that of the underlying disease i e myocardial infarction Survival for ten years has been reported by Young and Schwedel [204] Death usually occurs from congestive heart failure recurrent myocardial infarction and peripheral emboli

Periarthritis of the Shoulder (Shoulder Hand Syndrome) and Other Skeletal Lesions

Pain stiffness and marked limitation of motion of the shoulder joint shoulder girdle and arm frequently result from acute myocardial infarction [3, 33, 5, 130] The symptomatology may vary from mild pain on motion with little or no limitation to severe pain with almost complete limitation of motion especially of abduction and external rotation (frozen shoulder)[164] Edeiken and Wolferth[63] reported 14 cases of persistent pain in the shoulder joint, usually developing coincidentally with or within four weeks after acute myocardial infarction In severe cases it may persist from six months to two years usually it subsides spontaneously but it may recur

Usually the left shoulder and arm are affected but the right side or both sides may be involved The predominance of the involvement of the left shoulder region suggests a causal relation to the distribution of the cardiac pain because in patients without a history of angina pectoris or coronary thrombosis periarthritis of the right shoulder greatly exceeds that of the left Furthermore there is a tendency for the right shoulder to be affected when the pain of myocardial infarction radiates to the right side [31]

This complication has usually been attributed to reflex spasm of the muscles and ligaments around the shoulder secondary to cardiac pain impulses which are referred to the same segments of the spinal cord as innervate the affected muscles and ligaments Boas and Levy[22] and Askey[5] suggested that these reflexes accentuated a previously existing but subclinical periarthritis Ernstene and Kinell[31] attribute the complicating syndrome to protective disuse of the shoulder and abnormal tension under pain of the muscles of the shoulder girdle and my own observations have led me to believe that disuse is at least an important contributory factor This explanation accounts satisfactorily for the tendency to involvement of the shoulder to which the pain is referred since this is the extremity which is favored and not used Furthermore periarthritis of the shoulder occurs very commonly independent of cardiac pain under a variety of circumstances which involve disuse and abnormal posture of the affected extremity

Meyer and Binswanger[131] observed pain stiffness swelling and disability of the joints of the right hand and wrist following acute myocardial infarction in 3 patients whose pain during the attack had radiated chiefly down the right upper extremity Prolonged disuse because of the pain was also invoked to account for this complication Askey[5] observed pain stiffness and swelling of the finger joints with glossy skin and purplish red discoloration in association with the shoulder pain In some cases there developed a thick

of the palmar aponeurosis resembling the early stage of Dupuytren's contracture[9] Because of the changes in the skin and the latter development Askey[8] concluded that the syndrome was the result of sympathetic nerve disturbance caused by myocardial ischemia and preexisting shoulder and hand lesions Trophic ulcers of the hand have been noted following myocardial infarction[169] Johnson[3] noted disabling changes in the hands resembling sclerodactylia in 39 (21 per cent) of a series of 178 consecutive cases of acute myocardial infarction He attributed these changes to anoxia of the tissues of the fingers caused by reflex vasoconstriction induced by cardiac pain But this explanation fails to account for the interval of three to sixteen weeks between the pain of the infarction and the development of the changes in the hands For Treatment see page 583

Mental changes, including agitation, reactive depressions and various psychoses, are more common than is generally recognized I am seeing an increasing number of patients whose persistent symptoms especially weakness and disability, are attributed to the damage of myocardial infarction, but who respond favorably to electroshock and related forms of therapy

Post Myocardial Infarction Syndrome

Dressler described a post-myocardial infarction syndrome in 20 patients[41a] The syndrome was characterized by protracted or recurrent fever, chest pain of the pleuropericardial type and a tendency to relapse A pericardial rub was heard frequently and roentgenograms suggested the presence of pericardial effusion in many of the cases The clinical picture was attributed to pericarditis, pleuritis and pneumonitis Excellent therapeutic results followed the administration of prednisone

INFARCTION OF THE ATRIA

Infarction of the atria due to coronary artery occlusion[200] ■ has until recently been noted rarely in comparison with the frequency of ventricular infarcts Bean[16] observed 2 atrial infarcts in a series of 287 cases of myocardial infarction and Feil et al[4] 2 others in 34 cases of myocardial infarction But Cushing and associates[24] observed 31 instances of atrial infarction (17 per cent) in a series of 182 cases of myocardial infarction In 6 of these the atrium alone was affected Slapak[174] reported 10 cases of atrial infarcts occurring as extensions of a ventricular infarct Atrial infarction is easily overlooked on gross examination of the heart, but its presence may be suggested by the finding of atrial mural thrombi which occur in 80 per cent of the cases[193] It is often difficult to find an occlusion of the corresponding artery supplying the affected area, but extensive and severe atherosclerosis or occlusion is usually present in the larger coronary arteries The right atrium (especially the appendage) is involved much more frequently than the left and usually on its anterior surface

Atrial infarction may result not only from coronary atherosclerosis but also from periarteritis nodosa, and from less specific obliterating endarteritis of the small branches of the coronary arteries It has also been noted in a case of an occluded congenital single coronary artery[150] and in cases of bacterial endocarditis with ulcerating lesions In some instances hemorrhagic necrosis of the atrial wall resembling an infarct results from the perforation of a true or false aneurysm

Rupture of the atrial wall may result from infarction Of 710 cases of rupture of the heart collected by Krumbhaar and Crowell[85] and by Davenport[34] 7 per cent involved the atria Of 55 cases of atrial rupture collected by Clowe, Kellert and Gorham,[30] 39 were situated in the right atrium, 15 in the left, and 2 in the interatrial septum Clowe et al called attention to the high incidence of atrial rupture (47 7 per cent) before the age of 40 as compared to 6 7 per cent for ventricular rupture during this age period The rupture of the atrium usually extends into the pericardium, producing hemopericardium, but occasionally it extends into the pleural cavity

No distinctive clinical picture has yet been evolved for atrial infarction In some of the cases reported the symptoms and signs were indistinguishable from those due to ventricular myocardial infarction In many instances, atrial infarction is combined with ventricular infarction and the clinical picture is that of the latter Symptoms may first appear with rupture of the atria and may consist of shock and rapid death due to cardiac tamponade

Recent interest in infarction of the cardiac atria has centered in efforts to associate this condition with a distinctive electrocardio-

graphic picture Abramson et al[1] noted elevation of the P Q segment in lead I on cauterization of the left atrium of dogs and cats and depression of this segment on cauterization of either surface of the right atrium Depressions of the P T segments in leads II and III occur with similar injury to either atria Langendorf[20] first described a case of infarction of the right atrium in which characteristic electrocardiographic changes were noted Young and Koenig[69] described deviations of the P Q segment in 3 of their 4 cases of atrial infarction However Cushing et al[34] noted such P Q abnormalities infrequently in their 31 cases In the case of atrial infarction reported by Hellerstein[65] the diagnosis was made ante mortem on the basis of changing atrial mechanism heart block and elevation of P T_A segment in leads II and III (posterior wall atrial infarct) I saw a patient who experienced the clinical features of acute myocardial infarction but the electrocardiogram showed minimal abnormalities except for nodal bradycardia Postmortem examination showed thrombosis of the ostium of the right coronary artery with extensive infarction of the right atrium with less involvement of the posterior wall of the left and right ventricles

The *diagnosis of atrial infarction* in cases of clinical myocardial infarction may be suggested by (1) atrial arrhythmias especially if they change rapidly including atrial fibrillation or flutter atrial premature beats nodal rhythm sinus arrest (2) elevation or depression of P T_A segment especially depression since most of the infarcts are anterior (3) changing contour of the atrial T wave (T_A) (4) changing contour of the P waves (5) atrioventricular block[180 63]

Chapter 21

ACUTE CORONARY OCCLUSION AND MYOCARDIAL INFARCTION

Diagnosis, Differential Diagnosis, Prognosis, and Treatment

DIAGNOSIS OF ACUTE MYOCARDIAL INFARCTION

In most cases of acute myocardial infarction the diagnosis is relatively simple and may be ventured with reasonable certainty on the basis of the history and symptomatology alone. Missed diagnoses are due to (1) inadequate care in taking the history, (2) multiple attacks of chest pain within a short period of time without a clean cut sharp onset, (3) no chest pain or relatively mild pain overshadowed by pulmonary edema, paroxysmal dyspnea, weakness or shock, (4) no prolonged attack of pain at rest but angina pectoris on effort, usually more frequent and with less provocation, and often associated with fever which is overlooked. Under all these circumstances error will be avoided if the diagnosis of myocardial infarction is considered and serial electrocardiograms taken.

Chest Pain Suggesting Cardiac Infarction

Severe oppressive pain over the lower sternum or more extensively over the precordium or anterior chest lasting at least a half hour and not relieved by rest or nitrites is sufficient to warrant a tentative diagnosis of acute myocardial infarction in the absence of some other obvious cause of the pain. Characteristic radiation of the pain to the neck, shoulders or arms confirms the likely origin of the pain in the heart.

A rapid fall of blood pressure within 24 hours or even a more gradual fall in the next few days is an important confirmatory sign. A moderate elevation of temperature and leukocytosis, an accelerated rate of sedimentation of erythrocytes and an increase in serum transaminase (p. 519) are additional features supporting the diagnosis. If the pain is classic in its character, location, radiation, severity and duration, the diagnosis of *acute coronary occlusion* is proper regardless of electrocardiographic changes. If the pain is classic but the electrocardiogram is not distinctly that of acute myocardial infarction and there is no fever, an acute coronary occlusion without myocardial infarction should be considered. Classic chest pain with fever, leukocytosis, etc., justifies the diagnosis of acute myocardial infarction even without distinctive electrocardiographic changes, but one must be cautious to exclude other causes of chest pain. In general, the more definite and complete the clinical picture, the less the need for characteristic electrocardiographic changes to establish the diagnosis. But if the clinical picture is at all atypical or in any way uncertain, the diagnosis can only be certified by the presence of unequivocal electrocardiographic changes.

Shock, Syncope or Prostration Suggesting Acute Cardiac Infarction

Shock, prostration or syncope occasionally dominates the picture of acute myocardial infarction, but a careful history and clinical observation may disclose the presence of chest pain and other manifestations. A definite diagnosis, however, depends on the distinctive electrocardiographic changes.

Acute Pulmonary Edema Suggesting Acute Cardiac Infarction

Acute pulmonary edema without obvious cause should suggest the possibility of acute myocardial infarction, but electrocardiographic confirmation is necessary for a definite diagnosis.

Development or Intensification of Heart Failure Suggesting Acute Cardiac Infarction

When a person begins to experience attacks of nocturnal dyspnea or dyspnea on the mildest exertion or when a patient with such symptoms suddenly presents enlargement of the liver engorgement of the peripheral veins or peripheral edema the possibility of a recent cardiac infarction should be investigated The diagnosis then depends essentially on the exposition of characteristic electrocardiographic changes The electrocardiogram in this type of case having often been altered by a previous infarct the fresh infarction may be documented only by changes in the QRS or T waves without the distinctive pattern of a primary acute cardiac infarct

Other Symptoms Suggesting Acute Cardiac Infarction

The sudden and unexplained development of extreme fatigability or weakness attacks of dizziness or syncope indigestion brief episodes of dyspnea and pallor or cyanosis, palpitation and a cardiac arrhythmia, or the occurrence of systemic embolization may each prove to have been due to an acute myocardial infarction Frequent electrocardiographic examination is the only method of minimizing diagnostic oversight in this type of case Special attention is directed to the relative frequency with which cerebral vascular accidents are due to or associated with acute myocardial infarction and the necessity of routine electrocardiography to discover this association (p 541) Similarly unexplained postoperative fever shock or symptoms of cardiac failure often interpreted as direct complications of a surgical procedure may be found on electrocardiographic examination to be caused by cardiac infarction The diagnostic value of routine preoperative electrocardiograms for control purposes appears obvious

Electrocardiographic Diagnosis of Acute Cardiac Infarction

The electrocardiographic changes associated with acute myocardial infarction have been discussed in detail in a previous section to which the reader is referred (p 521) Although the diagnosis of acute myocardial infarction should be based on an appraisal of all the laboratory and clinical features as well as the electrocardiogram, certain electrocardiographic findings in themselves justify the diagnosis In the absence of the classic clinical symptoms and signs of acute myocardial infarction the relation of certain mild or nonspecific symptoms to cardiac infarction is sometimes betrayed only by electrocardiographic study However, occasionally the conventional 12 lead electrocardiogram may not show changes suggestive of myocardial infarction despite typical clinical features Sometimes, as in infarction of the posterobasal wall (high posterior wall) of the left ventricle, the spatial vectorcardiogram may indicate myocardial infarction when the conventional electrocardiogram is virtually normal (p 538)

Electrocardiographic Differential Diagnosis

Discordant RS T elevations and depressions in leads I and III may be encountered in conditions causing advanced *left or right ventricular hypertrophy* and *left or right bundle branch block* but in these cases the RS T segment is usually elevated and concave upward in the lead in which T is upright and depressed in the lead in which T is inverted Other features of the electrocardiogram of bundle branch block (p 396) also help to distinguish it from that of acute myocardial infarction The frequency with which bundle branch block conceals the electrocardiographic changes of acute myocardial infarction and the circumstances under which the latter may be recognized electrocardiographically when bundle branch block is present have been discussed (p 533) In the precordial leads Q waves and elevation or depression of the RS T segment may be due occasionally to left or right ventricular hypertrophy or dilatation [94]

Acute pericarditis like acute myocardial infarction may be documented in its early stages by RS T elevations But the RS T segment elevations in acute pericarditis are concordant i e they occur simultaneously in leads I and III (and usually also in lead II) (p 597), whereas those in myocardial infarction are discordant, i e, an elevated RS T in lead I is associated with a depression in lead III and vice versa The RS T elevation in acute pericarditis like that in acute myocardial infarction, may appear only in lead I or leads I and II, while the RS-T segment in lead III is isoelectric A distinction may still be made by the fact that the elevated RS T segment in acute pericarditis is either concave upward or horizontal to the crest of the T

wave whereas it is usually convex upward in cases of acute myocardial infarction The Q waves seen in lead I and in the precordial lead after anterior wall infarction or in leads II and III with posterior wall infarction do not occur with acute pericarditis alone

Electrocardiographic differentiation may be especially difficult when cardiac infarction is complicated by acute pericarditis as it is in at least 20 per cent of cases The combination of infarction with pericarditis is suggested by the presence of concordant ST elevations as in isolated acute pericarditis, in association with Q waves in lead I aVL and the precordial leads or in leads II and III and aVF The combination may also be revealed by transient concordant RST elevations as in pericarditis with subsequent discordant elevations and depressions in leads I and III as in myocardial infarction

Massive pulmonary embolism (acute cor pulmonale) may produce electrocardiographic changes suggestive of posterior wall infarction (p 961) Usually the electrocardiographic pattern of massive pulmonary embolism may be differentiated by the presence of a prominent S_1 a tendency to right axis deviation a low origin of the T wave in leads I and II with a staircase ascent of ST_1 or $_2$ and frequent inversion of the T wave in the precordial leads abnormalities not seen with posterior wall infarction Furthermore the T wave inversions in leads II and III appear within 12 hours after the onset whereas those associated with posterior wall infarction appear considerably later

Digitalis may produce electrocardiographic changes which may obscure those of acute myocardial infarction If the latter diagnosis is suspected but uncertain electrocardiograms should be made if possible before administering digitalis Usually digitalis causes a depression of the RS T segment and inversion of the T wave in all leads These changes should not be confused with those of acute myocardial infarction but they may modify and obscure the characteristic RS T segment elevations and T wave inversions associated with the latter Occasionally digitalis produces electrocardiographic changes which may be confused with those of posterior wall infarction namely an RS T elevation in lead III and an RS-T depression in lead I (and lead II) in electrocardiograms which previously showed left axis deviation A differentiation can usually be made by the presence of Q waves in leads II and III in cases of posterior wall infarction and by the upward convexity of the elevated R T segment in the former as contrasted with the upward concavity of the elevated R T segment due to digitalis The Q T interval is frequently shortened by digitalis and lengthened after acute cardiac infarction but this is not a dependable distinction

A *transverse position* of the heart may be associated with a large Q and inversion of the T wave in lead III These findings may be misinterpreted as indicating a posterior wall infarction if the electrocardiogram was made because of non specific abdominal or chest discomfort The Q_3 often present with myocardial infarction does not appear as a result of the transposition alone The Q_3 wave due to position may disappear and the T wave become upright in an electrocardiogram taken with the patient upright and the lungs in deep inspiration By the analysis of unipolar limb leads the Q and T changes may be revealed as the effect of the position of the heart and not of myocardial infarction When Q_3 is due to posterior wall infarction aVF the augmented unipolar left foot lead almost always presents a Q wave which is 25 per cent or more of the R wave when the Q_3 wave is due to transverse or semi transverse position of the heart a significant Q wave usually does not appear in aVF [95, 110] Esophageal leads at the ventricular level also reveal characteristic Q wave changes in the cases due to posterior infarction ■ In themselves Q_3-T_3 changes are insufficient for a diagnosis of posterior wall infarction unless fortified by the characteristic RST elevation and subsequent serial changes or by the clinical history and findings

Acute pancreatitis is associated occasionally with RS-T segment and T wave changes which may simulate those of acute myocardial infarction

DIFFERENTIAL DIAGNOSIS

Formerly any consideration of the differential diagnosis of acute myocardial infarction was apt to emphasize the frequency with which this condition was overlooked and mistaken for a variety of other conditions In recent years increased knowledge of the features of acute myocardial infarction a general awareness of its common occurrence and the widespread use of the electrocardiograph

often with exaggerated interpretations of minor or non specific changes have led to the opposite tendency of erroneously diagnosing numerous other conditions as instances of acute myocardial infarction In differentiating between cardiac infarction and the following diseases the physician must be alert to the possibility of error in either direction

ANGINA PECTORIS

The pain of acute myocardial infarction is distinguished from that of angina pectoris by its longer duration (more than 30 minutes and usually for hours) its persistence with the patient at rest if it began during exertion, its failure to respond to nitroglycerin (but trial of this drug is rarely necessary for the differentiation) It is also distinguished by its frequent association with dyspnea or other evidences of heart failure a fall in blood pressure and other evidences of shock and by the development of fever and leukocytosis and an increased sedimentation rate When pain is the only symptom of acute myocardial infarction especially when the pain is relatively mild and not very prolonged it may be difficult to distinguish cardiac infarction from angina pectoris In such instances definite differentiation can be made only by repeated examinations of electrocardiograms temperature blood count and sedimentation rate It should be reemphasized that paroxysms of angina pectoris which occur at rest after having previously occurred only on effort or suddenly increase in severity and frequency may actually represent attacks of myocardial infarction to be discovered only by objective clinical laboratory and electrocardiographic examination

As a rule the electrocardiogram is normal in patients who have recently suffered chest pain due to angina pectoris and there is no difficulty in differentiating it from acute myocardial infarction Electrocardiograms taken *during an attack of angina pectoris* may disclose concordant RS T depressions and occasional T wave inversions in the standard and in the precordial leads which, however, are transient (p 449) Wilson and Johnston[142] have noted in 5 cases of angina pectoris electrocardiographic changes similar in character and magnitude to those produced by myocardial infarction As a rule there were deep S waves and pronounced ST depressions in leads II and III with occasional T wave inversion during the attack of spontaneous or induced pain But these changes disappeared rapidly In one there was discordant RS T elevation in leads II and III with depression in lead I transiently during the pain When such changes persist after subsidence of the pain or progress through the stages described for acute myocardial infarction, one should question the diagnosis of angina pectoris When a patient happens to experience a transient attack of anginal pain during the recording of an electrocardiogram the interpretation of conspicuous electrocardiographic abnormalities should be deferred until another record is taken an hour or more after the pain subsides Since many patients with angina pectoris have suffered previous myocardial infarcts their electrocardiograms may disclose evidences of intraventricular conduction defects and Q and T wave changes due to the old infarcts

Acute Coronary Insufficiency

So-called coronary insufficiency, an ill defined term of varied and inconsistent usage (p 461) presents a problem in differential diagnosis under the following circumstances

1 Sometimes cardiac pain is intermediate in duration and severity between that usually associated with angina pectoris and that of acute myocardial infarction If there is no fever, leukocytosis and increased sedimentation rate, and no characteristic electrocardiographic signs of transmural myocardial infarction, acute myocardial infarction cannot be diagnosed The condition is one of *prolonged angina pectoris* probably due to an acute coronary occlusion without infarction or *to some determinable factor which diminished* coronary blood flow or increa ed the work of the heart

2 Sometimes the clinical history of pain suggests either angina pectoris or myocardial infarction and the electrocardiogram discloses persistent ST segment depressions and/or T wave inversions In such cases the basic pathologic change is revealed by other clinical findings Fever leukocytosis rapid sedimentation rate shock, pulmonary edema and rales at the bases of the lungs indicate that the pain represents myocardial infarction The electrocardiographic ST-T changes then merely localize the infarction to the subendocardium the absence of Q waves and discordant ST elevations and depressions denote absence of through and through (transmural)

infarction. Or the classic electrocardiographic changes of a new transmural infarct may be modified or obscured if there was a previous myocardial infarct or if there is considerable left ventricular hypertrophy. If fever, leukocytosis, and other signs are absent, then the diagnosis should be angina pectoris. The persistent ST depressions or T wave changes may then denote cardiac hypertrophy, old myocardial infarction, digitalis effect or subendocardial ischemia without infarction. In the latter circumstance the cause for *persistence* of the ischemia may be acute anemia, pulmonary embolism, shock, aortic stenosis or paroxysmal tachycardia, but most often it is due to an acute coronary occlusion without myocardial infarction. Transmural infarction, subendocardial infarction, coronary occlusion without infarction, subendocardial ischemia and angina pectoris are all consequences of coronary insufficiency; it is important to attempt to define the underlying pathology.

DISEASES OF THE CHEST

Pulmonary Embolism

When manifested by chest pain of a pleuritic type or hemoptysis, pulmonary embolism is easily diagnosed, but hemoptysis is usually absent and the pain may resemble that of myocardial infarction. Then the differentiation depends on the presence or absence of the characteristic electrocardiographic changes associated with myocardial infarction.

Cardiac Arrhythmias

The sudden advent of an arrhythmia, especially when associated with tachycardia, is sometimes attended by oppressive substernal pain which may be prolonged, and by palpitation, angor animi, cold sweat and occasionally by dyspnea and other evidences of heart failure. Such a picture is often mistaken for acute myocardial infarction. Discovery of the arrhythmia either by clinical or electrocardiographic examination does not always exclude an acute myocardial infarct, since the latter may be associated with certain arrhythmias at its onset. Cessation of the pain and other symptoms when the arrhythmia disappears and absence of the characteristic electrocardiographic changes of cardiac infarction in subsequent records exclude this condition. However, electrocardiographic changes resembling those of posterior myocardial infarction have been noted after cessation of a paroxysmal atrial tachycardia.[49, 40]

Occasionally acute myocardial infarction is associated with the electrocardiographic changes of the W P W syndrome.[15] Since the electrocardiographic changes of myocardial infarction may be obscured in the presence of a W P W pattern,[illegible] it has been suggested that the former will become more apparent if a normal conduction mechanism is first restored by the administration of quinidine.[181]

Acute Pericarditis

The combination of chest pain, fever and a pericardial rub may present difficulty in distinguishing between an acute pericarditis and acute myocardial infarction associated with pericardial involvement.[144] The differential diagnosis depends on serial electrocardiograms which sooner or later usually disclose the changes of myocardial infarction if the latter is the basic disease. Pericarditis independent of myocardial infarction may be suspected if there is another underlying causative disease such as rheumatic fever, tuberculosis, or neoplasm. Certain forms of benign idiopathic pericarditis (p. 603) occurring in young persons are often accompanied only by fever, mild pain and a considerable pericardial effusion, which is unusual in cases of cardiac infarction. However, in many such cases myocardial infarction (p. 603) had been diagnosed or considered. The electrocardiographic distinction has been discussed (p. 552).

Spontaneous Pneumothorax

This is distinguished by absence of the electrocardiographic changes of myocardial infarction and by distinctive physical signs and roentgen ray findings in the lungs.

Dissecting (Nonsyphilitic) Aneurysm of the Aorta[33, 77]

Like cardiac infarction, dissecting [illegible] aneurysm occurs predominantly among [illegible] between the ages of 40 and 70 with [illegible] hypertension. However, dis[illegible] aorta is not as uncommon [illegible] adults as was formerly beli[illegible] association with pregnancy [illegible] tion of the aorta. In young [illegible] tacular dissecting aneurysm [illegible] occur in the absence of h[illegible] there is an associated co[illegible]

Weakness of the med[illegible] disease is the basic d[illegible]

ture of branches of the vasa vasorum causes a tear through the intimal surface and permits subsequent dissection of the main aortic blood stream along the outer layers of the diseased media. The rupture and dissection may be favored by pronounced hypertension which may have mounted suddenly because of physical effort or emotional strain. But this relationship may only be a coincidence. The intimal tear occurs commonly a few centimeters above the aortic valve or near the origin of the left subclavian artery, but it may occur anywhere in the thoracic aorta and there may be multiple tears. When there is a transverse laceration across the commissures, the latter may slip down and the aortic cusps may not approximate, with consequent aortic insufficiency.[78] The tear may heal without rupture of the aorta or dissecting aneurysm and the patient may succumb eventually from congestive heart failure due to aortic insufficiency. Dissection through the pericardial wedge may cause pericarditis and a pericardial rub may be heard before the final blowout. Or else the blood may dissect its way throughout the thoracic and abdominal aorta involving various large branches such as the coronary, the innominate, carotid, subclavian, intercostal or iliac arteries. One or more of these vessels may be partially or completely occluded by blood clot. Transient strokes, other cerebral focal manifestations and differences in blood pressure and pulses in the two sides of the body may be noted.

Death usually occurs suddenly, after a relatively quiescent stage of a few hours or days, but sometimes only after months or years. According to Mote and Carr[90] dissecting aneurysm of the aorta is responsible for 1 per cent of non traumatic sudden deaths in coroners' statistics. Death is due usually to a perforation of the aneurysm through the adventitia into the pericardium with subsequent hemopericardium and cardiac tamponade. But the aneurysm may also perforate into the left pleural cavity or more rarely into the mediastinum, right pleural cavity or pulmonary artery, or into the abdominal cavity by way of the retroperitoneal tissues. Occasionally recovery is possible when the dissection leads back through a second intimal perforation into the original aortic lumen, producing the so-called double-barrelled aorta.[107] But even this healed channel is subject to subsequent rupture.[104]

Although many of the symptoms of dissecting aortic aneurysm resemble those of acute myocardial infarction, a careful history of the onset and development of symptoms, especially of the character, location and radiation of the pain, and detailed examination usually permit a distinction.[47] Persistence of hypertension even when there is evidence of shock is more likely to occur with dissecting aneurysm than with myocardial infarction. A difference in blood pressure in the two arms favors dissecting aneurysm. Repeated examinations often reveal changes in pulses. In both conditions there is severe retrosternal or precordial pain, but the pain of dissecting aortic aneurysm usually occurs more suddenly, is often of an immediate tearing quality and is apt to have more widespread radiation to the back of the head and neck, the posterior thorax, the lumbar region, the epigastrium or the lower extremities. Dizziness or syncope, nausea and vomiting, dyspnea and cold clammy extremities are common to both, but with dissecting aortic aneurysm, temporary loss of vision, numbness in one or both legs or arms, paralysis of an extremity, or transient changes in reflexes and hematuria are much more common at the outset. Dysphagia due to pressure of the false sac on the esophagus occurs rarely; when present, however, it is a distinguishing diagnostic feature, for it is not encountered with acute myocardial infarction.

There may be signs of aortic insufficiency not previously present, or of a left pleural effusion. Pulsations may be absent in branches of the subclavian or iliac artery. There may be bizarre neurologic changes in the legs due to circulatory deficiency of the cord caused by rupture into the intercostal or lumbar arteries.[135] Because of the absorption of old blood the icterus index may be elevated, the elevation sometimes persisting for two weeks if the patient survives that long. Pronounced anemia may occur and its presence favors a diagnosis of dissecting aneurysm rather than myocardial infarction.

Roentgenologic examination sometimes discloses a distinctive progressive widening of the aorta, which may appear irregular and distorted by shadows along its branches. Aortic pulsations are diminished.[116] Successive films may show distinctive evidence of extension of the dissection. Angiocardiography may reveal constriction of the aortic lumen.[11]

Absence of the typical electrocardiographic changes of acute cardiac infarction is a critical differential diagnostic feature, but there may be non specific RS T and T wave alterations Occasionally a dissecting aortic aneurysm may produce myocardial infarction by extending along a major coronary artery and thus forming a hematoma, the pressure of which occludes the lumen [100]

Spontaneous Interstitial Emphysema of the Lung (Mediastinal Emphysema)[45]

Hamman[44] called attention to the spontaneous occurrence of mediastinal emphysema without antecedent trauma in apparently healthy individuals and to the possibility of its confusion with acute myocardial infarction Occasionally spontaneous interstitial emphysema and myocardial infarction are associated [illegible] Spontaneous mediastinal emphysema may be characterized by an abrupt onset of severe chest pain in the substernal region radiating to the neck and left arm The true cause of the pain may be betrayed by the pathognomonic sign of very loud peculiar crunching crackling or bubbling sounds over the sternum and precordium synchronous with cardiac systole and occasionally also with diastole Roentgenograms of the chest may also reveal shadows of air in the mediastinum itself [45] There may be T wave changes in the electrocardiogram but not the characteristic changes of myocardial infarction In one reported case mediastinal emphysema complicated myocardial infarction [54]

According to Macklin[79] interstitial emphysema of the lung results from increased intra alveolar tension which forces air from the alveoli into the adjacent vascular sheaths along which the air dissects its way to the mediastinum It is important not to mistake mediastinal emphysema for acute myocardial infarction since the former condition runs a benign course with complete recovery in several days Occasionally however it may recur

Many *other diseases of the thoracic organs or chest wall* may on occasion simulate or be simulated by acute cardiac infarction These include syphilitic aortitis with aortic aneurysm pneumonia pleurisy, massive collapse of the lung carcinoma of the lung diaphragmatic or paraesophageal hernia herpes zoster costochondral arthritis rupture of the costochrondral junction and diseases of the spine or shoulder with referred pain to the anterior chest An awareness of these possibilities and a careful regard for the previous history development of symptoms and systematic examination including electrocardiography and roentgen examination of the chest will almost always permit a differentiation In instances of malignant neoplasms of the lung mediastinum or esophagus invasion of the pericardium and heart wall may occur resulting not only in chest pain but in electrocardiographic changes such as RS T elevations as in the case reported by Rosenbaum et al [108]

Attention should be called also to malingerers familiar with the symptoms of cardiac infarction whose complaints are designed to obtain disability insurance payments injections of opiates if they are addicts or other benefits Such dissemblers may even take digitalis to produce electrocardiographic changes which however are usually distinctive of that drug (p 209)

ABDOMINAL CONDITIONS RESEMBLING CARDIAC INFARCTION

Acute Indigestion

The error of diagnosing acute cardiac infarction as acute indigestion is becoming less common On the other hand I have observed a growing tendency to err in the opposite direction by labeling many episodes of indigestion as myocardial infarction A definite diagnosis of cardiac infarction should be made only if the clinical features the electrocardiographic changes or both are sufficiently characteristic

Acute Surgical Abdominal Disease

Radiation or predominance of the pain of myocardial infarction over the upper abdomen accompanied by evidence of shock may compose a clinical picture resembling an acute surgical condition of the abdomen [71] such as a perforated peptic ulcer cholelithiasis and acute cholecystitis acute pancreatitis acute intestinal obstruction or even acute appendicitis Conversely sometimes one of these conditions as well as an attack of renal or ureteral colic with reflex ileus and pain in the abdomen or chest biliary colic sigmoid spasm food poisoning a tabetic crisis or other abdominal disease may be mistaken for cardiac infarction Further ambiguity is contributed by the electrocardiographic changes which sometimes accompany

a perforated peptic ulcer, acute pancreatitis[52] and acute postoperative peritonitis.[5] However, these changes should rarely be confused with those characteristic of acute myocardial infarction. Careful study of the past and present illnesses will usually result in a proper differentiation.

Among other conditions reported as occasionally simulating cardiac infarction are diabetic coma, sickle cell anemia during a hemolytic crisis[131] and Addison's disease during a crisis.[113] Although electrocardiographic changes may occur in these conditions, they do not closely approximate the characteristic patterns associated with cardiac infarction (p. 521).

PROGNOSIS

MORTALITY RATE OF THE ACUTE ATTACK

The outcome of an attack of acute cardiac infarction is unpredictable, on the one hand because of the constant threat of sudden unexpected death even for persons convalescing favorably, and on the other hand because of the possibility of long survival even for persons apparently critically ill. The mortality rate from the acute attack of myocardial infarction (i.e., within four to six weeks after onset) has been reported by many observers as averaging about 30 to 50 per cent. However, Bland and White[15] reported an immediate mortality (first four weeks) of 19 per cent in 200 cases of coronary thrombosis (many of whom had already survived the critical period when first seen in consultation), and Master, Jaffe and Dack[84] reported a mortality rate of 16.5 per cent in 267 attacks. Among patients apparently suffering their first attack of acute coronary thrombosis these observers noted a mortality rate of only 8 per cent.

It is probable that as milder cases are identified, the mortality rate from first attacks of acute myocardial infarction, excluding those in which death struck before a physician was consulted, will not exceed 10 per cent. Many mild cases treated at home by the family physician are not included in the statistics reported from large hospitals or by cardiac specialists who are apt to see the most severe cases. Studies in which "mild" cases are segregated from severe ones on the basis of various early clinical features (p. 573) indicate that the mortality rate in the former group is less than 5 per cent.[6, 112] Autopsy findings indicate that death occurs in a great majority of instances after multiple coronary occlusions, thus, not only is survival the rule after the first occlusion but this attack is often unrecognizable or unrecognized clinically.

Most deaths from acute myocardial infarction occur within the first week and a large percentage within the first 48 hours. In a study of 342 cases of acute myocardial infarction by Ball et al.,[7] there was a mortality within 24 hours of 1 per cent from sudden death with shock and of 5 per cent from ventricular fibrillation. Another 7 per cent of the patients died of delayed ventricular fibrillation, and 6 per cent of heart failure or shock within the first week. An additional 5 per cent died of ventricular fibrillation and 2 per cent from congestive heart failure during the first month. Thus there was a total mortality of 26 per cent in one month. This study excluded 55 episodes of acute myocardial infarction which terminated fatally with associated clinical or autopsy evidence of thrombosis or embolism in vessels other than the coronary.

With allowance for the possibility of sudden unexpected death at any time, the outlook for survival of the acute attack improves as the first week elapses without complications. The second week remains a critical period with danger of sudden death from pulmonary embolism, ventricular fibrillation, cardiac standstill or cardiac rupture, or of more gradual death from congestive heart failure, bronchopneumonia, progressive myocardial infarction or peripheral emboli. After the second week recovery from the acute attack is probable if there is no fever, little or no evidence of heart failure and no other gross complications persisting from the earlier stages.

FACTORS INFLUENCING PROGNOSIS

Age

Most observers have found the mortality to increase with the age of the patient. Woods and Barnes[147] noted that the mortality was twice as great beyond the age of 60 as below. However, I have been impressed by the relatively high percentage of patients who died of their first attack of myocardial infarction below the age of 40. In most of these there was a bad family history of frequent coronary disease. But young persons who recover from

the acute attack survive much longer than older recovered patients, and are more likely to be free from evidence of congestive heart failure and angina pectoris

Previous Attacks of Myocardial Infarction

The mortality rate is significantly higher in patients presenting a history or evidence of previous attacks of acute myocardial infarction[147] This applies particularly to those patients who suffer from chronic heart failure as a result of the previous attack or whose fresh attack was characterized by the initiation or intensification of congestive heart failure

Severity and Duration of Pain

When *severe pain* persists for more than 24 hours when it appears intractable and is incompletely alleviated by opiates the outlook for survival is usually unfavorable

Shock

When myocardial infarction is accompanied by an extreme degree of shock or when evidence of shock persists after several days the outlook is unfavorable That the mortality has been found relatively high (80 to 90 per cent) in patients whose blood pressure falls to 80 mm Hg or less or whose pulse pressure is 20 mm or less expresses the same fact since these merely attest to the severity of shock Occasionally this extravagant drop in blood pressure is followed by a considerable rise after a few hours and the patient subsequently recovers

Heart Failure

Since heart failure is one of the chief causes of death during the acute attack the development of acute pulmonary edema or of other symptoms of left or right-sided heart failure is inauspicious Yet it should not necessarily be viewed ominously unless the pulmonary edema persists more than 24 hours Some evidence of left ventricular failure occurs frequently at the very onset of acute myocardial infarction and is not significant for prognosis A heart rate of 110 or higher persisting during the first week of the attack usually is associated with heart failure with or without shock and has been found to be an unfavorable prognostic sign

Fever and Leukocytosis

In general temperatures of 104 or higher or a white blood count above 20 000 denotes extensive or progressive myocardial infarction or a serious complication and is associated with a high incidence of mortality[1 2] A similar significance is attached to the persistence of even moderate fever and leukocytosis for more than one week after the onset of the attack

Diabetes

The mortality from acute myocardial infarction is strikingly higher among diabetic than among non-diabetic patients[20] The late survival rate following myocardial infarction is substantially lower among diabetics since less than 20 per cent lived five years and only 3 6 per cent for ten years

Electrocardiographic Changes

Although it was formerly thought that a typical electrocardiographic pattern of anterior wall infarction augured a somewhat higher mortality rate than that of infarction of the posterior wall it now appears that the location of the infarct has not in itself prognostic significance[147] But my clinical impression persists that posterior wall infarction is usually associated with a less stormy course and a more favorable outlook than infarction of the anterior wall of the left ventricle When the electrocardiographic changes are not clearly those of either anterior or posterior wall infarction the mortality rate seems to be higher[147 23] perhaps because the indefinite electrocardiographic patterns usually denote multiple cardiac infarcts

Cardiac Arrhythmias

The mortality rate is probably significantly increased when atrial fibrillation or flutter ventricular tachycardia or signs of intraventricular block are present However Edeiken[44] recorded recovery from acute myocardial infarction of a patient with a ventricular rate exceeding 300 According to Askey and Neurath[4] cardiac infarction is associated with a higher mortality when atrial fibrillation is present than in its absence but the mortality rate is strikingly increased only if the fibrillation persists A very high mortality rate is associated with the development of complete heart block especially when symptoms of the Adams-Stokes syndrome appear Premature beats occurring infrequently are of no significance But Woods and Barnes[147] noted that among patients with one or more premature ventricular beats in every ten normal beats 14 of 17 died whereas all of the group with one premature beat in twenty or more survived

Embolization

The occurrence of pulmonary, cerebral visceral or peripheral embolism is associated with a high mortality

PROGNOSIS AFTER RECOVERY FROM THE ACUTE ATTACK

Following recovery from the acute attack, the patient's outlook is much more favorable than was formerly recognized. At least 40 per cent of the patients survive for more than ten years and at least 70 per cent for five years or longer. Of Bland and White's[15] 162 patients who recovered from the immediate attack, 31 per cent survived for ten years or longer, and 18 per cent were alive at their last follow up. The younger the patient at the onset, the longer was the period of survival. In a study of 100 consecutive patients with coronary thrombosis followed since 1930, Smith[115] found that there were 66 survivors after ten years, and 16 known survivors at the end of twenty years. Sixty nine were known to be dead and 15 lost to follow up at the end of twenty years. However, 25 per cent died within the first year after the myocardial infarction, indicating a relatively favorable outlook with survival beyond that time. Similarly, Cole et al.[8] reported that 43.9 per cent of 285 patients survived for more than ten years and one-tenth for more than fifteen years after their initial attack of myocardial infarction. Among 211 patients who lived more than two months after a first attack of acute myocardial infarction, Weiss found that 77 or 36.5 per cent survived for more than ten years.[140] Recently, Drake[35] reported a proven case of cardiac infarction in which the patient survived for forty years after the first attack at the age of 40. These statistics are presented not to minimize the seriousness of acute myocardial infarction, but to mitigate in part the excessive pessimism it inspires. The thought of possible long and useful survival is particularly sustaining to patients who associate "heart attack" only with sudden death, limited duration of life and invalidism.

RESIDUAL SYMPTOMS AND REHABILITATION AFTER ACUTE CARDIAC INFARCTION

Unfortunately, in many cases recovery from the acute attack is followed by distressing symptoms, restricted activity or invalidism. Palmer[10] found that of 212 patients who had survived three months or longer after coronary thrombosis, about one fourth were able to lead fairly active lives. Similarly, Bland and White,[1] in a study of 162 private patients who survived the acute attack, noted that about one third could pursue a fairly active life with little or no restriction because of cardiac symptoms. Bland and White[15] found the longest period of survival in this relatively asymptomatic group, 56 per cent of whom survived for at least ten years, and only 1 of whom developed congestive heart failure. When death eventually occurred in patients of this most favorable group, it was usually caused by another and fatal coronary occlusion or it came suddenly and unexpectedly.

Patients who are able to resume gainful employment after surviving the acute attack of myocardial infarction represent a larger percentage than the asymptomatic group because many who continue to suffer anginal pain or mild dyspnea are nevertheless able to work. According to Ball et al.,[7] 26 per cent of 253 patients who survived an acute myocardial infarction were able to return to their usual activity, and 21 per cent to resume lighter activity. More than two fifths of 500 patients who suffered a coronary occlusion and were studied by Master and associates[36] made a complete functional recovery, and 85 per cent of these resumed employment, 65 per cent full time and 20 per cent part time work. When activity was restricted, it was due to symptoms such as angina pectoris, dyspnea on effort or at rest, and weakness or easy fatigability. These symptoms individually or in combination are present in about two thirds of patients following acute myocardial infarction.[15]

Angina Pectoris

Occasionally, patients who have suffered from angina pectoris lose their pain after an attack of acute myocardial infarction, probably because the anoxic muscle responsible for the pain is no longer viable. Much more often attacks of angina pectoris on effort or at rest persist after cardiac infarction, and in about half of the cases in which angina pectoris is absent before the attack, it develops after recovery from the acute infarct. Palmer[10] observed angina pectoris in about 60 per cent of the patients who had recovered from an acute cardiac infarct, a higher incidence than before the attack. Furthermore, the attacks of angina pectoris usually occurred more often, and were more persistent and more readily induced by minor exertion or at rest than previously. Bland and White[15] found that one third of their patients who recovered from the acute attack were limited in their

activity by angina pectoris alone In this group only one third survived for ten years or longer as compared to 56 per cent in the recovered group without symptoms

Hypertension

The blood pressure remains at relatively normal levels in one third to one half of the cases in which hypertension existed before the attack [35] In the remainder the blood pressure gradually rises to a hypertensive level which is somewhat below that prior to the attack [101] According to Chambers [9] 58 per cent regain hypertension within two years Occasionally the blood pressure eventually exceeds that before the cardiac infarction In patients with normal blood pressure before cardiac infarction the blood pressure may gradually return to the previous level but often it is 10 to 20 mm lower and may even remain at hypotensive levels (below 100 mm)

Observations as to the influence of hypertension on the subsequent course of the disease including the development of heart failure and the duration of life are in disagreement but in my experience heart failure occurs more frequently and the outlook for life tends to be less favorable in those in whom hypertension recurs

Heart Failure

Dyspnea is a consistent complaint in more than half of the patients while objective evidences of heart failure usually of the left ventricle are observed in about one quarter of the patients Dyspnea restricted the activity of about one third of the patients followed by Bland and White[15] who had survived an *acute attack of coronary occlusion* This group pursued a much less favorable course than either those who were free from symptoms or even those who suffered from angina pectoris after their recovery from the acute attack None of them survived a ten year period and 75 per cent of the patients with dyspnea succumbed because of congestive heart failure It is interesting that symptoms or signs of left heart failure which appear in half to two thirds of the patients during the acute attack disappear in a majority of those who recover Occasionally dyspnea and angina pectoris are present in the same patient

Cardiac enlargement following recovery from myocardial infarction is observed in more than half the cases When it is of considerable degree it is associated with persistent and overt manifestations of congestive heart failure Consequently restriction of activity occurs much more regularly when cardiac enlargement follows myocardial infarction [m] Conversely a normal cardiac size following recovery from the acute attack usually promises a better clinical recovery and a favorable outlook for normal activity

Electrocardiographic Changes Following Recovery

The electrocardiogram returns to normal in about 15 per cent of cases usually within a year after the attack In the remainder Q waves inverted T waves or T waves of low voltage or slurred notched and prolonged QRS complexes persist without necessarily denoting an unfavorable prognosis In patients with a previous myocardial infarction a fresh infarction of the other wall may result in normalization of the electrocardiogram although usually evidence of one or both infarcts is apparent In a recent study of the electrocardiograms of 51 patients one year after an acute myocardial infarction Gittler et al found that return to a normal electrocardiogram occurred in only one case [60]

SUBSEQUENT ATTACKS OF CARDIAC INFARCTION

Regardless of the outcome after an acute cardiac infarction the further outlook for the patient is clouded by the danger of further episodes of coronary occlusion and cardiac infarction It should be emphasized that there is insufficient knowledge of the probability of subsequent attacks of myocardial infarction in any group to permit this knowledge to be used as a control basis to evaluate the influence of diet or any other therapeutic agent in preventing subsequent attacks Clinical studies suggest that such additional attacks recur in about 30 per cent of cases usually within two years after the first attack However pathologic studies attest to a much higher incidence of recurrent coronary occlusion These new episodes are often overlooked because the clinical features either are not as characteristic as those of the first attack or are overshadowed by symptoms and signs of congestive heart failure and because the electrocardiographic changes when superimposed on previous abnormalities are often not specific Each additional attack of cardiac infarction either increases the probability of a fatality or leaves the patient more subject to the development or intensification of congestive heart failure or disabling attacks of angina pectoris than after the first infarct

EFFECT OF PATIENT'S COOPERATION AND MORALE

In concluding this discussion of factors modifying the prognosis after cardiac infarction it is well to emphasize the importance of certain less easily measured influences These include the cooperation of the patient with his physician in making the necessary modifications in his diet in the use of tobacco, in his hours of sleep and rest and in the character and duration of his work or other activities without resentment or moroseness at his unfortunate fate The success with which these adjustments are accomplished is dependent in general on the patient's capacity for a healthy optimism and contented readjustment despite essential restriction and also in large measure on the wise and tactful management of an understanding reasonable and practical physician

TREATMENT OF ACUTE CARDIAC INFARCTION

The treatment of acute cardiac infarction is designed (1) to reduce the work of the heart until the infarcted area is healed (2) to alleviate pain or other discomfort, (3) to overcome shock and cardiac failure if present and (4) to cope with dangerous cardiac arrhythmias or any complications that may arise (For a detailed discussion of individual measures see below beginning p 562)

SYMPTOMATIC TREATMENT

Pain

As a rule *morphine or other opiates* (p 571) are administered to control severe *pain, restlessness and anxiety* at the onset of the attack but morphine is not essential if the pain is relatively mild and can be relieved by meperidine (Demerol) codeine or weaker analgesics If the pain has already subsided, none of these drugs need be used but mild sedatives may be advisable (p 579) If extremely severe pain is unrelieved by opiates, it may sometimes be controlled by oxygen therapy (p 570) and by the intravenous administration of aminophylline (p 285)

SHOCK

Prompt treatment is essential

General Measures

Certain general measures such as rest in bed and the alleviation of pain restlessness and anxiety by opiates are indirectly helpful But in the absence of pain and great restlessness opiates should be withheld, because they tend to depress pulmonary and tissue respiration, intensify the anoxia already present and interfere with diuresis The application of external heat to the extremities, other than by blankets adequate to preserve body warmth, is now considered of dubious value, if not detrimental, in the treatment of shock Furthermore external heat may intensify perspiration in patients who are already dehydrated from loss of fluids Oxygen is administered continuously by mask or in a tent Associated pulmonary edema or cardiac arrhythmias are treated by appropriate measures and anticoagulant therapy is instituted if there is no contraindication

Specific Measures

Ideally, specific agents employed for the treatment of shock should act directly on the heart to bolster the sharply reduced cardiac output which is responsible for the shock of myocardial infarction Usually they are intended to raise the mean aortic pressure and thereby secondarily benefit the heart by augmenting coronary perfusion pressure and coronary flow They are designed to enable the patient to survive a critical period until the heart recovers its ability to maintain the blood pressure without outside aid

Specific measures include (1) vasopressor drugs, (2) intravenous infusions of blood plasma or plasma expanders, (3) intra arterial transfusions

1 **Vasopressor Drugs** A number of vasopressor drugs which are sympathomimetic amines, closely allied in structure to epinephrine, ephedrine and paredrine, mark the first really encouraging advance in the treatment of shock in acute myocardial infarction [60 67 69 116] The preferred drugs are norepinephrine (Levophed noradrenaline), mephentermine (Wyamine) methoxamine (Vasoxyl) and phenylephrine (Neo-synephrine) Norepinephrine is most extensively used because it is the most powerful and because it can be most readily controlled and administered by intravenous drip transfusion for the prolonged periods of time that are frequently necessary *Aramine*[levo 1 (m hydroxyphenyl) 2 amino-1 propanol] a new long acting sympathomimetic amine which not only raises aortic pressure but also was shown to increase cardiac output and coronary flow by increasing cardiac contractility in dogs, also gives promise of therapeutic effectiveness [117]

The use of pressor drugs in shock is based on the belief that the sympathetic vasoconstriction of shock has not produced maximal increase in peripheral resistance and that these drugs can further magnify this resistance and raise the blood pressure. In this manner it is hoped that an adequate perfusion pressure is restored to vital organs such as the heart and brain and the diminished blood flow redistributed in favor of these organs. However, it is apparent that a rise in blood pressure despite an increase in peripheral resistance occurs only if there is an increased force of cardiac contraction in response to the increased work load. It is uncertain whether the increased peripheral resistance induced by vasopressor drugs is itself the adequate stimulus for augmented cardiac output or whether these drugs have a direct beneficial cardiac effect.

Recent studies actually indicate that norephinephrine and other pressor amines have such a direct action on the myocardium in shock. Sayen et al [118] noted that Levophed increased the oxygen tension of myocardium made ischemic by ligation of a coronary artery. Gazes and associates,[68] using strain gauge techniques in fully conscious trained dogs showed that l norepinephrine produced substantial increments in the cardiac contractile force, in addition to its recognized pressor effects. Sarnoff et al [117] observed that Aramine caused a sustained increase in myocardial contractility and increased cardiac output, ventricular work, aortic pressure and coronary flow, while left atrial pressure fell. These findings were interpreted to indicate that vasopressor drugs are effective in shock because of direct action in the heart as well as their pressor action.

l-Norepinephrine or l arterenol (Levophed) [66, 67, 24] Norepinephrine is two to three times as effective as epinephrine in augmenting coronary flow and possesses the advantages of not accelerating the heart rate or stimulating the nervous system or producing cardiac arrhythmias. In administering Levophed, care must be taken to avoid extravascular infiltration as it may result in severe necrosis and ulceration of the skin.

DOSAGE AND ADMINISTRATION Levophed is available in ampules containing 4 cc of a 0.2 per cent solution (or 8 mg) of Levophed bitartrate, equivalent to 4 mg of Levophed base. One ampule is dissolved in 1000 cc of 5 per cent glucose in distilled water (or physiologic saline if there is no objection to the sodium ion). The final dilution represents 8 micrograms of Levophed bitartrate or 4 micrograms of Levophed base per cubic centimeter of solution. This is administered intravenously by needle or polyethylene tubing through the necessary tubing with clamp, and a drip bulb to control the rate of flow. The latter is adjusted to maintain the blood pressure at about 100 mm Hg in most patients or 120 mm Hg in previously hypertensive patients. One may begin with a flow rate of 20 drops per minute but this may be hastened or retarded according to the blood pressure which is determined continuously or very frequently by a physician or nurse in constant attendance. If the rate of flow must be increased to more than 40 drops per minute, one or more additional ampules of Levophed are added to the solution or an additional flask with a higher concentration of Levophed is connected to the first flask by means of a Y tube.

As a rule one to four ampules of Levophed dissolved in the 1000 cc glucose solution running at the rate of 20 to 30 drops per minute (10 to 60 micrograms of Levophed bitartrate per minute) succeed in maintaining the blood pressure at the desired level, but occasionally much higher doses may be required for satisfactory response. Usually however if there is no satisfactory response to 60 micrograms of Levophed bitartrate per minute, higher concentrations will also prove ineffective but they should be given a trial if necessary. The rate of flow is also determined according to fluid requirements. If fluid restriction is necessary the concentration of Levophed can be increased and inflow regulated to provide no more than 500 to 1000 cc in 24 hours.

At first the concentration and rate of flow of the Levophed solution may require several changes, but usually the blood pressure can be stabilized at a desired level after a few hours without much modification of the solution or rate of flow thereafter. As the patient improves attempts are made to diminish the dosage of Levophed and finally to discontinue it. It may be necessary to maintain the Levophed for 12 to 36 hours commonly or occasionally for several days to a week.

RESULTS That Levophed is capable of raising and maintaining the blood pressure in cases of shock due to myocardial infarction is unquestionable Any doubt of this is dispelled by the numerous cases in which the blood pressure is so low that it cannot be measured in the brachial artery but is promptly elevated to 100 mm Hg or more by Levophed There after for a period of many hours or days the blood pressure repeatedly falls to zero each time an attempt is made to discontinue the drug, whereas there is a prompt restoration of adequate blood pressure when the drug is resumed Although a pressor effect following Levophed has been noted in 80 to 95 per cent of cases in most reports *persistent* relief of shock i e for twelve or more hours after the pressor drug is discontinued is attained less regularly, perhaps in 25 to 55 per cent of cases

The extent to which Levophed and similar pressor amines save lives is more difficult to evaluate [14] The rate of survival after nor epinephrine has varied according to different reports but in the larger series of cases the survival rate was 30 to 50 per cent The mor tality rate in cases of shock with acute myo cardial infarction is said to vary between 70 and 80 per cent Actually there is no satis factory control series which provides the desired information The criteria for shock are not well defined nor do all observers agree in the diagnosis in individual cases This is indicated by great differences in the reported incidence of shock in myocardial infarction In some series this incidence ranges between 45 and 55 per cent while in other series it ranges between 10 and 20 per cent of the cases of myocardial infarction These differences are clearly due to different criteria for shock since the average mortality is 80 per cent in the various series with low incidence of shock and only 35 per cent in those series with a higher incidence of shock It is apparent that the interpretation of the effectiveness of vaso-pressor drugs or other agents will depend on whether the control mortality rate from shock in myocardial infarction is taken to be 80 per cent or 35 per cent Fewer and more severe cases of shock will be included if one insists on systolic blood pressures of 80 mm Hg or less than if one accepts systolic blood pressures of 90 mm Hg or less as evidence of shock More cases and less severe ones will be included if pressures of 100 mm Hg are accepted as evi dence of shock in patients who were previously hypertensive Furthermore, hypotension, per se, is an inadequate criterion of shock unless there are also clinical manifestations due to inadequate blood flow and sympathetic stim ulation such as tachycardia cold moist skin, oliguria, and dulled sensorium In the ab sence of uniform criteria of shock in acute myocardial infarction or of controlled studies of mortality rate, the effectiveness of Lev ophed or other pressor amines in saving lives cannot be determined

Sampson and Zipser[118] reported that 20 (67 per cent) of 30 patients treated with norepinephrine survived the episode of shock and 16 (53 per cent) recovered clinically and were later discharged from the hospital The mortality rate was higher among patients who were in shock longer than three hours before therapy was instituted Griffith and as sociates[65] reported that shock was present in 161 (19 7 per cent) of 816 cases of acute myocardial infarction One hundred and twenty eight (80 per cent) of the patients with shock treated with various measures but not with pressor amines succumbed On the other hand, in a subsequent series of 134 cases of shock in myocardial infarction treated by pressor amines and other specific forms of shock therapy, the mortality rate was sub-stantially less viz 47 8 per cent More sig nificantly the mortality rate was only 13 per cent among 60 patients treated within three hours whereas the mortality rate was 76 per cent among 74 patients in whom specific therapy was instituted more than three hours after the onset of shock Of 30 cases treated with norepinephrine (Levophed) shock was controlled in 17 As in other forms of shock treatment of the shock of myocardial infarction is reported to be more effective the earlier the pressor drugs are administered On the other hand, in an undetermined number of cases, shock subsides spontaneously within one to three hours after onset or because of simple measures to relieve pain The ef fectiveness of early treatment may then ap pear to be influenced by the inclusion of cases in which shock would have subsided without the use of specific vasopressor drugs

Mephentermine (Wyamine) may be admin istered slowly by vein injecting 1 cc of Wyamine sulfate containing 15 mg of Wya

mine base as a priming dose [redacted] The drug is then given as a continuous intravenous infusion at the rate of 1 mg per minute and modified as desired Thirty to 75 mg of Wyamine base (2 to 5 cc) may be dissolved in 100 cc of 5 per cent glucose in water and administered by slow intravenous drip over a period of approximately an hour (15 to 20 drops per minute) The rate of flow and the concentration of the solution are regulated and modified according to the blood pressure which is checked continuously It is also possible to obtain and maintain a continuous pressor effect by the intramuscular injection of 15 to 30 mg at half hour intervals or longer I have used Wyamine chiefly to initiate treatment since it can be administered intramuscularly or intravenously without much dilution until Levophed dilution and set up can be arranged

Methoxamine (*Vasoxyl*)[88] This drug is administered intravenously in a dose of 5 mg or intramuscularly in a dose of 15 mg but the dose may be increased and repeated as necessary to attain and maintain the desired elevation of the blood pressure[38] It may be given as a continuous intravenous infusion containing 100 mg per liter at a rate determined by the blood pressure

Phenylephrine (*Neo-synephrine*)[1] is available in 1 per cent solution for parenteral use A dose of 5 to 15 mg (0 5 to 1 5 cc) may be given intramuscularly or 2 to 5 mg slowly intravenously as an initial dose followed by a continuous intravenous infusion at the rate of 2 5 mg of Neo-synephrine every 15 minutes

Isopropylepinephrine (*Isuprel*) is used only when shock is associated with complete heart block and Adams-Stokes syndrome It is given in a dose of 2 or 3 mg slowly intravenously and then [redacted] to 15 mg doses may be given sublingually at 10 to 30 minute intervals

Metaraminol (*Aramine*) has been administered by intravenous infusions of 50 to 200 mg per liter of 5 per cent glucose in water at the rate of 2 to 6 cc per minute [redacted] Following a single intravenous injection of 3 to 15 mg of Aramine a maximal pressor response is attained in five minutes and the rise in blood pressure persists for 25 minutes[128] Although Aramine is somewhat less potent than norepinephrine it possesses advantages of more prolonged action and greater ease of controlling its administration and dosage

Steroid Hormones Manchester[82] described 7 cases of acute myocardial infarction and severe shock unresponsive to vasopressor drugs Urine ketosteroid determinations and blood eosinophil counts indicated adrenal insufficiency which was attributed to the stress of myocardial infarction and prolonged shock Following the administration of hydrocortisone and desoxycorticosteroid together with adequate amounts of sodium and norepinephrine there was a dramatic vasomotor response and improvement

2 **Intravenous Infusions and Transfusions.** For a period of time infusions of plasma or small transfusions of 150 to 250 cc were advocated and used in the treatment of shock accompanying acute myocardial infarction[113, 41] Occasionally these appeared to be beneficial at least temporarily but it is doubtful that they had any significant influence on the outcome There is always a danger of inducing pulmonary edema although in most cases no such complication was reported If as is often the case pulmonary edema is already associated with the shock transfusions and infusions of plasma are contraindicated At the present time transfusions do not appear to be indicated because of the availability and superiority of the pressor drugs

3 **Intra arterial Transfusions**[1, 4, 13] These were designed to combat the cardiogenic shock of acute myocardial infarction by bringing blood directly where it is needed i e on the arterial side without overloading the weakened myocardium as intravenous transfusions are theoretically likely to do Actually if the circulation is maintained blood or other fluid introduced on the venous side reaches the arterial side and blood introduced intra arterially traverses the venous segment Recent controlled experiments in hemorrhagic shock have shown no statistical difference in the effectiveness of intravenous or intra arterial transfusions when the infusion rates were the same [redacted] [27, 68] However intra arterial transfusion of oxygenated blood appears of value in cases of shock with virtual cardiac stoppage in order to provide a priming elevation of arterial pressure and an adequate coronary perfusion pressure Thereafter pressor amines may be used to maintain the desired blood pressure A method of arterializing the blood and transfusing it intra arterially under pressure was described by Silber and associates[1, 4] Shock was controlled

in 3 of 9 cases of acute myocardial infarction, but only 2 survived. Two hundred and fifty cc of blood may be administered in 10 to 30 minutes at a progressively higher inflow pressure, up to 100 to 120 mm Hg. Arterial transfusions are rarely employed at present, because of the superiority of the pressor amines.

In summary, the intravenous administration of Levophed or other pressor amines represents the treatment of choice in shock accompanying acute myocardial infarction. These drugs are undoubtedly effective in restoring an adequate blood pressure in the large majority of cases. They probably also increase the chances of survival but there is less certainty regarding this point.

Shock and Pulmonary Edema

This combination occurs frequently and often poses a therapeutic problem. The shock may be treated as discussed with vasopressor agents but due regard must be paid to minimizing the quantity of intravenous fluids and using glucose instead of sodium chloride. In addition morphine, oxygen and intravenous aminophylline are administered as in the treatment of uncomplicated pulmonary edema. Digitalis may be injected intravenously (p. 262) if these measures are ineffective. Mercurial diuretics are given only after these emergency measures are completed. Phlebotomy is contraindicated in severe shock. Occasionally the control of shock by vasopressor agents with consequent improvement in cardiac function, abolishes pulmonary edema and the need for specific measures to counteract it.

ACUTE LEFT VENTRICULAR FAILURE

In the presence of acute left ventricular failure characterized by pulmonary edema, immediate and sometimes drastic therapeutic measures must be instituted (p. 292). Morphine or other opiates should be administered subcutaneously as indicated in order to control intense dyspnea as well as anxiety or pain. If morphine is ineffective the *slow intravenous injection of 0.5 gm. of aminophylline* in 20 cc. solution may control pulmonary edema.

While the question of using *digitalis or strophanthin* in acute left ventricular failure due to cardiac infarction is moot (see below, p. 579), dramatic relief of acute pulmonary edema sometimes follows the intravenous injection of 0.25 mg. (1/240 grain) of ouabain (p. 258), repeated if necessary in one-half hour to one hour, in patients who have not received digitalis in the previous two weeks. Under less urgent circumstances, 4 cc. of Cedilanid may be administered intravenously.

Oxygen should be administered in high concentration (80 per cent or more), or preferably under positive pressure[8] but only if there is no shock. Usually this measure is effective in controlling the anoxemia and cyanosis associated with severe pulmonary edema.

Rotating tourniquets on the four extremities should be used, as in other cases of pulmonary edema (p. 292).

In extreme cases of pulmonary edema with increased systemic venous pressure, the removal of 350 to 500 cc. of blood may be lifesaving when all other measures have failed but this should not be performed if there is severe anemia.

INDIVIDUAL THERAPEUTIC MEASURES AND DRUGS

Bed Rest

It was formerly thought that patients suffering from an acute myocardial infarction should be put to bed for an average period of four to six weeks. Rest is a traditional principle of treatment of a diseased organ, and as applied to the heart is intended to diminish its work. This recommended rest period is based on relatively limited pathologic studies which indicate that six weeks are required for the infarct to be converted into a firm scar[80] and experimental studies showing that two or three weeks are necessary for the development of a collateral circulation to supplement the interrupted blood supply.[■ 11] It seems unreasonable, however, that the same fixed period of bed rest should be prescribed for all patients with acute myocardial infarction whether they are critically ill or asymptomatic after a brief episode of pain, whether there be relatively high and prolonged fever or slight fever for only a few days, and whether or not they suffer from shock, pulmonary edema, congestive heart failure or serious complications.

Most of the fatalities and complications from acute myocardial infarction occur during the first week, a more moderate number in the second week and relatively few in the third week. For this reason, it is my policy to recommend a minimum of two to three weeks of rest in bed. But, as discussed below, this

does not mean complete immobility or even complete restriction to bed for every minute of that period. For an additional period of three to four weeks (making an average total of six weeks) the patient is confined to bed part or most of the time. But within the confines of his bedroom or his hospital room he is permitted moderate liberties which do not involve more than the simplest exertions and do not result in mental or emotional strain.

This average period of six weeks is designed to permit recovery from the acute attack and permit healing of the infarct. It does not include a further period of weeks or months of convalescence to permit the gradual resumption of a permanent routine. Furthermore, this average period does not allow for the occurrence of complications, the development of chronic left- or right-sided heart failure, frequent attacks of angina pectoris, or extreme weakness, which may extensively prolong the period of rest in bed or of greatly limited activity.

The rigid severity with which bed rest was enforced has led to considerable public expression with regard to the dangers of the exaggerated application of this therapeutic measure. It has long seemed quite reasonable to assume that "complete rest" is desirable for the acutely infarcted heart muscle until healing ensues. Physical exertions have been feared because of the risk of rupture of the softened myocardium. Myocardial infarcts produced experimentally in dogs were found to heal with a small strong scar when the dogs were rested for six days after infarction, whereas aneurysmal bulging and a thin scar resulted if the dogs were exercised in the first three days after infarction.[2,3] On the other hand, it may be questioned whether most patients would be harmed by such simple activities as feeding themselves or using a commode instead of a bedpan, or even going to a nearby bathroom once daily for a bowel movement. Moreover, the advantages of bed rest must be weighed in individual cases against the deterioration of morale, the frequency of constipation and abdominal distention, the circulatory strain often involved in the use of the bedpan, the occurrence of disabling muscular and ligamentous strains, especially of the back or the shoulders, the development of bedsores, the risk of decalcification of the bones, especially in the elderly, and the occurrence of urinary disability if not retention in patients with moderate prostatic hypertrophy.

If patients with orthopnea, cardiac asthma, or pulmonary edema are forbidden to sit in a chair or upright in bed, disability is increased. The disadvantages of recumbency to such patients have been mentioned (p. 194). The dangers of hypostatic congestion and bronchopneumonia increase with the degree of immobility of the patient. But most important of all, pulmonary embolism, one of the very common causes of death from myocardial infarction, may be attributed primarily to venous stasis and thrombosis of the leg veins caused by strict and prolonged bed rest. Pulmonary embolism is sometimes precipitated by extreme straining at stool, and this danger is enhanced in many patients who are forced to use the bedpan even when this necessitates excessive straining.

These considerations should lead to careful reflection before ordering complete bed rest for a fixed period of time as soon as the diagnosis of acute myocardial infarction has been made. It has long been my custom to permit patients to feed themselves, to move freely in bed, and to perform leg exercises (especially dorsiflexion of the feet with contraction of the calf muscles) at regular frequent intervals as soon as possible after the onset of the attack. If the patient is capable of using the commode and has found real difficulty in using a bedpan, I have permitted the former. Most patients are permitted to use the lavatory once daily at a regular time for a bowel movement. Above all, management should be sufficiently elastic to permit desirable modification in individual cases. The recent tendency to liberalize the meaning of bed rest in cases of myocardial infarction will prove to be beneficial only if it does not lead to the opposite extreme of utterly neglecting this fundamental therapeutic measure.

Rest in bed for the patient recovering from acute myocardial infarction means not only avoidance of physical exercise but complete mental repose and protection from emotional strain. These aims cannot always be fully realized, but as far as possible they should be attained by isolation of the patient from outside communications and contacts which produce mental strain or upset him emotionally, by confident reassurance that he will get well

by efficient examination and care of the patient on the part of the doctor and nurse with as infrequent disturbance as possible and by sufficient medication to keep him free from pain or other discomfort and to provide adequate sleep

Armchair Treatment[70, 143, 85, 11]

If complete bed rest is associated with disadvantages and even with danger, it does not follow that no bed rest at all is preferable Nevertheless it has been recommended that patients with acute myocardial infarction be treated continuously in a chair during waking hours, except in the presence of shock or extreme debility Improvement of morale relief of orthopnea and avoidance of pulmonary embolism are some of the claimed advantages A diminution in cardiac output and in the work of the heart in the sitting position is another listed benefit of chair treatment

Many patients do prefer sitting in a chair to lying in bed after the first few days but few of them prefer sitting in a chair all day long if they are not allowed to get up and walk about Patients with orthopnea are more comfortable sitting in a chair than lying *flat* in bed, but not necessarily more comfortable than when they sit up in bed But this claimed advantage of chair treatment indicates a confusion between *recumbency* and *rest* The problem of recumbency or upright position is not really directly related to the treatment of acute myocardial infarction It is a problem in the management of left-sided heart failure with orthopnea or cardiac asthma There has not been and there *is no question about* permitting the patient who is orthopneic to maintain an upright position in bed, at the side of the bed, or in a chair until such time as the heart failure is controlled This has nothing to do with the problem of bed rest versus chair rest in acute myocardial infarction per se

The claim that chair rest may prevent pulmonary embolism is also based on a confusion—between *chair treatment* and *early ambulation* Although early ambulation in acute myocardial infarction, as in postoperative management may reduce the incidence of thromboembolic complications there should be no pretense that chair treatment means early ambulation Rather, at least on theoretical grounds, one would anticipate that chair treatment would predispose to stasis and phlebothrombosis in the lower extremities and to consequent pulmonary embolism

Assumption of the upright position reduces the venous flow and the cardiac output and hence the work of the heart Little is known about the effect on the cardiac output of a prolonged stay in the sitting position We know of course the advantage of diminishing the venous return in patients with pulmonary congestion in left sided heart failure, but this is not the particular problem in most patients with acute myocardial infarction Much of the difficulty in the latter is due to an inadequate cardiac output, one may therefore question the advantage of further reduction in the cardiac output The problem of reducing cardiac work in treating coronary thrombosis may be less important than the problem of cardiac work in relation to coronary blood supply The sitting position would not be advantageous if the coronary flow were diminished more than the cardiac work There is evidence that blood flow to the brain and kidneys is diminished in the upright position Perhaps there is a similar effect upon the coronary circulation It is apparent that there is much to be learned or proved before we invoke physiologic arguments to support our prejudices for either bed rest or chair treatment

It is apparent that the outcome in the vast majority of cases of acute myocardial infarction will not be determined primarily by the use of bed rest or chair treatment Recovery or a fatal outcome probably depends chiefly on the nature and severity of the myocardial injury and the response of the heart and other organs to that injury Repeated references to the 'dangers' 'abuse' and "myth' of bed rest have served to call attention to the need for reexamination of the basis for a long standing axiom But it would be unfortunate if these discussions distracted us from grappling with the more important factors in mortality from acute myocardial infarction Bed rest, especially when intelligently carried out modified and individualized, is not a significant factor in this mortality, neither is chair treatment the cure Sitting in a chair for limited periods for patients who can profit from such change in position, as part of an elastic individualized program of bed rest, is certainly permissible or desirable, sitting in a chair throughout the day, as a rigid prescribed form of therapy, is not recommended

Hospital versus Home Care

Most patients with acute myocardial infarction can be treated satisfactorily at home. Hospitalization may be preferable when certain measures such as oxygen therapy and anticoagulant therapy are essential and cannot be properly carried out at home, when the patient's home is at a considerable distance from his physician and the severity of the attack and its complications warrant frequent and prompt medical attention, when satisfactory dietary or nursing care cannot be obtained at home, when the patient's activities or intrusions by relatives, friends or business associates can only be controlled in the hospital, or when other environmental conditions at home are undesirable. The patient's progress as determined by frequent observation and by electrocardiographic or other laboratory tests can usually be followed more easily and complications treated more promptly at a hospital. If for any of these reasons hospitalization appears preferable, the physician should not be deterred by the exaggerated fear of moving the patient, provided this can be done by ambulance with the aid of trained attendants. An opiate should be administered before transporting him, and other available emergency measures instituted if necessary.

Sometimes hospitalization appears preferable to home treatment for the first two or three weeks, after which treatment may be continued at home. Under these circumstances also there is no objection to moving the patient if he is recovering satisfactorily and if no excessive exertion on his part is required in the transfer, which should be by ambulance.

Nursing Care

Good nursing care can be a valuable adjunct to treatment. Its purpose should be to help the patient avoid undesirable exertions, to protect him from the telephone and from visits by his business associates, friends and relatives, and to provide a cheerful atmosphere, as well as to administer medications and other therapeutic measures. As indicated above, "too good" nursing may be fraught with danger if it involves complete restriction of the patient to the point where he lies in bed like an inanimate log.

Diet

In the first week the diet must be varied according to the patient's condition. When severely ill he may take only small amounts of fluid at a time, such as fruit juices, milk, broth, tea, ginger ale or water. Care should be taken to avoid distressing abdominal distention in persons intolerant to milk or excessive amounts of fruit juice. Some patients who tolerate milk may be given the Karell diet (200 cc. of milk every four hours) for 24 hours or longer. Sodium intake should be restricted if there is evidence of congestive heart failure.

If there is persistent vomiting during the first day or two, 50 cc. of 50 per cent glucose can be given intravenously at regular intervals to provide fluids and carbohydrate, or a continuous infusion of 5 per cent glucose in distilled water may be given. These are discontinued as soon as fluids can be taken orally.

As soon as they are tolerated, soft foods are given in addition to fluids. Cooked cereal, soft boiled egg, milk toast, stewed fruit, junket, mashed or baked potato and simple puddings may be given at brief intervals if necessary, but only in small amounts at any one time.

When the very acute symptoms have subsided (or in mild cases from the very onset) I allow between 1000 and 1200 calories daily and increase this gradually as the patient is permitted to get out of bed and resume moderate activity.

The diet should eliminate foods which are usually difficult to digest, which are likely to cause distention or to which the patient has a sensitivity or special aversion. Raw fruits, fruit juices in excess, fried foods and gravies, spices and condiments, onions, corn, members of the cabbage family, pastries, chocolates, corned or smoked meats and fish, fatty meats and fish, cheeses, nuts, dates, figs and raisins should be avoided. The intake of salt should be minimized in the presence of congestive heart failure.

When the patient resumes moderate activity, his caloric intake should be such as to maintain his weight if it is normal, or to reduce it if he is overweight. Whenever feasible the daily caloric allowance should be divided into five meals to avoid an excessive quantity at any one time.

In the presence of diabetes mellitus, the caloric allowance should be apportioned properly among carbohydrates, proteins and fats. Insulin is discussed below.

For a discussion of diet in relation to the underlying *atherosclerosis*, see page 436.

Tobacco Alcohol, Coffee

Coffee in moderation is allowed if it does not increase restlessness or cause sleeplessness *Alcohol* is usually permissible if the patient desires it or is accustomed to it It has long had the reputation of clinical benefit in angina pectoris and often appears to benefit the patient during convalescence from an acute myocardial infarction However I do not prescribe it for patients who do not take alcoholic drinks ordinarily or who dislike it To patients who complain of weakness or depression and especially to elderly patients I often suggest a trial of alcohol in doses of 15 to 30 cc (½ to 1 oz) repeated twice daily, its continuation is dependent on the patient's subjective reaction The alcohol is given in the form of whiskey, brandy sherry or other wine Wine sherry and beer often act as satisfactory soporifics Alcoholic beverages should not usually be prescribed if there is prostatism, and they often are detrimental to other possible associated conditions such as definite sinusitis, peptic ulcer gout, and irritable colon

Despite uncertainty as to the effect of tobacco in cases of myocardial infarction, I usually prohibit its use (p 416)

Care of Bowels

After a severe attack it is undesirable that the patient be disturbed or urged to move his bowels for the first three days as straining at stool may be a dangerous exertion Usually the patient is constipated during this period because of the low intake of food and especially because of the administration of opiates Soft easy bowel movements may be effected thereafter with the aid of mineral oil (*½ to 1 oz on retiring) and if necessary* small doses of milk of magnesia (½ to 1½ oz) each night If there is distention a small saline enema may be given preferably after mineral oil with or without a small dose of milk of magnesia has been administered on the previous night A rectal tube may also be used to help control distention

Whenever obstipation abdominal distress and distention are associated the possibility of a fecal impaction induced by opiates should be considered and a rectal examination made If present the impaction should be relieved manually

Oxygen Therapy (see also p 288)

The administration of oxygen has become an important therapeutic measure in the management of acute cardiac infarction However its usefulness is probably limited to relatively severe cases Levy and Barach[75] have reported striking relief of pain and restlessness slower and less labored respiration, diminution or abolition of cyanosis disappearance of Cheyne-Stokes respiration and other objective signs of improvement within one to three hours after beginning the administration of oxygen Unfortunately for its evaluation all of the dramatically favorable results observed in individual cases following oxygen therapy can be matched by a similar sequence of events in other cases without the aid of oxygen

Cyanosis is the clearest clinical indication for oxygen therapy, but mild degrees of cyanosis are easily overlooked clinically, and in the presence of shock cyanosis may be manifested as a grayish or ashen hue Borden et al[17] found the mean arterial oxygen saturation to be 94 1 per cent in a group of patients with myocardial infarction without pulmonary edema or shock, and 80 8 per cent in those with pulmonary edema or shock Oxygen therapy is often useful for acute pulmonary edema, especially when supplied by the positive pressure technique[8] Oxygen, without positive pressure is administered during shock Persistent dyspnea is a more definite indication for oxygen therapy but has not always been effectively controlled by it Dramatic relief from intractable pain has been reported by some observers I have yet to note such an impressive and fortunate occurrence although I have occasionally witnessed the partial amelioration of severe pain and the relief of mild pain by oxygen therapy *It should be emphasized that coronary occlusion results primarily in anoxia confined to* the affected myocardial tissue which cannot usually be significantly altered by the administration of oxygen

In practice it has been my custom to give oxygen therapy a trial in all cases in which there is severe or persistent pain, dyspnea cardiac asthma, pulmonary edema, shock, Cheyne-Stokes respiration and of course cyanosis This therapy is continued if there is any evidence of objective or subjective improvement of the symptom for which it was administered As the patient improves and the oxygen is discontinued it is promptly resumed if there is evidence that the patient was more comfortable during its administra

tion or if objective signs reappear which had been abolished by the oxygen

When the indication for oxygen therapy is clear cut I prefer to use an oxygen tent supplying a concentration of 50 to 60 per cent of oxygen when the latter runs in at the rate of 9 to 10 liters per minute The temperature in the tent which together with the humidity should be carefully regulated to the patient's comfort is usually maintained between 60 and 68 F If a tent is not available or if the patient is not easily managed in the tent oxygen can usually be administered satisfactorily by means of (1) a BLB mask (provided for oronasal or nasal breathing with a regulator which can deliver up to 100 per cent oxygen) (2) small transparent plasticele face tents which with a flow of 8 liters per minute can deliver a concentration of 40 to 60 per cent or (3) a bilateral nasal or a unilateral oronasal catheter The latter will provide about 35 per cent oxygen if the flow from the tank is 5 liters per minute but it is not usually tolerated by the patient

Drug Therapy

Morphine Morphine or one of its substitutes is the drug of choice in cases dominated by pain and restlessness paroxysmal or constant dyspnea or pulmonary edema The usual dose is 15 mg (¼ grain) hypodermically but it may be given intramuscularly when more rapid action is desired Often this dose must be repeated in one-half to one hour if the symptoms are not alleviated as much as 60 mg (1 grain) over a period of four hours may be required in extreme cases But not more than this total should be given within 12 hours In extreme cases a prompt effect may be obtained by giving 15 mg of morphine diluted in 5 to 10 cc of sterile water into a vein but respirations should be observed carefully and the injection stopped if the desired result is obtained before the full dose has been administered

Nalorphine (*Nalline*) *hydrochloride* should be available for treatment of excessive narcosis or respiratory depression Five to 10 mg of Nalline is given intravenously if the respiratory rate falls below 12 per minute and the dose may be repeated in 15 minutes if necessary Coramine (1 to 3 cc of a 25 per cent solution intravenously) or Metrazol (100 to 300 mg in ampules of 1 or 3 cc of a 10 per cent solution) may be used for the same purpose but are less effective *Aminophylline* is the drug of choice for Cheyne-Stokes respiration due to respiratory depression (p 285)

Because of the respiratory depression which morphine causes large doses must be given with caution and the patient observed carefully Standing orders for morphine with the decision as to its further use left to a nurse should not be countenanced It should also be emphasized that morphine should not be given routinely as soon as the diagnosis of myocardial infarction has been made Mild pain can often be controlled by Demerol or codeine and in some cases even these analgesics are unnecessary Even if morphine appears desirable 10 mg doses (⅙ grain) often suffice after the initial larger dose Aside from its tendency to depress or paralyze the respiratory center morphine has other disadvantages due to its constriction of smooth muscle and vagal stimulation The former results in pronounced constipation which may be extremely distressing and in predisposed persons in urinary retention due to spasm of the sphincter of the bladder The vagal stimulation poses at least the theoretical danger of causing coronary vasoconstriction and of rendering the heart muscle susceptible to ectopic ventricular rhythms

Other Opiates and Analgesics In my experience most patients vomit after receiving morphine and I have usually substituted *Dilaudid* which causes vomiting much less frequently Dilaudid is a synthetic drug related to morphine with proportionally more analgesic and less soporific and respiratory depressant effect Its therapeutic dose is about ⅕ that of morphine Usually 3 mg (1/20 grain) is approximately equivalent to 15 mg (¼ grain) of morphine

Pantopon which is a mixture of opium alkaloids containing chiefly morphine is said to cause vomiting infrequently but in my experience it induces vomiting as often as does morphine The dose of 20 mg (⅓ grain) of Pantopon is about equal to 15 mg (¼ grain) of morphine It is probable that its effectiveness is due entirely or almost entirely to the morphine it contains and for this reason it is associated with the same disadvantages and toxicity Methadone (Dolophine) 5 to 10 mg hypodermically is equivalent to morphine in its analgesic effect but is less sedative less narcotic and less likely to cause mental confusion

Demerol (meperidine) is a synthetic analgesic, chemically related to morphine and atropine It may be substituted for morphine after the early severe pain subsides and more moderate pain persists or recurs frequently after the first day But in many cases Demerol alone suffices to control the pain from the very outset Unlike the above opiates it does not result in respiratory or profound cerebral depression It is administered orally, hypodermically or intramuscularly in doses of 75 to 100 mg and may be repeated if necessary at four to six hour intervals Its effect is usually observed within 20 minutes after intramuscular injection and 30 minutes after oral administration In the above dosage it is more effective than 1 grain of codeine and does not have the constipating effect of codeine or morphine

Codeine in doses of 0 03 to 0 06 gm (½ to 1 grain) hypodermically or orally may also be substituted for morphine when the severe pain lessens or if the pain is moderate from the beginning

Anticoagulants *Evaluation and Indications*[109, 110, 111] Although it is now ten years since anticoagulants have been recommended and extensively used in the treatment of acute myocardial infarction, there is a persistent disagreement as to their effectiveness, their indication and as to the choice of patients to whom they should be administered[122] This dispute is the more remarkable since objective statistical studies show an unusually consistent advantage in favor of those patients who receive anticoagulants, with respect to both mortality and the occurrence of thromboembolic complications Why then the conflict? The answer must be discussed with respect to two distinct issues (1) Do the anticoagulants benefit the clinical course and outcome in acute myocardial infarction sufficiently to justify their use despite the risks involved? (2) Assuming the effectiveness of anticoagulants, should they be used in all cases of acute myocardial infarction or may they be omitted in a large group of so-called mild cases in which the mortality rate is relatively low?

1 *Do anticoagulants benefit the clinical course and outcome?* The rationale for the administration of anticoagulants is based on (a) the probability that thrombosis is less likely to occur if clotting of the blood is impaired, (b) experimental evidence that mural thrombi formation and extension of coronary thrombosis in dogs could be prevented by anticoagulants,[126] (c) evidence that a substantial portion of the mortality from acute myocardial infarction is due to extension of a coronary thrombosis, cardiac mural or peripheral venous thrombosis and embolism, and the thought that these thromboembolic phenomena might be minimized by anticoagulants, (d) statistical evidence in controlled series of clinical cases of acute myocardial infarction showing a highly significant reduction in the incidence of thromboembolic complications and in mortality rate when anticoagulants were administered[129] None of these is conclusive The process of intravascular thrombosis is complex and its mechanism still uncertain, anticoagulants whose action is measured by "prothrombin time" in vitro have not been shown definitely to control intravascular thrombosis Likewise the experimental evidence is not regarded as transferable to the human disease Therefore the case for anticoagulants rests essentially on clinical tests comparing the mortality rate and the incidence of thromboembolic complications in comparable series of patients with acute myocardial infarction who do and do not receive anticoagulants

Such studies have almost universally presented data attesting to a notable reduction in thromboembolic complications and in mortality associated with the administration of anticoagulants Following early favorable reports, the possible value of anticoagulants in acute myocardial infarction was investigated by a committee of the American Heart Association on anticoagulants, which reported on a cooperative study of 1031 cases in 16 hospitals[130] There was a mortality of 16 per cent in the patients treated with anticoagulants in contrast with a mortality of 23 4 per cent in the control group during the period of observation When the death rates were considered for the period of effective anticoagulant therapy, namely from the fourth day of anticoagulants through four days after the last dose the contrast was even more striking the mortality rate was 9 5 per cent for the treated and 17 4 per cent for the control group Evidence that the reduction in deaths was due primarily to anticoagulant therapy and not to any difference between the two groups is provided by the observation that the contrast in death rates occurred dur

ing the weeks when coverage with anti coagulants was most complete whereas during the remainder of the six week period of observation deaths in the control and treated groups differed insignificantly This interpretation is also supported by the observation that 42 per cent of the deaths in the control group and only 23 per cent of the deaths in the treated group were preceded by clinically diagnosed thromboembolic complications In terms of the total number of cases this contrast is even more striking for death preceded by a thromboembolic complication occurred in only 2 2 per cent of the treated as compared with 7 per cent of the control cases during the period of presumed effective anticoagulant therapy

Finally a review of 21 other controlled studies[180] of the use of anticoagulants in myocardial infarction involving 2812 cases revealed a similar favorable effect since the mortality rate was 14 8 per cent in the treated cases and 29 5 per cent in the controls These findings were consistent in that the results favored the use of anticoagulants in 19 of the 21 studies showed no advantage in one study and a disadvantage in only one In the one series in which the mortality rate was said to be unaffected by anticoagulants[181] there was no actual control series in the one series with a higher death rate in the treated cases there was a bias in the selection of cases since the anticoagulant was administered out of turn to some of the more severely ill patients[22] Even more impressive than the consistently favorable results in cases treated with anticoagulants is the consistency in the quantitative results in the various series a large majority (16 of the 21 series) showing a higher mortality rate of 50 to 200 per cent in the control over the treated cases

A recent analysis of anticoagulant-treated and untreated fatal cases of acute myocardial infarction examined at autopsy confirms the clinical observations on the advantages of anticoagulants[30b] The incidence of embolic complications in these fatal cases treated with anticoagulants was only 9 per cent in contrast with an incidence of 41 per cent among the untreated cases Similarly there was a marked reduction of thrombophlebitis and fewer mural thrombi in patients receiving anticoagulants These observations are especially important because embolic phenomena are often overlooked clinically hence clinical studies are less likely to reveal the benefits of anticoagulants in the prevention of embolic complications

In the light of these findings the indication for and effectiveness of anticoagulants in the treatment of acute myocardial infarction appear unassailable Whatever rationalizations may be offered to justify their omission the most potent objection is the trouble and expense involved in obtaining prompt accurate determinations of prothrombin time In addition there is often anxiety as to the risk of bleeding due to inaccurate prothrombin determination improper dosage of anticoagulant or unusual sensitivity of the patient Much of the opposition to anticoagulants would disappear if a simple accurate bedside method for determination of the prothrombin time became available The capillary blood prothrombin test proposed by Manchester[92] is a step in this direction but is still too difficult to perform accurately without great skill and experience

Another objection raised to the reported studies indicating effectiveness of anticoagulants is the serious difficulty of matching control and treated cases There is a great variability in the severity of cases of acute myocardial infarction and the results will depend in great measure on severity regardless of the treatment employed It is also difficult to assess the influence of anticoagulants on thromboembolic complications because of the imperfect criteria for their clinical diagnosis

2 *Should anticoagulants be administered in 'mild' as well as severe cases of acute myocardial infarction even assuming that they are of important benefit in the latter group?*

'Mild' or good risk cases selected from hospital records were found to have a death rate without anticoagulants of 3 1 per cent and an incidence of thromboembolism of 0 8 per cent[132] Cases of acute myocardial infarction were classified in the good risk category *if there were none of the following* (1) previous myocardial infarction (2) intractable pain (3) extreme or persistent shock (4) significant enlargement of the heart (5) gallop rhythm (6) congestive heart failure (7) arrhythmias such as atrial fibrillation or flutter ventricular tachycardia or intraventricular block (8) diabetic acidosis or other states predisposing to thrombosis Other studies have indicated that the mor

tality rate in first attacks of acute myocardial infarction in patients treated at home (presumably because they are mild cases) is only 3 to 8 per cent[6] [illegible] [11] Based on these varied observations it has been concluded that the mortality rate and incidence of thromboembolism in so called "mild" or "good risk" cases are so low that anticoagulants cannot be expected to improve the outlook significantly and any slight benefit is neutralized or outweighed by the complications of anticoagulant therapy[111]

Both the evidence and logic leading to this conclusion are subject to criticism The validity of the data drawn retrospectively from hospital charts has been challenged There is uncertainty as to the reliability of any criteria for determining prognosis *in the individual patient* on the first day of his acute attack This is when anticoagulant therapy should be begun if it is to be given I have frequently observed patients from whom anticoagulants have been withheld because they were labeled "mild" on the first day but who later fell into the poor risk category because of serious complications In a study of 107 patients with acute myocardial infarction,[57] the prognosis was ventured after 24 hours and again after 48 hours The initial decision as to "mild" or "severe risk" was reversed in 31 cases (30%), emphasizing the difficulty of evaluation when the patient is first observed in the early stage of the disease Francisco and Wright[45a] reported a high incidence of serious thromboembolic complications among so-called "good risk" cases of acute myocardial infarction There is need for further study of one's accuracy in distinguishing so-called "good risk" cases at the very onset of the illness

Perhaps it is the use of the term "mild" or "good risk" that [illegible] most misleading No disease that is associated with 5 per cent mortality can be called mild If anticoagulants are beneficial in very seriously ill patients with myocardial infarction, what evidence [illegible] there that they may not be significantly beneficial also in somewhat less seriously ill patients?—for a patient with [illegible] 5 per cent possibility of dying [illegible] seriously ill If anticoagulants can reduce the mortality in these cases by one third to two thirds, the saving cannot be disregarded if one is concerned with the individual patient Neither [illegible] there adequate evidence to indicate that the hemorrhagic complications of anticoagulant therapy result in fatalities sufficient to neutralize or outweigh their possible benefits There is obviously need for controlled studies to determine the comparative mortality rate with and without anticoagulants in the so-called "good risk" category of patients Thus in a study reported by Burton,[25b] there was a mortality of 2 per cent and thromboembolic complications occurred in [illegible] per cent of 156 "good risk" cases treated with anticoagulants whereas the mortality rate was 5 per cent and the incidence of thromboembolic complication was 11 [illegible] per cent among 58 "good risk" cases not treated with anticoagulants

CONCLUSION The over all mortality rates in controlled studies of anticoagulant therapy in acute myocardial infarction strongly suggest that anticoagulants should be employed routinely in this disease The difficulties imposed by great variability in the severity and clinical course of cases of myocardial infarction and the problem or impossibility of exactly matching control and treated cases necessitate some reservation as to the significance of the statistical evidence However, for the present, the weight of statistical *evidence* if not opinion is so uniformly favorable to anticoagulant treatment that good medical practice requires every physician to employ it Omission of anticoagulants is justified only by lack of laboratory facilities to perform accurate prothrombin determinations or by the presence of firm contraindications (infra) The difficulty and expense of "prothrombin" determination point to a need for correction of these defects, not for rejection of anticoagulant therapy

It has been proposed that in certain cases not associated with the most unfavorable features and euphemistically termed "mild," the possible advantages of anticoagulant therapy are relatively small and do not justify its risk, its trouble and its costliness Until it can be demonstrated that "good risk" cases can be accurately and consistently distinguished at the very onset of the illness, and until controlled studies of such "good risk" cases with and without anticoagulant therapy disclose no advantage of anticoagulants in these cases I prefer to assume that if anticoagulant therapy is beneficial in the treatment of seriously ill patients this benefit

should also be afforded to those who appear less seriously ill

Toxicity of Anticoagulants HEMORRHAGIC PHENOMENA AND TREATMENT The only important risk of anticoagulant therapy is that of hemorrhagic manifestations As a rule hemorrhagic complications can be avoided by careful control of the dose of anticoagulants according to a reliably determined prothrombin time Furthermore attentive clinical supervision should limit hemorrhagic manifestations to minor ones which are discovered early and promptly controlled by reduction or omission of anticoagulant or by the administration of vitamin K_1 Careful questioning and clinical and laboratory evidence of bleeding are important because occasionally bleeding occurs when the prothrombin time is reported in the therapeutic range Conversely there may be no evidence of bleeding in some cases despite prolongation of the prothrombin time well beyond the usual therapeutic range

Early evidence of bleeding tendency may be disclosed by black and blue marks with minimal trauma or unusual bleeding from minor cuts during shaving or from the gums after brushing the teeth Hematuria is one of the commonest manifestations of anticoagulant overdosage Before hematuria is discovered renal bleeding usually produces abdominal pain or classic ureteral colic The pink color of the urine produced by phenindione (Hedulin or Danilone) should not be confused with hematuria Gastrointestinal bleeding (often producing tarry stools) epistaxis and hemoptysis are overt signs of excessive anticoagulant dosage The occurrence and localization of bleeding in anticoagulant therapy is often determined by preexistent organ disease Thus gastrointestinal bleeding is apt to occur in an individual with peptic ulcer bleeding may be started from an ulcer which has been asymptomatic for years Hemoptysis appears to occur more readily when myocardial infarction is complicated by marked pulmonary congestion or recent pulmonary edema Hemorrhagic pleural effusion occurs not infrequently I have seen a hemopericardium in at least five cases in which I have performed a pericardial tap and suspected it in others In all of these there was evidence of excessive anticoagulant therapy and also evidence of pericarditis at the onset of the myocardial infarction Myocardial rupture and hemopericardium appear to be occurring more frequently since the use of anticoagulants[137] (p 543)

When there is only minimal tendency to bleeding anticoagulant effect may be maintained at more moderate therapeutic levels by omitting the dose for a day or two But if bleeding is more serious or if there is no wish to continue anticoagulation the prothrombin time may be restored to therapeutic levels in 4 hours and to normal within 24 hours by the administration of vitamin K_1 Transfusions of blood are given only for excessive blood loss

PHYTONADIONE (MEPHYTON K_1)[1 8 11] This is a commercial synthetic preparation of vitamin K_1 a 2 methyl 3-phytyl 1-4 naphthaquinone available as a 5 per cent aqueous emulsion in 1 per cent lecithin for intravenous use It must be kept cool and protected from the light It is far superior to the water soluble vitamin K_1 preparations as treatment for excessive hypoprothrombinemia Its method of action is unknown but after its administration bleeding due to hypoprothrombinemia ceases in 2 to 4 hours and may be partially controlled in 15 to 30 minutes A safe prothrombin time is attained in 3 to 6 hours and the prothrombin time is restored to normal in 8 to 14 hours For actual bleeding Mephyton is administered slowly intravenously in a dose of 50 mg (1 cc) in a period of 1 to 2 minutes Blood may be drawn up into the syringe mixed with the emulsion and the injection is made If there is significant blood loss the blood may have to be replaced by transfusion For minor hemorrhage only 10 mg of Mephyton need be given orally if anticoagulant treatment is to be continued Only 0 5 to 2 5 mg orally may suffice to reduce a prolonged prothrombin time (without bleeding) to therapeutic levels Restoration of a normal prothrombin time by Mephyton has the disadvantage that the patient becomes refractory to anticoagulants for several days There are 5 mg oral tablets of Mephyton

Contraindications to Anticoagulants Anticoagulants are contraindicated in patients with significant hepatic renal or hematologic disturbances This refers more specifically to liver disease in which there is impaired formation or storage of fibrinogen vitamin K etc renal insufficiency which may exaggerate the

concentration of anticoagulant or hematologic disturbances associated with a bleeding tendency. Anticoagulants should not be given if there is uncertainty as to the differential diagnosis between acute myocardial infarction and dissecting aneurysm of the aorta. They are contraindicated in the presence of active bacterial endocarditis, ulcerations and open wounds, recent surgical operations on the brain or spinal cord, postoperative tube drainage of wounds or viscera, or recent ulceration of and bleeding from the gastrointestinal tract.

Administration of Anticoagulants. Heparin, repository heparin, Dicumarol, Tromexan and phenylindanedione are the anticoagulants most commonly employed, but a number of newer preparations have been used recently and will be discussed.

In practice, blood is drawn for determination of the Lee White coagulation time and for a prothrombin time and if these are normal 200 to 400 mg. of Depo-Heparin (repository form of heparin by Upjohn) is injected intramuscularly. At the same time I administer orally 1500 to 1800 mg. of Tromexan and either 300 mg. of Dicumarol or 200 to 300 mg. of phenylindanedione (marketed as Hedulin or Danilone). The heparin is designed to give an immediate anticoagulant effect lasting at least 24 hours. The Tromexan acts most rapidly of the oral anticoagulants and prolongs the prothrombin time adequately by the end of 24 hours. Finally the phenylindanedione or Dicumarol becomes effective by the end of 48 hours, the former usually earlier than the latter. Since therapy is to be continued with either the indanedione or the Dicumarol, 100 mg. of the former or 150 to 200 mg. of the Dicumarol is ordered the second day. A second dose of Depo-Heparin (200 mg.) may be given after 12 or 24 hours if the coagulation time is inadequately prolonged and if the Tromexan has not yet prolonged the prothrombin time satisfactorily. Tromexan is not repeated. After 48 hours therapy is continued with the indanedione (Hedulin or Danilone) or Dicumarol. The oral anticoagulants are given in such dosage as to maintain the prothrombin time at 2 to 2½ times the control value. When the *control time*, as determined by the one stage Quick or Link Shapiro method on a normal subject not receiving anticoagulants is 12 to 13 seconds, the induced prothrombin time in the patient should range between 25 and 35 seconds. This corresponds to a prothrombin *concentration* of about 10 to 30 per cent of normal, when determined by serial dilution of plasma. However, normal, pathologic and anticoagulant treated plasmas cannot be compared accurately by this method of serial dilution. If the prothrombin time is also determined on 12.5 per cent plasma, the prothrombin time should be prolonged two to four times that of the control, e.g., to 70–140 seconds when the control is 35 seconds. It should be noted also that while heparin is being used this drug will prolong the prothrombin as well as the coagulation time. The administration of anticoagulants is continued for at least three weeks, the period of highest incidence of thromboembolism, and until the patient is ambulant. Long term anticoagulant therapy is discussed below.

Individual Anticoagulants[9, 24, 30, 148] HEPARIN SODIUM. Heparin may be injected intravenously or intramuscularly. The dosage is adjusted to prolong and maintain the coagulation time to between 30 and 60 minutes in contrast to a normal coagulation time of 9 to 15 minutes by the Lee-White method. About 300 mg. is administered in 24 hours with some variation according to the age and weight of the patient. It may be administered in a slow, continuous intravenous infusion of 5 per cent glucose in distilled water, containing the 300 mg. of heparin sodium in a liter of fluid. It may also be administered by intermittent intravenous injection in 50 mg. doses every 4 to 6 hours or a concentrated *aqueous solution* of heparin may be administered intramuscularly in 100 mg. doses every 8 hours.

REPOSITORY HEPARIN (Lederle) OR DEPO-HEPARIN (Upjohn). These are long acting preparations containing 200 mg. per cubic centimeter in an aqueous menstruum containing 16 or 18 per cent gelatin and 7.5 or 8 per cent dextrose and are generally preferred to heparin sodium because only one or two injections are necessary in 24 hours. Two hundred to 400 mg. are injected deep intramuscularly at the onset and 200 mg. may be repeated after 12 to 24 hours according to the coagulation time.

The heparin should not be administered in patients with hemorrhagic diseases, or recent active gastrointestinal ulceration or when the coagulation time is prolonged 60 minutes by the Lee-White method. Excessive heparin

effect may be neutralized by the slow intravenous administration of *50 to 200 mg of protamine sulfate* (Lilly) Transfusion of blood may be necessary rarely if there is excessive bleeding

DICUMAROL (bishydroxycoumarin) is a coumarin preparation which was introduced early and is still widely used although some of the newer anticoagulants appear preferable The initial dose is 300 mg But only 200 mg is given to patients with right sided congestive heart failure or small individuals Correspondingly 200 mg or 100 mg respectively is given the following morning Thereafter 50 to 150 mg is given daily, preferably in divided doses according to the prothrombin time Most patients require 50 to 100 mg after the desired prothrombin level is attained Smaller doses may suffice in patients with hepatic or renal disease or congestive heart failure Satisfactory anticoagulation is usually attained with Dicumarol in 48 to 72 hours and its action persists for 3 to 8 days after the drug is discontinued Mild diarrhea headache and rash have been encountered occasionally If the prothrombin time is prolonged excessively (more than three to four times the control time) or if bleeding occurs Dicumarol is temporarily discontinued and if necessary vitamin K_1 (Mephyton) is administered (p 575)

TROMEXAN[111, 138] (ethyl biscoumacetate—Geigy) is also a coumarin derivative which possesses the advantage over Dicumarol of a more rapid onset of effective action usually in 18 to 36 hours and more rapid dissipation of action 36 to 72 hours after it is discontinued However the drug is relatively expensive and in my experience provides less constant control of the prothrombin time I usually employ a single dose of 1500 to 1800 mg at the onset at the same time that some other preferred but slower acting anticoagulant is administered However when Tromexan is used continuously the average daily maintenance dose is 300 to 900 mg in divided doses after the desired prothrombin time is attained

PHENYLINDANEDIONE[133, 31] (Hedulin—Walker or Danilone—Schieffelin) available in 50 mg tablets is not a coumarin derivative It possesses the advantage of a more rapid onset of effective action than Dicumarol in 24 to 36 hours Its activity is dissipated in 2 to 4 days The initial dose is 200 mg and 100 mg is given the following morning When a satisfactory prolongation of the prothrombin time is attained the maintenance dose is 25 to 50 mg *twice* daily

DIPHENADIONE (Dipaxin—Upjohn)[64, 103, 44] This is a new prothrombinopenic oral anticoagulant of the indanedione group namely 2-diphenylacetyl 1 3 indanedione With an initial dose of 30 mg therapeutic anticoagulant effect is attained in about 40 hours according to Katz et al, but a longer period was reported by other observers using a dose of 25 mg[103] The effect persists between 6 and 10 days but this can be abbreviated by vitamin K_1 Its chief merit appears to rest on the claim that the daily maintenance dose fluctuates little in the same or different individuals, and averages 3 to 5 mg Katz and associates[44] have employed an initial combination of 1500 mg of Tromexan with 30 mg of Dipaxin and continued with maintenance doses of Dipaxin alone In this manner the advantage of early anticoagulant effect of Tromexan could be attained without its disadvantages with prolonged use According to Field and associates [illegible] Dipaxin is especially useful for long term maintenance therapy of patients with thromboembolic diseases since prothrombin determinations may be necessary only at intervals of two or more weeks Field et al[44] gave an initial dose of 20 to 30 mg followed by 10 to 15 mg the second day Then maintenance therapy was continued according to the individual's response

CUMOPYRAN[109, 8] (Cyclocumarol—Abbott) (Methopyranorin or 4 hydroxycoumarin) is another coumarin derivative which produces satisfactory prolongation of prothrombin time in 36 to 48 hours but its action persists even longer than that of Dicumarol 12 to 14 days after discontinuation The initial dose is 150 mg and the maintenance dose 12 5 to 50 mg daily Control of prothrombin time is more difficult than with the other preparations mentioned but Brunton et al[25] found that cumopyran produced a constant individual response to a therapeutic dose and that it was one of the best of the 4 hydroxycoumarin group of anticoagulants

MARCUMAR[18, 106] *is a new oral anticoagulant* and like Dicumarol is a 4 hydroxycoumarin derivative [3 (1 phenyl propyl)-4 hydroxycoumarin] Pharmacologically it acts by depressing both the proconvertin and prothrom

bin in the plasma When Marcumar is given in therapeutic doses anticoagulant activity is detected after 24 hours reaches its peak after 48 hours and persists between 4 and 5 days although Prior[106] found that it persisted 9 to 14 days Compared with Dicumarol its activity starts earlier is more prolonged and is twenty times as great per milligram of dose However its onset is somewhat later than that of Tromexan The recommended dosage of Marcumar[8] is 21 mg in a single dose on the first day 9 mg the second day and thereafter a usual maintenance dose of 3 mg daily These doses are modified as necessary in order to maintain the undiluted prothrombin time between 20 and 35 seconds (control 15 seconds) and the diluted prothrombin time between 70 and 160 seconds (control 38 seconds) Excessive reduction in prothrombin time may be controlled by vitamin K_1 (p 575)

Table 9 Oral Anticoagulants Time of Action and Dosage*

ANTICOAGULANT	ONSET OF THERAPEUTIC LEVEL HRS	PERSISTENCE OF ACTION AFTER DISCONTINUATION DAYS	INITIAL DOSE (FOLLOWING DAY GIVE ½ TO ⅔) MG	MAINTENANCE DOSE AFTER THERAPEUT LEVEL MG
Dicumarol	48 72	4 7	200 300	50–150
Tromexan	18 36	1½ 3	1500–1800	300–900
Phenindanedione (Hedulin Danilone)	24–48	2–4	150 200	[illegible] 100
D phenadione (Dipaxin)	24–72	more than 7	30	3 5
Cumopyran (Cyclocumarol)	36–48	12 14	150	12 5 to 50
Marcumar	24 48	4 5 (9 14)	21 (9 mg 2nd day)	3
Warfarin (Coumadin)	18 36	5–7	50 75	5 25 mg at 1–3 day intervals
Sinthrom (Acenocoumarin)	24–48	2	20	4 6

* Dosage is approximate and must be controlled by determination of prothrombin time and careful observation of the patient for evidence of bleeding

WARFARIN (Coumadin sodium—Endo) is a synthetic anticoagulant with the chemical name 3 (α acetonylbenzyl) 4 hydroxycoumarin Warfarin sodium administered orally or intravenously produces therapeutic hypoprothrombinemia in appropriate dosage[243, 105] By both routes a therapeutic range is usually achieved within 24 (16 to 36) hours and is maintained for 5 to 7 days The intravenous route is indicated only when oral medication cannot be tolerated The initial dose of the intravenous or oral medication is 1 mg per kilogram of body weight but rarely exceeds a maximum of 75 mg Subsequent dosage based on prothrombin time determination is given when the peak effect is achieved usually on the third or fourth day The next dose is approximately two thirds the initial dose Maintenance dosage of 12 5 mg or 25 mg is given daily or every other day occasionally every third day according to the prothrombin time and whether it is rising or falling According to Pollock[105] the maintenance dose is 5 to 20 mg daily, average 10 mg The prothrombin *concentration* should be 10 to 30 per cent (usually 25 to 35 sec prothrombin time with control of 12 sec)

Warfarin possesses the advantage of rapid therapeutic effect similar to that of Tromexan but its action is more prolonged and it is easier to control the hypoprothrombinemia at stable levels

SINTHROM (Acenocoumarin—Geigy) a new 4 hydroxycoumarin oral anticoagulant is effective in small doses and is reported to be quite satisfactory with respect to ease of controlling the prothrombin time and relative safety[120] The initial dose is 20 mg followed by 8 to 16 mg on the second day The maintenance dose is 4 to 6 mg daily In 85 per cent of the patients, the therapeutic range of prothrombin time was attained in 48 hours or less The prothrombin time approached normal 30 hours after the drug was discontinued[141a]

Long Term Anticoagulant Therapy [1, 97, 6, 135] The prolonged administration of anticoagulants is now being recommended to prevent further attacks of acute myocardial infarction Favorable results have been reported by Nichol et al [97] in a series of 295 patients treated from three months to seven years and by Tulloch and Wright[134] in 227 patients Such therapy is employed chiefly in those patients who have suffered recurrent myocardial infarction especially when complicated by other evidences of thromboembolism This is obviously a project which will require a long period of time to evaluate and one in which it will be difficult to prove the efficacy of the procedure because of the absence of control and of matching cases and the variable outlook in reported series of cases of coronary thrombosis However Suzman et al [136] treated 82 patients with anticoagulants for 3 to 76 months following myocardial infarction whereas a group of 88 patients who had received anticoagulants only during the acute attack served as controls The mortality rate was 7 3 per cent in the group receiving long term treatment and there were 7 recurrences of myocardial infarction In the control group the mortality rate was 33 per cent and there were 24 recurrences Favorable effects of long term anticoagulant therapy were also reported by Keyes et al [65] by Manchester [91] and by Murr [96]

During the course of long term therapy repeated determination of the prothrombin time is essential but in most patients the prothrombin times and anticoagulant dosage become sufficiently stabilized to permit intervals of one two or occasionally three weeks between determinations Hemorrhagic complications are more frequent in patients on long term anticoagulant therapy than in those receiving such treatment only during an acute myocardial infarction Hematuria hematoma or ecchymoses occur most commonly But melena epistaxis menorrhagia hematemesis hemoptysis and other forms of hemorrhage have also been noted As a rule these can be controlled by temporary discontinuance of the drug and by the administration of vitamin K_1 (Mephyton)

Sedatives and Soporifics Sedatives are among the most widely used and most valuable drugs in the treatment of cardiac infarction They are employed after subsidence of severe pain eliminates the need for morphine or similar opiates In certain cases with little or very transient pain, sedatives and soporifics may be the only drugs required *Phenobarbital* in doses of 15 or 30 mg (¼ or ½ grain) three times daily is commonly given to allay apprehension anxiety or restlessness and often causes mild drowsiness It may also reduce the susceptibility to ectopic rhythms especially ventricular tachycardia It is often advisable to maintain the patient in a somewhat drowsy state during the first days of the acute illness Phenobarbital may have to be supplemented by soporifics such as Seconal 0 1 gm (1½ grains) Nembutal (pentobarbital) 0 1 gm (1½ grains) barbital 0 3 gm (5 grains) Ipral calcium 0 12 gm (2 grains) Sedatives and soporifics should not be given to the point of causing respiratory or mental depression In some patients the barbiturates cause excitement instead of depression especially with large doses Continued use may cause a dermatitis in susceptible individuals

Bromides 1 gm (15 grains) or chloral hydrate 0 3 to 0 6 gm (5 to 10 grams) alone or in combination with bromides may be substituted or alternated with the phenobarbital During the period of recovery Demerol for occasional or persistent moderate pain or codeine for milder pain administered orally or hypodermically may be combined with sedation

Digitalis Digitalis should be employed in the treatment of acute myocardial infarction only when there is congestive heart failure or an arrhythmia with very rapid ventricular rate While there is general agreement as to the indication for digitalis whenever heart failure develops many physicians avoid it when the heart failure is associated with acute myocardial infarction Following is an evaluation of the objections mostly theoretical which have been raised to the use of digitalis in acute myocardial infarction

1 By increasing the force of cardiac contraction digitalis it is argued may rupture the weak infarcted muscle or dislodge a mural thrombus This purported danger implies that digitalis increases the intraventricular pressure Neither congestive heart failure nor digitalis has a consistent effect on the systolic blood pressure On the contrary an increased diastolic pressure is produced not by digitalis but by cardiac failure

2 Because the ischemic myocardium is

hyperirritable following acute coronary occlusion, it is feared that digitalis may increase this irritability and promote the probability of ventricular tachycardia and ventricular fibrillation While digitalis has been known to cause extrasystoles it has also diminished or abolished them No justifiable conclusion can therefore be drawn that digitalis will cause this serious arrhythmia when given in therapeutic doses to humans The basic reason for serious arrhythmias after coronary occlusion is the consequent myocardial anoxia, since digitalis improves the metabolic efficiency of the failing heart muscle, it may diminish rather than increase their frequency Askey[2] found no evidence of an increase in ventricular ectopic rhythms in a group of 50 patients with proved myocardial infarction who were given digitalis in therapeutic dosage as compared with a control group who were not treated with digitalis

3 It is feared that digitalis may further diminish the already depressed cardiac output which is associated with cardiac infarction and shock But although digitalis reduces the cardiac output in health it increases the cardiac output when heart failure is present (p 250)

4 Another objection to the use of digitalis after acute coronary occlusion is the belief that digitalis causes constriction of the coronary arteries But the available experimental and clinical evidence is contradictory as regards this contention

In the absence of more convincing objections it has been my practice to administer digitalis for the treatment of heart failure after myocardial infarction unless the heart failure is readily controlled by the more immediate measures of bed rest opiates oxygen therapy and occasionally venesection If there is gross right and left sided heart failure digitalis is administered whenever these manifestations appear But in the presence of very mild left sided failure alone digitalis is usually not administered until a week after onset when the acute features of the disease have disappeared or become stabilized When heart failure is characterized by acute pulmonary edema which does not respond to other emergency measures strophanthin may be given in the form of ouabain beginning with 0 25 mg intravenously and repeated in an hour if necessary An additional 0 25 to 0 50 mg may be given intravenously or intramuscularly 12 hours later This drug should not be given if the patient has been receiving digitalis immediately prior to the attack Other digitalis preparations for intravenous digitalization have been discussed (p 262), e g Cedilanid, 4 cc intravenously, if there is no immediate emergency [illegible]

For less severe left ventricular failure characterized by persistent dyspnea or paroxysmal dyspnea, as well as for the fully developed symptoms and signs of right- and left sided heart failure with or without sinus rhythm, the patient should be digitalized in the manner previously outlined (p 259) As always, the most important guide to digitalis dosage is the clinical response of the individual patient

Rales at the extreme bases of the lungs posteriorly are commonly present from the outset of acute myocardial infarction, but in themselves are insufficient indication for the use of digitalis or diuretics in the first days of illness They do not necessarily represent fluid retention, but rather indicate a redistribution of blood to the pulmonary circulation due to the acute injury to the left ventricle They usually disappear spontaneously before the end of the first week

Mercurial Diuretics These preparations (p 271) are indicated chiefly in cases of acute cardiac infarction which are characterized by right and left sided congestive heart failure from the very beginning, and in cases in which congestive heart failure becomes manifest after the patient resumes activity They are less widely used, but are also of striking benefit for the treatment of recurrent nocturnal paroxysms of cardiac asthma which may develop early after cardiac infarction Like digitalis mercurial diuretics are not administered early unless there is gross, right sided heart failure or persistent pulmonary edema After a week a mercurial may be given if there are persistent symptoms and signs of left- or right-sided heart failure

Quinidine Quinidine is employed during the treatment of acute cardiac infarction to combat the development of numerous and troublesome premature contractions, persistent atrial flutter and fibrillation without cardiac failure and ventricular tachycardia (see below) There is no significant basis to justify its routine use for the purpose of preventing these arrhythmias [illegible]

Antibiotics These drugs are frequently used

in the treatment of acute myocardial infarction either because there is a definite complicating pneumonia or because it is sometimes difficult to distinguish between extensive pulmonary congestion (especially when complicated by infarcts) and bronchopneumonia. Roentgenologic examination is not always feasible and does not easily distinguish between pulmonary infarction and pneumonia. In general it is preferable to administer penicillin in the form of crystalline procaine penicillin in an average single daily intramuscular dose of 300,000 units. Or else penicillin 400,000 units and streptomycin 1 gm. are administered in combination or a broad spectrum antibiotic such as tetracycline 250 mg. four times daily is administered orally. Some physicians routinely prescribe antibiotics as a prophylactic if there is evidence of pulmonary congestion (moist rales at the bases) and fever.

Insulin. The question of the use of insulin arises frequently because cardiac infarction is common in diabetics and because the risk of hypoglycemic shock is especially great for the ischemic myocardium. Hyperglycemia and mild transient glycosuria are fairly common after acute coronary occlusion; in themselves they are no indication for the use of insulin and they may not denote any more than potential diabetes (p. 520). On the other hand, insulin should be used in patients with uncontrolled diabetes, which is often intensified by the occlusion, but the dosage should be such as to permit a mild glycosuria or at least a moderately elevated blood sugar as a margin of safety. In my experience in such cases regular insulin administered as needed according to the findings in fractional specimens is preferable to and safer than routine orders of protamine zinc insulin.

Corticosteroids. The problem of administering cortisone or other adrenocorticosteroids for associated disease sometimes arises during the course of an acute myocardial infarction. On the one hand, it is theoretically possible that the inhibition of inflammatory reaction might beneficially permit better penetration of the infarct by collateral vessels; on the other hand, inhibition of healing might predispose to cardiac rupture or imperfect scar formation. Johnson and associates[61] reported that cortisone administration begun at the time of experimental ligation of a coronary artery in dogs resulted in strikingly smaller infarcts and other benefits as compared with the findings in operated dogs which did not receive cortisone. However, such benefits were not observed in similar studies by others.[33, 62] In fact, there was usually a slight inhibition of the rate of removal of necrotic muscle with consequent delay in healing. Clinical observations have not been decisive in my experience, but it appears preferable to interrupt the administration of cortisone, unless absolutely essential, at least during the first three weeks after an acute myocardial infarction.

Other Drugs. Atropine is not used for the treatment of acute myocardial infarction but may be employed if there is heart block without Adams-Stokes syndrome.

Neither are the xanthine drugs employed any longer except that *aminophylline* is given intravenously or as a rectal suppository for the control of Cheyne-Stokes respiration and for the control of paroxysmal dyspnea or cardiac asthma.

Papaverine has not been found to be beneficial for the myocardial infarct. It has been used occasionally intravenously (0.1 to 0.2 gm.) to relieve arterial spasm at the onset of peripheral embolization.

Nitrites are not employed in the treatment of acute myocardial infarction and are regarded as potentially dangerous because they may induce a fall in blood pressure. However, many patients who have been taking nitrites for preceding episodes of angina pectoris often take them at the onset of acute myocardial infarction. Often it is the failure of the nitrites to relieve pain which leads the patient to summon his physician, or which indicates to the physician that he is dealing with a case of acute myocardial infarction and not angina pectoris.

The intravenous injection of trypsin was claimed to dissolve experimentally induced coronary thrombi[1] and to have a beneficial anti-inflammation effect in human cases of thromboembolism including coronary thrombosis.[62] Studies by Taylor and Wright[131] failed to provide evidence to justify the use of parenteral trypsin as a therapeutic agent in man.

TREATMENT OF COMPLICATIONS

The management of cardiac shock (p. 562), acute pulmonary edema (p. 566) and other forms of congestive heart failure has been

discussed above as the treatment of intrinsic manifestations of acute cardiac infarction rather than of complications

Arrhythmias

Premature beats, usually ventricular are common, rarely affect the prognosis, or require treatment However, when ventricular premature beats recur frequently and cause subjective annoyance Pronestyl (p 340) or quinidine may be administered (p 341)

Ventricular Tachycardia Pronestyl and quinidine are the drugs of choice in its treatment, but potassium and magnesium salts and other drugs have been recommended (p 374)

Atrial Fibrillation Usually paroxysms of atrial fibrillation in the course of cardiac infarction subside spontaneously after several hours and thereafter require no treatment When persistent, quinidine may be given in an effort to restore regular rhythm (p 365) When atrial fibrillation is associated with congestive heart failure or a high ventricular rate, digitalis should be given according to the principles previously outlined (p 259) Subsequently digitalis may be stopped temporarily and quinidine administered in an effort to restore sinus rhythm

Embolism

Since *pulmonary embolism* arises almost exclusively from venous thrombi in the lower extremities, prevention of such thrombosis is more important than efforts at treatment after embolization occurs This is accomplished by early leg exercises and early ambulation, e g to the lavatory

Embolization of a Peripheral Artery Embolectomy is the most important single therapeutic measure and promises restoration of circulation in a high percentage of cases if the operation can be performed within 12 hours after the occurrence of the embolism [65, 128, 141] The results of embolectomy are rarely satisfactory, even as regards the restoration of circulation, if more than 24 hours have elapsed However, Atlas[4] reported recovery of a patient operated upon successfully for an aortic embolus 60 hours after its occurrence As a rule, embolectomy is indicated when the embolus is situated at the bifurcation of the aorta, of the common iliac artery or of the femoral artery But embolectomy is only occasionally or rarely necessary for embolization of the upper extremity or of the popliteal or more distal arterial branches of the lower extremity, because there is an adequate collateral circulation In the latter instances an attempt at surgical removal of the embolus should be performed only if there is loss of function of the muscles supplied by the affected artery, or progressive changes

Although the ultimate outlook for patients with embolization is poor, with or without embolectomy, because of the serious underlying cardiac disease, many lives and more extremities could undoubtedly be salvaged by embolectomy Griffiths[54] found that 87 per cent of patients with arterial embolism who were not operated upon died within a fortnight and the remainder required a major amputation On the other hand Key[65] reported successful embolectomies in 216 cases Even in cases of saddle embolus of the aorta, which is almost invariably fatal, recoveries have been reported following embolectomy [78, 141, 119a]

The immediate treatment of peripheral arterial embolism includes the administration of opiates for the severe pain that is usually present The ingestion of alcoholic beverage may also be helpful, because of both its analgesic and antispasmodic action When the lower extremity is involved the head of the bed should be elevated or the legs should be hung down over the side of the bed periodically The application of heat is dangerous and should be avoided But the room should be kept warm and a cradle with one or two electric light bulbs may be placed over the extremity Warm packs may be applied to the unaffected extremities Papaverine (60 to 120 mg) or tolazoline (Priscoline) (25 to 50 mg) may be administered intravenously or intra arterially proximal to the occlusion If effective, this can be repeated if local circulatory insufficiency recurs Paravertebral lumbar sympathetic block with procaine or alcohol may be beneficial if these measures fail This procedure is designed to relieve associated arterial spasm and thus improve the collateral circulation But it is probably safer to avoid paravertebral block if anticoagulants are to be administered, as they should be The Sanders oscillating bed may be employed with the maximal low foot and minimal low head adjustment

Anticoagulants should be administered as soon as possible Heparin in doses of 50 mg should be administered intravenously every 4 hours and oral anticoagulants should be

started as described on page 576 If these various measures are ineffective within 4 to 6 hours embolectomy should be performed[17] This is most often necessary for embolism of the abdominal aorta or common iliac artery If the surgeon desires the effect of the heparin may be neutralized preoperatively by the administration of protamine sulfate intravenously But anticoagulant therapy should be instituted postoperatively If it is too late for embolectomy and there is evidence of beginning gangrene refrigeration of the extremity may be tried With the development of gangrene amputation is usually necessary

Diabetic Acidosis

Although diabetic acidosis and coma complicating acute cardiac infarction may be difficult to control because of the active cardiac process the general principles of controlling diabetic acidosis should be followed Parenteral fluids and insulin should be administered promptly and in sufficient amounts to control hyperacetonemia dehydration and shock The danger of hypoglycemic shock must be avoided and if the acidosis is controlled insulin should not be pressed to the point of completely abolishing glycosuria and hyperglycemia One should also avoid the danger of precipitating pulmonary edema by giving excessive quantities of fluid especially fluids containing sodium The necessity of hospitalizing patients with acute myocardial infarction and diabetic coma for continuous observation and frequent physical and laboratory examinations appears obvious

Periarthritis of Shoulder and Disturbances of Hand

Pain and disability of the shoulder and arm and trophic disturbances of the hand usually run a protracted course and are resistant to treatment As a rule the shoulder arm symptoms subside spontaneously after three to twelve months or longer depending on their severity Procaine infiltration of local trigger zones and various physiotherapeutic and orthopedic measures have been employed with uncertain effect Prednisone (Meticorten) in doses of 20 to 60 mg daily is often effective Roentgen ray therapy has frequently afforded relief when all other measures failed Relief has also been reported following the local injection of 50 mg of hydrocortisone into local trigger areas[12] Adequate analgesics or even occasional opiates are required for relief of pain and should be administered Motion should be encouraged as tolerated but not to the point of pain active manipulation should be avoided Stellate ganglionectomy upper dorsal sympathetic blocks with procaine or surgical dorsal sympathectomy has been recommended by Steinbrocker and his associates[17]

Aneurysm of the Ventricle

Excision of a ventricular aneurysm (ventriculoplasty) has been recommended because of the frequent association of intractable heart failure persistent angina pectoris and arterial emboli[74] This is still in the realm of research

Rupture of Ventricular Wall or Interventricular Septum

Whenever the diagnosis of perforation of the interventricular septum is made in the course of acute myocardial infarction the defect should be repaired as soon as shock can be controlled If cardiac rupture is suspected a pericardial aspiration should be performed If blood is obtained the patient should be typed and suitable blood should be made available for transfusion if necessary If rupture of the ventricle is indicated by recurrent tamponade despite aspiration a thoracotomy should be performed and the ventricular rupture repaired

Sudden Death

It seems paradoxical to discuss the treatment of sudden death in myocardial infarction yet often the immediate cause of death and death itself are not irreversible if treatment is instituted promptly When death is due to a disturbance in cardiac mechanism usually ventricular fibrillation or cardiac standstill it is possible to restore the normal cardiac mechanism as described under cardiac arrest (p 1109) without recurrence of the cardiac arrest Thus Beck et al[10] described the case of a physician who died from an acute myocardial infarction while leaving the hospital A thoracotomy was performed and cardiac massage instituted within three minutes Ventricular fibrillation was observed and sinus rhythm was restored by electric shock applied to the heart The patient recovered A similar case was reported by Reagan et al[106]

CONVALESCENCE AND REHABILITATION

The duration of convalescence and the decision as to whether and when a gainful occupation may be resumed must be determined individually in each case Patients with pro

nounced and persistent symptoms of congestive heart failure, with angina pectoris recurring frequently at rest or after minimal effort or with extreme weakness may require an indefinitely prolonged period of convalescence It is often necessary to adjust the patient to the necessity of indefinite or permanent retirement from work or business and psychotherapy becomes a dominant element in medical management

The physician should not enforce prolonged invalidism merely because the patient has experienced a severe attack Nor should the patient be led to believe that chronic invalidism is the inexorable consequence of myocardial infarction even if the symptoms do not permit a complete restoration of previous activity The physician must assess the comparative merits of a miserable enforced invalidism, of which the effect on longevity is questionable against a less confined but happier life which may involve slight theoretical risks

Patients who recover from the acute attack and who experience little or no distress as they become ambulant should nevertheless spend a variable period after recovery in gradually resuming normal care of themselves in the home and short walks outdoors When this is accomplished a holiday of two weeks or longer is often desirable to induce a philosophic and psychologic readjustment

The resumption of physical exertion after convalescence often presents a problem Many patients complain of weakness and experience dyspnea on moderate exertion Careful *evaluation is necessary to determine* whether these symptoms are the consequence of extensive myocardial infarction and congestive heart failure if so, limitation of physical exertion must be continued and treatment designed to improve the cardiac and circulatory status On the other hand, these symptoms are often the consequence of inactivity poor muscular tone and other related disturbances which go under the heading of lack of training Under these circumstances fatigability weakness and dyspnea on exertion may be best managed by graduated exercises and the gradual resumption of muscular activity At least a fair trial should be made to determine whether the response to such a graduated regimen is favorable or not Sometimes fear and anxiety associated with the knowledge of having suffered a heart attack leads to an almost neurotic timidity of any physical effort The need for reassurance and explanatory discussions is obvious

An increasing number of patients have come to my attention with complaints of weakness and disability which are attributed to persistent residuals of acute myocardial infarction, but which are found to be manifestations of a reactive depression Despite some risk in the procedure, electric narcosis therapy has been administered to many such patients with excellent results Others have benefited from the use of reserpine and/or chlorpromazine (Thorazine) in large doses

About one third of the patients are well enough to return to their previous work and engage in all their normal activities Although "moderation in all things" should be recommended, no long list of restrictions is justified [74] There is no objection to climbing a flight or two of stairs if this can be done without distress i e, if there is no angina pectoris or heart failure Sexual relations may be resumed if there are no distressing symptoms Nitroglycerin may be taken prophylactically if sexual activity results in angina pectoris Walking golf fishing riding and swimming are permissible in the absence of heart failure and angina pectoris Similarly air travel is permissible but above 8000 feet flying must be done in properly pressurized cabins [illegible] Flying should be avoided if heart failure is *present and for at least two months after an* acute myocardial infarction I uniformly recommend that smoking be discontinued

Economic as well as medical considerations *often dictate the extent to which the patient* can modify his type of work, the conditions and hours of his employment, periods of rest and vacations In some instances through the *effort of individuals in others through* the work of various local heart associations the cooperation of employers has been enlisted in finding suitable work for patients who have suffered an acute cardiac infarct These activities should be broadened and extended In many cities there are now *cardiac work classification units* in which a coordinated effort by cardiologist, psychiatrist social worker and other professional workers serves to determine the patient's capacity for work to help in his rehabilitation and to aid in finding suitable employment [illegible, 36a]

Self-employed business and professional men should be persuaded to obtain an assistant or to delegate more and more of the less

important and especially the more strenuous and time consuming duties to other associates. The objective should be the elimination of severe physical exertions of prolonged hours of work of emotional tensions of excessive duties of the pressure of dead lines or of work which does not permit reasonable and regular hours for meals relaxation and vacations

For those patients who are compelled or prefer to retire completely from work some program should be formulated to avoid ennui if not actual depression The resumption of an old hobby or the development of a new one is particularly desirable This often provides a test for the physician s initiative ingenuity persuasiveness and enthusiasm Television and the movies are often sought to fill the days and evenings Considerable discretion and censorship may be necessary to choose programs which amuse and relax and do not bore or excite Card playing may be a pleasurable form of diversion but in general play for stakes of any kind should be prohibited Patients who become too excited even when no stakes are involved should not play at all

PART V

STRUCTURAL ABNORMALITIES OF THE HEART

Chapter 22

ACUTE PERICARDITIS

Pericarditis is an inflammation of the enveloping membranes of the heart, i.e., the visceral or parietal pericardium or both. It is almost always a part of, secondary to, or a complication of some other disease. It may be the result of a bacterial infection or a manifestation of some general disease such as rheumatic fever. Pericarditis may represent the sole cardiac lesion or it may develop in combination with myocarditis, endocarditis or both. Diagnostically, the term pericarditis is itself incomplete; whenever possible the etiologic agent or disease should be determined and expressed.

The *incidence of pericarditis* of all types based on necropsies has been given as between 4 and 12 per cent[11] and that of acute pericarditis between 3 and 7 per cent[10] of all autopsies. The incidence of pericarditis as determined clinically is much lower for some cases produce no significant symptoms and a great many with symptoms are undiagnosed.

CLASSIFICATION AND ETIOLOGY

Pericarditis may be classified etiologically according to the causative bacterial agent when known, or according to the disease of which it is a part or a complication. The following etiologic varieties of pericarditis have been noted:

1. Rheumatic pericarditis
2. Uremic pericarditis
3. Bacterial pericarditis (pneumococcus, streptococcus, staphylococcus, etc.)
4. Tuberculous pericarditis
5. Acute nonspecific pericarditis
6. Pericarditis secondary to myocardial infarction. Pericarditis in periarteritis nodosa
7. Pericarditis due to malignant neoplasm
8. Traumatic (usually bacterial) pericarditis
9. Pericarditis following mitral commissurotomy
10. Pericarditis of Libman-Sacks disease (lupus erythematosus)
11. Syphilitic (gummatous) pericarditis
12. Actinomycotic pericarditis
13. Pericarditis associated with parasitic disease, especially echinococcus and cysticercus
14. Other forms. Goldman and Lau[41] reported 2 cases of acute pericarditis in association with serum sickness following tetanus antitoxin.

The records of 96 cases of acute pericarditis diagnosed in a general hospital in 16 years[41] showed that rheumatic fever was responsible for 40.6 per cent, bacterial infection for 19.8 per cent, tuberculosis for 7.3 per cent, benign non specific pericarditis was present in 10.4 per cent, uremia in 11.5 per cent, neoplasm in 3.1 per cent and so-called "collagen disease" in 2.1 per cent. Males predominate over females in cases of acute pericarditis.

PATHOLOGY

Pericarditis has been classified pathologically according to the type of pericardial reaction and exudate. The following are the most common forms: fibrinous pericarditis, serofibrinous pericarditis, hemorrhagic pericarditis, purulent or suppurative pericarditis and adhesive pericarditis. Combinations of the above are not infrequent. Pericarditis has been classified also into certain clinical pathologic groups usually: (1) acute fibrinous pericarditis, (2) pericarditis with effusion, (3) chronic adhesive pericarditis, (4) constrictive pericarditis.

Hemorrhagic pericarditis is a variant of serofibrinous pericarditis in which the effusion contains sufficient blood to give it a grossly hemorrhagic appearance. It occurs

most commonly in neoplastic, lymphomatous and tuberculous pericarditis but may occur in other chronic types Hemorrhagic pericarditis is to be distinguished from hemopericardium (p 604)

Chylopericardium is characterized by a milky pericardial effusion due to obstruction of the thoracic duct by neoplasm[118] or as a result of trauma[3]

Cholesterol pericarditis in which the effusion is rich in cholesterol has been reported[89] In Alexander's case the fluid had the appearance of gold paint Cholesterol pericarditis is usually associated with myxedema, but may occur with hemopericardium or tuberculous pericarditis A case of chronic constrictive cholesterol pericarditis was successfully treated by pericardiectomy

CLINICAL FEATURES

SUBJECTIVE SYMPTOMS

There are three groups of symptoms (1) pain or precordial distress (2) dyspnea and other symptoms resulting from compression of the heart and adjacent thoracic structures and (3) general symptoms due to the pericardial inflammation or to the general disease of which the pericarditis is a part

1 Pain

Precordial pain has long been considered a characteristic symptom of acute pericarditis, but it is probably absent as often as it is present When pain occurs it may be sharp and severe or dull and vague It is usually situated over the precordium but it may radiate to the left shoulder neck and arm to the epigastrium and to the left scapular region and thus simulate the pain of coronary occlusion When the pain is exclusively abdominal, an acute abdominal complication may be erroneously diagnosed the thoracic origin of the pain being entirely overlooked The pain is often intensified by deep inspiration by movement of the chest wall and by cough observations which suggest a relationship to involvement of the costal or diaphragmatic pleura

The *pathogenesis of pain in pericarditis* has been greatly clarified by Sutton and Lueth[85] Capps[19] and others[2] The visceral pericardium is entirely insensitive to pain Pain fibers from the phrenic nerve present only in the lower part of the parietal pericardium may account for pain referred to the left side of the neck The following mechanisms appear to be concerned in the pain associated with pericarditis[19]

(a) Pericardial effusion may produce a dull oppressive pain (protopathic pain) by distention of the entire pericardial sac and therefore of the pain sensitive lower parietal pericardium

(b) An associated (contiguous) pleuritis of the diaphragmatic costal or mediastinal pleura and not the pericarditis, occasions the pain This accounts for the occurrence of sharp pain and for pain with distant radiations outside of the neck

(c) Myocardial ischemia and not an associated pericarditis accounts for pain in cases of coronary thrombosis with myocardial infarction

2 Dyspnea and Other Compression Symptoms

Dyspnea is an early, frequent and usually the most prominent symptom in cases of pericarditis with effusion Objective manifestations are a rapid respiratory rate, shallow and forced respirations and the extreme orthopneic position assumed by the patient

The pathogenesis of the dyspnea is uncertain It is likely that the dyspnea results at least to some extent from actual mechanical compression of the bronchi or lungs and in cases of huge effusions, from the diminished vital capacity caused by encroachment on the available thoracic space This mechanical explanation of dyspnea is consistent with the observation that patients with pericardial effusions are somewhat or moderately relieved by leaning far forward (in contrast to those with pulmonary congestion who merely elevate the head and shoulders) so that the effusion is shifted down from the base of the heart and anteriorly against the chest wall

Occasionally other symptoms besides dyspnea are produced by compression of the trachea bronchi, lungs, and esophagus There may be a dry hacking cough, hoarseness or dysphagia These symptoms are most likely to occur in cases with very large effusions such as are encountered most often with tuberculous pericarditis

3 General Symptoms

General symptoms may be due to the pericardial infection or inflammation as such or to the general disease with which the pericarditis is associated *Fever*, sweating chills, fatigability or weakness loss of weight anxiety de-

pression or delirium may be present, according to the etiology of the pericarditis

OBJECTIVE SIGNS

The objective evidences of acute and subacute pericarditis are (a) changes in physical signs in the chest due to inflammation of the pericardium and the presence of an effusion (b) manifestations of altered circulatory dynamics due to cardiac tamponade or compression caused by elevated intrapericardial pressure and (c) general manifestations of the pericardial inflammation and the associated disease

Physical Signs in the Chest

1 **Pericardial (Friction) Rub** This is a superficial, scraping scratchy or grating sound or occasionally one with a coarse leathery quality There are usually to and fro sounds which phonocardiograms disclose are due to vibrations set up during ventricular and atrial systole and occasionally also during the phase of rapid ventricular filling early in diastole [25]

The pericardial rub is usually heard in the pulmonic area or just to the left of the lower sternum fairly well localized to a small area Its location may shift with a change in the patient's position It is best heard if the patient leans forward and moderate pressure is made on the chest wall with the bell of the stethoscope The pericardial rub is often very evanescent, it may be audible for a few hours at a time and intermittently for a few days, occasionally it persists for weeks or even months Persistent rubs are heard most commonly in pericarditis due to neoplasm but also in uremia, benign pericarditis and occasionally in tuberculous pericarditis

A pericardial rub is usually associated with a dry fibrinous pericarditis However as recognized long ago by Stokes [87] a pericardial rub is often heard also in the presence of a pericardial effusion Conner[23] noted a friction rub in 24 out of 34 cases of pericarditis with effusion While a pericardial rub is a sign of either an acute fibrinous pericarditis or a pericarditis with effusion the following signs are elicited only in the presence of a significant effusion

2 **Increased Width of Cardiac Dullness at the Base of the Heart** The left border of cardiac dullness in the second and third left interspace is significantly shifted to the left This results in a widened area of dullness at these levels especially with the patient in the recumbent position This area of dullness becomes definitely narrower if the patient sits up since the effusion settles lower because of gravity [73]

3 **Generalized Increase in Cardiac Dullness** When there is a considerable pericardial effusion percussion reveals a generalized enlargement of the area of cardiac flatness which assumes a globular shape if the patient is recumbent There may be a characteristic rapid increase or decrease in the area of flatness during the course of the disease There is a sharp transition along the left border from pulmonary resonance to cardiac flatness without the intermediary of relative cardiac dullness

4 **Ewart's or Pins Sign** In cases with large pericardial effusions, there is often a patch of dullness below the angle of the left scapula occasionally extending one third or more of the way over the left lower posterior chest wall Over this dull area there is bronchial breathing and usually also bronchophony or egophony Râles are usually absent although occasionally a few scattered moist rales may be heard While these signs were observed earlier, their significance was stressed first by Pins,[77] the Viennese, and later by Ewart [32] whose name is now attached to this sign in English speaking countries Ewart's sign is due to compression of the base of the left lung by the pericardial effusion which extends posteriorly This explanation has been disputed but in my opinion remains the most plausible

5 **Other Physical Signs** The cardiac impulse is often weak and wavy or may disappear entirely Similarly the heart sounds are usually muffled and distant especially when the patient is recumbent However, I have several times felt a strong apical impulse and heard loud heart sounds in the presence of significant pericardial effusions

There may be a distinct increase in cardiac dullness to the right of the sternum in the fifth intercostal space (Rotch's sign) [85] But percussion is often unreliable in this area and the dullness may be obscured by compensatory emphysema

Cardiac Tamponade

The term cardiac tamponade or acute cardiac compression denotes an interference with the diastolic filling of the heart and with cardiac contraction due to an increase in intrapericardial pressure This occurs in many

cases of pericarditis with effusion, as well as in cases of acute hemopericardium[114]

Hemodynamics of Cardiac Tamponade The following hemodynamic changes in cardiac tamponade have been observed experimentally[94] following the injection of fluids under pressure into the pericardium of dogs,[3, 70] and in clinical studies of human cases of pericardial effusion[111] and hemopericardium[111]

(1) There is a progressive rise in the right intra atrial and venous pressure and in the right ventricular diastolic pressure as the pressure within the pericardium rises (2) There is a reduction in the stroke output and later in the cardiac output per minute as well (3) The cardiac rate increases (4) The arm to tongue circulation time is prolonged (5) The vital capacity diminishes (6) There is a late fall in blood pressure especially in the systolic pressure Since the right ventricular diastolic pressure rises whereas the right ventricular systolic pressure is unchanged or falls slightly, the right ventricular pulse pressure falls

The stroke output diminishes because the elevated pericardial pressure compresses the right atrium and interferes with the venous inflow from the great veins Studies by means of ventricular function curves have disclosed that the major circulatory defect in acute cardiac tamponade is a restriction in diastolic expansion of the ventricles by the pericardial effusion The rise in venous pressure helps to maintain filling but the concomitant rise in atrial pressure diminishes the effective filling pressure difference The rise in venous pressure is a measure of the disparity between the venous return and the ability of the heart to accept and expel that return Venous infusions may increase the venous and right atrial pressure and thereby restore the normal cardiac output or increase it[24, 35]

A normal cardiac output is temporarily maintained by a compensatory tachycardia, probably effected by the elevated venous and right atrial pressure through the Bainbridge reflex The blood pressure is at first maintained by peripheral vasoconstriction But at a critical level of intrapericardial pressure (100 to 150 mm saline) there is a sharp fall in stroke and cardiac output and the blood pressure falls The pulse pressure diminishes because of a greater reduction in the systolic pressure If the intrapericardial pressure is reduced by paracentesis these circulatory abnormalities are reverted more or less toward normal

In clinical pericarditis with effusion, as in the experimental form, the development of cardiac tamponade depends on the rise in intrapericardial pressure, the latter is determined by the quantity of the effusion and its speed of formation A very acute effusion of 150 to 250 cc (in hemopericardium or suppurative pericarditis) can cause tamponade, while slowly developing effusions of a liter or more (tuberculous effusions) may be tolerated if the pericardium is given time to distend and the pressure is only slightly elevated

Clinical Manifestations of Cardiac Tamponade

1 An *acute compression triad* has been stressed by Beck[9] and consists of a rising venous pressure, a falling arterial pressure and a small quiet heart The latter is best observed by fluoroscopy Tachycardia is also a prominent manifestation If the cardiac output is greatly reduced, there is a fall in blood pressure and a clinical picture of shock In cardiac tamponade associated with rapidly formed but relatively small effusions the physical signs of (large) pericardial effusion described above are absent

2 *Systemic venous congestion* occurs with subacute or chronic tamponade due to effusions which develop more slowly In these cases a compensatory increase in circulating blood volume may tend to maintain the cardiac output, but later causes systemic congestion *Engorgement of the cervical veins increased venous pressure* and *enlargement of the liver* are the usual manifestations Compression of the venae cavae may result in increasing cyanosis of the lips face and neck and occasional facial edema If the cardiac output falls sharply during the stage of venous congestion, the clinical picture of shock may be added to that of congestive heart failure

3 *Paradoxical pulse*[89] is an almost constant manifestation of cardiac tamponade There is a *distinct* diminution in pulse amplitude during inspiration This may be revealed more clearly by a fall in blood pressure of 10 to 20 mm Hg or more at the end of inspiration

In the normal person there is a tendency to paradoxical pulse, because the slightly increased venous return during inspiration is more than outweighed by the greater volume of blood accommodated in the chest There-

fore, at full inspiration the cardiac stroke output from the left ventricle and consequently the pulse and blood pressure are diminished In cases of pericardial effusion or other causes of cardiac compression this phenomenon is intensified as follows The increased venous return during inspiration cannot be translated into an increased cardiac output because of the pericardial obstruction to inflow On the other hand, the increased pulmonary vascular capacity during inspiration diminishes the venous return to the left heart The combination of impaired venous inflow and the enhanced pulmonary capacity and retention of blood during inspiration cause the reduction in left ventricular output and in size of the pulse (paradoxical pulse) A pulsus paradoxicus may also be observed in cases of tracheal obstruction and other conditions associated with exaggerated respiratory excursions and therefore with an abnormal increase in pulmonary vascular capacity during inspiration Other explanations have been offered by Wenckebach[11] and by Gauchat and Katz[40]

Inspiratory swelling of the cervical veins commonly accompanies pulsus paradoxicus in cases of pericardial effusion (and constrictive pericarditis) but is absent when the pulsus paradoxicus is due to laryngeal stenosis etc The cervical veins swell because the increased venous return during inspiration cannot be handled by the compressed right atrium with its high intra atrial pressure Normally the increased venous return is adequately received and ejected without permitting a rise in venous pressure or venous distention

General Signs

Fever, sweating weakness and loss of weight have already been mentioned A polymorphonuclear leukocytosis is usually present its severity in proportion to the height of the fever In cases of tuberculous pericarditis however there is usually a relative leukopenia or normal white blood count, even with moderate fever Very marked leukocytosis and polynucleosis suggests a bacterial suppurative pericarditis In rheumatic pericarditis pallor and anemia are often prominent features

The *general appearance* of the patient with pericardial effusion is noteworthy He is anxious suffering restless cyanotic or pale and assumes a characteristic posture Usually he sits up completely and leans far forward Rarely the patient assumes the knee chest position (signe de la prière Mahométane), this is observed also in occasional cases of mediastinal neoplasms or lymphomata

ROENTGENOLOGY

Roentgenologic examination may suggest or confirm the presence of a pericardial effusion[1] Its value is greatly increased if serial films are taken at brief intervals and if the patient is examined in both the recumbent and upright (or sitting) positions Roentgenologic abnormalities, like the abnormalities in physical signs depend essentially on the size and distribution of the effusion and not on the intrapericardial pressure It is doubtful whether effusions of less than 250 cc in adults produce a significant effect on the cardiopericardial silhouette But in infants and children 150 cc or less may suffice to alter the shadow The following are the most valuable roentgenologic signs (Fig 115)

1 The well-demarcated normal outlines of the individual cardiac chambers and great vessels are obliterated, resulting in a smoothing of the cardiac borders with loss of the angular curves In particular, the waist of the silhouette on the left border (pulmonary arterial segment) is filled out to give a straight or slightly convex left cardiac outline A pear shaped or water bottle type of silhouette results

2 The vascular supracardiac shadow becomes shortened and somewhat widened due to the filling of the superior recess in front of the great vessels by fluid Widening is due also to engorgement of the superior vena cava

3 The posterior inferior recess (as viewed in the right anterior oblique or lateral view) is normally demarcated by a straight line or one that is slightly concave posteriorly When an effusion forms the fluid encroaches early on the clear space in this recess and the straight or concave line becomes a bulge which is convex posteriorly[78]

4 There may be a diminution or almost complete absence of visible pulsations of the heart A wavy undulation may replace the alternating contraction and relaxation The diminution or absence of pulsation may be more clearly demonstrated by roentgen kymography or electrokymography

5 *Serial roentgenograms may reveal rapid changes in the si e of the silhouette corresponding*

to a speedy increase or resorption of the effusion (Fig 115) According to Besterman and Thomas[1] a sudden increase in the cardiothoracic ratio and straightening of the left border were the most consistent and earliest signs of pericardial effusion

6 Induction of pneumopericardium following aspiration of the pericardium is helpful in distinguishing pericardial from pleural effusion as well as in revealing the size of the cardiac shadow[34] (Fig 115) Sacculated effusions may occur chiefly in suppurative rheumatic or chronic pericarditis and localize in regions where cardiac motion is least active, e g, near the great vessels or along the lower right border These sacculated collections of fluid may produce a localized bulge usually on the right cardiac contour, and must be differentiated from aneurysm of the aorta or sinus of Valsalva, a pericardial diverticulum, pleural or mediastinal effusions, or benign pericardial tumors Pericardial effusion may be differentiated from cardiac enlargement by the disappearance in the former of the intersections between vascular, cardiac and diaphragmatic contours on the right and the atrioventricular contour on the left, by absence of the changes in size and shape of the silhouette during the Valsalva and Muller maneuver which persist with cardiac enlargement and by disappearance of the bronchial bifurcation[4]

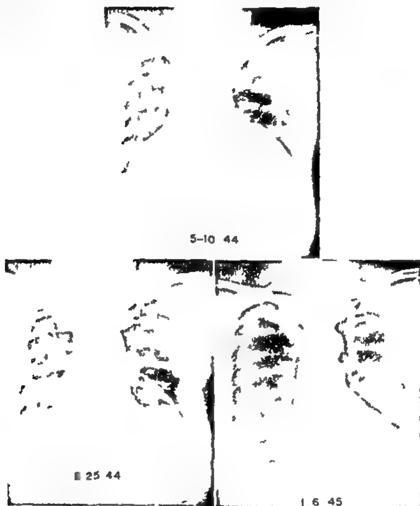

Fig 115 Pericarditis with effusion Upper before paracentesis Lower left after paracentesis with air injected into pericardial space Lower right after recovery seven and a half months later

7 Angiocardiography reveals a characteristic shadow due to fluid surrounding the opacified cardiac chambers[115 61]

THE ELECTROCARDIOGRAM

Distinctive electrocardiographic abnormalities were observed by Winternitz and Langendorf[116] in 46 (61 per cent) of 76 cases and

by Bellet and McMillan[10] in 80 per cent of 57 cases Similarities to the changes in myocardial infarction may indicate that the electrocardiographic abnormalities of acute pericarditis are actually due to associated subepicardial myocardial lesions [106, 111]

The various electrocardiographic changes occurring in cases of acute pericarditis include the following [55, 114, 111, 101]

1 RS T Changes

The most consistent and significant electrocardiographic alteration in acute pericarditis is an elevation of the RS T segment in all three standard leads in leads I and II in leads II and III or in lead I If the RS T segment is elevated in leads I and II or lead I alone it is not depressed in lead III if it is elevated in leads II and III it is not depressed in lead I (Fig 116) Thus the reciprocal elevation and depression of the RS T segment in leads I and III which are characteristic of myocardial infarction are not found in acute pericarditis

The RS T segment differs from that seen in myocardial infarction in that it runs obliquely upward in a straight line or with an upward concavity to a positive T wave In cases of myocardial infarction with RT elevation this segment shows an upward convexity However in later stages of acute pericarditis when the T wave becomes negative the RS T segment may show an upward convexity as with acute myocardial infarction

Since the elevation of the RS T interval may last as briefly as three days and rarely more than three weeks, this abnormality is usually not observed later in the course of the disease Harvey and Whitehill[16] and others failed to note an elevation of the RS T segment in their cases of tuberculous pericarditis which were usually seen more than a month after the onset of symptoms But in two cases of tuberculous pericarditis seen by Holzmann[61] in the first eight days of the disease and in a third seen on the fourteenth day there were elevations of the RT segment in two leads Similar changes were observed by Bellet and McMillan[10] in 2 out of 20 cases

In precordial leads also there may be an elevation of the RT segment or inversion of T waves [10, 107]

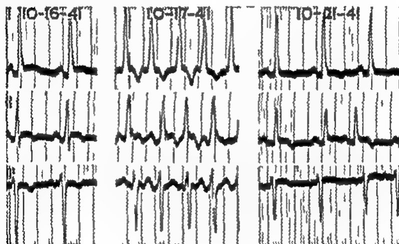

Fig 116 Acute and subacute pericarditis in bacterial endocarditis Progressive changes RT elevations in leads I and II followed by T wave inversions

2 T Wave Changes

The T wave undergoes progressive flattening as the RS T segment returns to the isoelectric line (Fig 116) The upward concavity of the ST segment disappears During this stage Winternitz and Langendorf[114] have also noted a double T wave, a delayed T wave and a linear oblique drop from the R to the T wave

Several weeks after the onset of the pericarditis the T wave becomes inverted Diagnostically an inversion in all three of the standard leads is most significant More often the T waves are inverted in leads I and II or in leads II and III At this stage the ST segment may be curved convexly upward and lead into a sharply inverted T wave resembling the cove-plane coronary T wave of myocardial infarction (p 525)

The inversions of the T wave persist longer than the RS T changes but they usually revert to normal within two to three months In chronic cases of tuberculous pericarditis, inverted T waves may persist throughout the course of the disease

3 Diminution in QRS Voltage

A diminution in the voltage of the QRS complex was noted as a sign of pericardial effusion by Oppenheimer and Mann,[74] who suggested that it was due to short circuiting of the electrical impulses of the heart by the surrounding fluids Low voltages of the QRS and T waves are in themselves insufficient evidence of myocardial or pericardial disease Low voltage of the QRS complex as well as negativity of the T wave is especially frequent in cases of tuberculous pericarditis This electrocardiographic abnormality cannot be well correlated with the size of the pericardial effusion for Harvey and Whitehill[66] noted that following aspiration of a tuberculous effusion the voltage of the QRS complex diminished almost as often as it increased

The duration of the Q T interval is not prolonged as it is in most cases of congestive heart failure, a distinction of limited diagnostic value[104] McGregor and Baskind[64] presented evidence that simultaneous alternation of atrial and ventricular complexes (electrical alternans) is frequently associated with pericardial effusion

Differences in Electrocardiograms of Pericarditis and Myocardial Infarction

The following are the chief distinctions (1) The RS T elevation in pericarditis occurs without the reciprocal RS-T depression in leads I or III seen in myocardial infarction (2) The T wave in pericarditis may be inverted in all three standard leads, this is rare with myocardial infarction unless both aspects of the heart are involved (3) The positive initial deflection in chest leads is rarely absent with pericarditis often absent with acute myocardial infarction (4) Q waves are rarely significant in the standard leads of cases with acute pericarditis, a deep Q_1 or Q_3 commonly accompanies a negative T in the same lead in cases of acute myocardial infarction In combined anterior and posterior infarction there may be an elevation of the RS T segment or an inversion of the T-waves in all standard leads as in acute pericarditis but there is often also a deep Q_1 or Q_3 and the positive initial deflection in the chest lead is usually absent

When pericarditis complicates myocardial infarction, there may be an early elevation of the RS T segments in the standard leads indicative of the pericarditis followed by the characteristic pericardial inversion of the T waves, but often disappearance of the RS T elevation is succeeded by the typical deep Q_1 and negative T_1 or deep Q_3 and negative T_3 of myocardial infarction (see p 525)

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

To diagnose acute pericarditis one must be aware of the possibility of this complication in those conditions which are most often associated with it Precordial pain and fever, unexplained dyspnea and tachycardia, evidence of systemic venous congestion without apparent heart disease, should suggest a search for acute pericarditis A pericardial rub, characteristic water bottle enlargement of the heart, Ewart's sign, a paradoxical pulse, extreme diminution of cardiac pulsations and the characteristic electrocardiographic changes are the most important diagnostic features Aspiration of the pericardial sac may serve both to confirm the diagnosis of pericarditis and to determine the etiologic type Stained smears and cultures of the aspirated fluid should be made and some of the fluid may have to be inoculated in guinea pigs if tuberculosis is suspected Pericardiotomy has been performed to permit direct inspection of the peritoneal sac to remove and examine pericardial fluid by smear and culture and to obtain pericardial biopsies[71b]

Diagnostic difficulty may occasionally arise in distinguishing acute pericarditis from cardiac enlargement of undetermined origin, congestive heart failure, pleuropulmonary disease, pulmonary embolism dissecting aneurysm valvular heart disease when the rub is confused with a murmur myocardial infarction because of precordial pain and somewhat similar electrocardiographic changes, from acute abdominal complications when the pain radiates to the abdomen and from aneurysm or tumor when there is a sacculated effusion Angiocardiography is helpful in distinguishing some of these conditions The circulation time is normal in cases of large pericardial effusion prolonged in cases of cardiac enlargement and heart failure[11] This difference may be used in differential diagnosi

COURSE AND PROGNOSIS

The course and prognosis of acute pericarditis are determined usually by the disease of which it is a complication e g rheumatic fever uremia Suppurative and tuberculous pericarditis usually have a progressive course and fatal outcome but these may be favorably altered by antibiotic and surgical therapy This is discussed further under purulent pericarditis (p 601) and tuberculous pericarditis (p 602)

TREATMENT

As a rule treatment is directed toward the underlying disease and not the pericarditis per se Occasionally the pain of pericarditis is severe enough to require meperidine (Demerol) or morphine for relief during the very acute phase In cases of rheumatic pericarditis full doses of salicylates usually relieve the pain and hasten the resorption of the pericardial fluid (p 851) In benign pericarditis and rheumatic pericarditis adrenocortical hormones appear preferable to salicylates (p 852) The sulfonamides and antibiotics are indicated in the treatment of pyogenic bacterial pericarditis Occasionally recovery is attributed to such drugs alone administered intrapericardially as well as intramuscularly or intravenously But often surgical drainage of the pericardium must be performed (infra) Recovery from acute tuberculous pericarditis may follow streptomycin and isoniazid therapy When the pressing need is to relieve cardiac tamponade pericardial aspiration should be performed and repeated if necessary In cases of recurrent pericardial effusion with cardiac tamponade cure was effected by creating a foramen between the pericardial and left pleural cavities[illegible] The fluid draining into the pleural cavity was readily reabsorbed Pericardial effusion due to malignant neoplasm or lymphoma may be controlled by the instillation of radioactive gold into the pericardial sac[illegible]

PERICARDIAL ASPIRATION

Indications

Aspiration of the pericardium is performed (a) to confirm the diagnosis of pericardial effusion (b) to determine the etiologic agent or (c) to relieve symptoms of cardiac compression

In rheumatic pericarditis pericardial aspiration may be necessary if there is extreme dyspnea and the effect of medication is not rapid enough I have had to remove as much as 1200 cc at one time but usually the removal of 200 to 400 cc provides relief If the diagnosis of suppurative pericarditis is reasonably certain it may be preferable to institute prompt surgical drainage without previous aspiration But the latter may be necessary to relieve acute cardiac tamponade or to prove the diagnosis In cases of tuberculous pericarditis aspirations may be performed for treatment as well as for diagnosis

Site of Pericardial Aspiration

The following are the sites most commonly entered for pericardial aspiration Roentgenograms should be available to aid in determining the most favorable site

1 The fifth left intercostal space about 2 cm inside the left border of percussion dullness is the site most commonly used If there is a distinct apical impulse the needle may be introduced 1 or 2 cm lateral to the impulse

2 The angle between the xiphoid process and the left costal arch is the site recommended when there is a large effusion and the lower portion of the pericardial sac is to be drained It is often used for aspirating suspected purulent effusions because in this region the lung does not cover the heart

3 The right fourth intercostal space 1 cm medial to the right border of cardiac dullness is the site used when most of the pericardial effusion seems to be sacculated on the right side I have had more than a liter of fluid removed through this site in a patient with rheumatic pericarditis after only a few cubic centimeters could be obtained by the first mentioned approach

4 The seventh or eighth left intercostal space posteriorly in the midscapular line the left arm of the patient being elevated to remove the scapula is the site employed when there are evidences of a large effusion with pulmonary compression (Ewart's sign) and fluid cannot be obtained readily elsewhere This site of aspiration has been especially recommended by Conner[33] and by Sutton[illegible] It should not be used in cases of suspected purulent pericarditis because of the danger of infecting the pleura

Technique of Pericardial Aspiration

Pericardial aspiration is performed with precautions as to surgical asepsis The exact

site of insertion of the needle and the subcutaneous tissue are anesthetized with 2 per cent procaine solution A 3 inch aspirating needle of 18 to 16 gauge with short bevel, connected directly or through a connecting piece of tubing to a 20 or 30 cc syringe is inserted through the anesthetized area between the ribs until it is felt to penetrate the resistant pericardial membrane Usually this occurs at a depth of 3 to 5 cm If the posterior site is chosen, a 4 inch needle should be used as the pericardium may be penetrated at a depth of 5 to 8 cm from the skin surface If the effusion is thick a trocar may have to be substituted for the needle in order to avoid blocking the lumen

When the needle is inserted into the left fifth intercostal space it is directed inward and backward toward the spine, when inserted in the left xiphoid costal angle, it is directed backward, upward and slightly inward when inserted in the right fourth intercostal space the needle is directed backward and medially toward the spine, when inserted posteriorly the needle is directed forward and somewhat medially

Gentle suction is made by withdrawing the barrel of the syringe If a free flow of fluid is not obtained, the needle should be tilted carefully in various directions, withdrawn slightly, or carefully inserted somewhat more deeply If no fluid is obtained despite these maneuvers and there is reasonable certainty as to the existence of a pericardial effusion the needle should be inserted in one of the other sites mentioned Sometimes a two-way or three-way stopcock is placed between the aspirating needle and syringe so that no air will enter the pericardium and the fluid may be discharged into a container without disconnecting the syringe If large quantities of fluid are to be removed, the needle may be connected by tubing to a bottle containing a partial vacuum as in performing a thoracentesis for pleural effusion

Occasionally the needle is felt to come in contact with the heart There is little danger from perforation of the ventricular wall, but the needle should be withdrawn slightly if cardiac pulsation is felt Rarely one may cause a hemopericardium by cutting a coronary artery or perforating the thin walled atrium Other dangers of pericardial aspiration include injury of the internal mammary artery and the infection of pleura or peritoneum in cases of purulent pericarditis

SURGICAL DRAINAGE

If the diagnosis of purulent pericarditis is fairly certain, or has been proved by pericardial aspiration, adequate drainage should be obtained by surgical incision Appropriate sulfonamide and antibiotic therapy should be given

Numerous surgical approaches have been suggested including a trans sternal, right or left parasternal, chondroxiphoid, or a combination of trans sternal and left parasternal Often, exposure of the pericardium is effected in the region along the left side of the lower sternum where the pericardium is not covered by lung This is known as the interpleural space or triangle of safety After the superficial tissues are reflected the fifth sixth and if necessary the seventh left costal cartilages are resected and sometimes also a portion of the adjacent sternum[90] Bigger[13] resected the fourth and fifth left costal cartilage and Bunch,[18] the sixth In general the site of exposure should be as low as possible in early cases Ross[85] prefers a chondroxiphoid approach, i e, through the angle between the xiphoid process and left costal margin He splits the rectus muscle to reach the pericardium from below in order to obtain dependent drainage from the oblique pericardial sinus posterior to the heart In late cases of pericarditis especially with large effusions, a posterolateral approach is utilized[103] because of the accumulation of fluid in the posterior recesses behind the heart The seventh rib is resected near the midaxillary line Because of adhesion of the pericardium to the pleura in the cases reported, it was possible to perform a pericardiotomy without producing a pyopneumothorax

Drainage may be maintained with the aid of rubber tubes or tissue, extending down to but not into the pericardial cavity Irrigation with warm normal saline is employed if drainage is unsatisfactory or if the patient fails to do well Two drainage tubes should be inserted if irrigation is employed so that one of the tubes may permit egress of the fluid injected through the other Otherwise the injected fluid may be trapped and may cause cardiac tamponade Some surgeons suture the

opened pericardium to the soft parts and do not use rubber or other drains

After drainage has been established it is important to look for and drain purulent foci elsewhere (especially empyema or osteomyelitis) The persistence of fever even after pericardiotomy should always suggest the possibility of empyema an undrained sacculation of pericardial fluid or a suppurative focus elsewhere

INDIVIDUAL FORMS OF PERICARDITIS

RHEUMATIC PERICARDITIS

This is probably the most common type of pericarditis and is part of a rheumatic pancarditis [101] Its clinical features are discussed in the chapters on rheumatic fever

UREMIC PERICARDITIS

This occurs in the end stages of renal insufficiency as noted by Bright[17] and emphasized by Taylor [104] Pathologic studies reveal a pericarditis in 8 to 45 per cent of cases of nephritis [6, 8, 11] In the presence of uremia regardless of etiology pericarditis probably occurs in more than 50 per cent of cases Wacker and Merrill[108] reported that a pericardial rub was heard in 18 per cent of 77 cases of acute renal failure whereas 22 of 43 patients with chronic renal failure had clinical and pathologic evidence of pericarditis

The pericarditis is usually of the dry fibrinous type but there may be a sterile serofibrinous or hemorrhagic effusion [7, 8] Not infrequently there is a terminal secondary bacterial infection The development of uremic pericarditis has been related to metabolic chemical alterations in the blood Healing and the formation of fibrous adherent pericarditis occur in those patients who survive several weeks after onset of the pericarditis

The pericarditis is asymptomatic and its diagnosis is made by discovering a pericardial rub which is occasionally heard in the left interscapular region [1] as well as in its more common precordial location Death usually occurs within one to three weeks after onset of the pericarditis[3] but survival for months is not as uncommon as is generally believed [8, 66] Remissions and recurrences of uremic pericarditis have been noted [66] Six out of 14 patients with pericarditis due to acute renal failure survived [108]

BACTERIAL (PURULENT) PERICARDITIS

This was one of the commonest forms of pericarditis [89, 93] but is encountered less frequently since antibiotics have become widely used The causative organisms are usually the staphylococci the pneumococci and hemolytic streptococci but a variety of other microorganisms are occasionally responsible including the meningococcus [75] Hemophilus influenzae[117] and P tularensis [96] In one case of tularemic pericarditis constrictive pericarditis developed [93]

A purulent pericarditis arises (a) by direct extension of an intrathoracic infection (b) by hematogenous bacterial dissemination (c) by traumatic introduction of bacteria through the chest wall or (d) occasionally by extension or perforation of the diaphragm from a subdiaphragmatic suppurative focus such as a liver abscess [111] Osteomyelitis staphylococcal or streptococcal sepsis pneumococcal or streptococcal empyema especially of the left pleural cavity, are common preceding diseases Bacterial pericarditis may be fibrinous at its onset and then serofibrinous or serohemorrhagic before it becomes purulent

The clinical features of purulent pericarditis are obscured by those of the general or local primary disease Fever leukocytosis and toxemia are common Unexplained dyspnea with or without cyanosis cervical venous engorgement a falling blood pressure and weak rapid pulse are indicative of purulent pericarditis especially in the presence of the usual causative conditions The presence of a pericardial rub is diagnostic Electrocardiographic changes (RT segment elevations) and fluoroscopic evidence of pericardial effusion or of minimal cardiac pulsation are confirmatory

Early and adequate antibiotic therapy of the primary infection prevents the development of a bacterial pericarditis The mortality of practically 100 per cent for medically treated cases of suppurative pericarditis has been reduced to between 25 to 50 per cent by instituting surgical drainage [103, 91] The combination of chemotherapy antibiotics and early surgical drainage (p 600) has further greatly reduced the mortality Recovery depends on simultaneous adequate surgical and medical therapy of other suppurative foci as well as the pericarditis

TUBERCULOUS PERICARDITIS

This occurs in about 1 per cent of all autopsies[58] and in about 5 to 10 per cent of those on tuberculous subjects[49, 81] There is a striking predilection for males and for the aged But it occurs frequently in young adults or children[78] Among 27 patients with tuberculous pericarditis in the Armed Forces, 25 were males 22 were below the age of 30 and 16 (59 per cent) were Negroes, although only 1 per cent of the Armed Forces were Negroes[44]

Pathogenesis

Tuberculous pericarditis arises by contiguous extension of tuberculous lesions of the hilar or mediastinal lymph nodes, or of pleuropulmonary tuberculosis[illegible] There may be direct contact,[55] or infection of the pericardium may result from retrograde lymphatic extension More rarely tuberculous pericarditis results from hematogenous dissemination, but the pericarditis is usually an insignificant element in the generalized miliary tuberculosis Although pathologically tuberculous pericarditis is always secondary to tuberculous lesions elsewhere, clinically it may appear as the sole or primary manifestation[78, 95]

Pathology

The pericarditis starts as an acute fibrinous reaction which is followed by a subacute or subchronic stage of effusion and pericardial thickening The thickening is due to the development of tubercles, caseous masses and connective tissue Even in the chronic stage characterized by fibrosis there may be large persistent collections of serofibrinous or hemorrhagic fluid or occasionally cheesy pus Eventually the pericardial layers become adherent to each other and to the myocardium or neighboring structures and may cause constriction of the heart (p 608) Calcification of the pericardium may appear

Clinical Picture

The clinical picture is often vague and usually overlooked The onset is insidious, with symptoms such as weakness fatigability, loss of weight anorexia and low grade fever[21] *Cough* may be a prominent and early feature but expectoration and hemoptysis are uncommon Precordial pain may or may not be present and is rarely as severe as with rheumatic pericarditis There may be a friction rub in the early stages of the disease This may last from two days to three weeks[85] Fever may be absent but usually it is high and swinging[46]

When an effusion develops, as it almost always does, the patient suffers from *dyspnea* and other evidences of circulatory embarrassment Owing to cardiac compression the cervical veins become engorged, the venous pressure elevated, the liver enlarged and there may be subcutaneous edema and ascites A pronounced tachycardia is common The clinical picture may simulate that of congestive heart failure or chronic constrictive pericarditis[8] In the acute and subacute stages the clinical picture may be that of a chronic wasting disease with unexplained pyrexia There may be physical signs of a pericardial effusion Pleural effusions are commonly associated[illegible, 48] Atrial fibrillation and partial heart block have been noted

Diagnosis

The diagnosis involves recognition of the pericarditis and determination of the tuberculous etiology It should be considered in cases of unexplained fever and/or congestive heart failure, especially in elderly males who present no evidence of cardiac disease The diagnosis of pericarditis may be supported by the presence of a pericardial rub, paradoxical pulse, and roentgenologic signs of pericardial effusion and inverted T waves in the electrocardiogram Early diagnosis has become extremely important since the availability of effective antibiotics

The etiologic diagnosis can be made only by aspirating the pericardial effusion and discovering the organisms in the centrifuged specimen or by determining their presence through inoculation of a guinea pig If a hemorrhagic effusion or one of very large size (over 1000 cc) is obtained, a tuberculous etiology[117] is suggested After aspiration an artificial pneumopericardium may be produced by the injection of air and a small heart demonstrated roentgenographically This and the absence of murmurs and of leukocytosis help to differentiate tuberculous from rheumatic pericarditis with effusion

Prognosis

Formerly the outcome was generally unfavorable death occurring in 50 to 85 per cent within three to six months[illegible, 44, 117] Death usually occurs from cardiac failure or miliary tuberculosis With the introduction of streptomycin and isoniazid treatment of tuberculosis

there has been a brilliant improvement in the rate of recovery [85 ■ 87] Goyette et al reported an over all mortality of 8 per cent, or 15 per cent in the definitely proven cases treated with these antibiotics

Treatment

Rest in bed and general supportive measures are necessary during the acute stage Analgesics or narcotics may have to be administered if pain is severe Repeated aspirations may have to be performed but only when these are necessary for diagnosis or to relieve dyspnea or severe systemic congestion Generally half as much air is replaced as the amount of fluid removed [113] The fundamental and specific therapy consists of the administration of 300 mg of isoniazid daily and 2 gm of streptomycin every third day [44] This is continued for a minimum of 4 months and preferably for 8 to 12 months Or it may be continued for at least 3 months or preferably for 6 months after cessation of all activity [44] Five of the 27 patients studied by Goyette et al [44] developed constrictive pericarditis If constrictive pericarditis develops pericardiectomy (decortication) is performed only after the tuberculous process becomes inactive with the aid of antibiotic therapy [47] However occasionally in such cases it is necessary to operate even during tuberculous activity if the patient s condition grows steadily worse and the venous pressure rises despite the fact that the pericardial cardiac shadow decreases in size [■ ■]

ACUTE BENIGN PERICARDITIS

This is a nonspecific form of acute serofibrinous pericarditis of unknown cause [7 64] It has been attributed to a viral infection or a hypersensitivity reaction without noteworthy evidence It is being recognized with increasing frequency in recent years [20 42 43 43] The disease has been noted chiefly in young adults but has been observed also at all ages from infancy to beyond the age of 60 There is a great predominance of males The pericarditis is commonly preceded by an upper respiratory infection one or two weeks earlier

The onset may be acute or gradual and is characterized by pain in the chest malaise and fever The pain may be localized substernally and radiate widely especially to the neck back and shoulder It is frequently intensified by respiration but also by bodily motion and occasionally by coughing or swallowing Cough and dyspnea occur commonly A pericardial rub is audible in almost every case and usually persists a week or two or occasionally longer A pericardial effusion is usually present and pleural effusion also develops in about one quarter of the cases The pericardial fluid is straw colored or hemorrhagic A moderate leukocytosis is the rule and the erythrocyte sedimentation rate is accelerated Atypical pneumonia may be associated The initial pain and electrocardiographic abnormalities may simulate acute myocardial infarction [64 7 43] Occasionally the electrocardiographic changes persist [20] The disease subsides spontaneously within a few weeks but occasionally produces an adhesive pericarditis The average duration in one large series of cases was 7½ weeks with a range of 2 weeks to 3 months [■] The course is benign but fatal cases have been reported [86 79]

In a follow up of 41 patients for 2 years or longer Carmichael et al [20] obtained a history of more than one attack of pericarditis in 6 and four recurrences in each of 2 patients Recurrent attacks of pericarditis have been reported by others [63 102 43] In one case roentgenologic follow up revealed calcification of the pericardium The large majority of patients were in excellent health

In the differential diagnosis the disease is most frequently to be distinguished from acute myocardial infarction tuberculous pericarditis and rheumatic pericarditis [■ 47] It may simulate acute abdominal disease [79] Pericardial aspiration may be necessary to confirm or exclude the diagnosis of tuberculous pericarditis before embarking on a prolonged program of antibiotic therapy It may also be necessary to relieve cardiac tamponade in cases with large effusions [79]

Despite some favorable reports antibiotics are ineffective in idiopathic pericarditis Adrenocorticotropic hormones usually give a dramatic symptomatic response[87] and should be tried if tuberculosis and other bacterial causes have been excluded

OTHER FORMS

Pericarditis in Acute Myocardial Infarction (p 503 517)

Pericarditis in Periarteritis Nodosa Pericarditis in association with temporal arteritis has been reported [34]

Pericarditis due to Malignant Neoplasms.[14] This is almost always due to extension of primary or secondary malignancies of the thoracic organs, especially carcinoma of the lungs or breast, to the pericardium. There is usually an effusion which is serofibrinous or hemorrhagic but which may become purulent because of secondary bacterial infection. Further discussion may be found in the chapter on neoplasms of the heart (Chapter 45).

Traumatic Pericarditis (Chapter 44).

Postcommissurotomy Pericarditis (p. 675).

Pericarditis in Libman-Sacks Disease (Lupus Erythematosus) (p. 634). Clinically this is only occasionally revealed by a pericardial rub. At postmortem examination I have observed a macroscopic, a local or diffuse fibrinous or serofibrinous pericarditis or a dense universal adhesive pericarditis in 14 out of 23 cases of this disease. Massive pericardial effusion responsible for clinical symptoms has been noted in 2 cases.[6]

Syphilitic (Gummatous) Pericarditis (p. 895).

Actinomycosis of the Pericardium (p. 913).

Coccidioidal pericarditis has also been observed.[60]

Parasitic Disease of the Pericardium (p. 915).

Roentgen-ray therapy has produced pericardial inflammation or a chronic massive pericardial effusion when employed in a case of hyperthyroidism[44] and in a case of carcinoma of the breast, respectively.[16]

Pericarditis in association with infectious mononucleosis has been reported.[7]

Dissecting Aneurysm of the Aorta. A pericardial rub may be heard due either to dissection or perforation into the pericardium or to secondary occlusion of a coronary artery with consequent myocardial infarction.

PERICARDIAL CYSTS AND DIVERTICULA

Congenital true pericardial cysts[5] may be celomic (mesodermal),[109] lymphangiomatous,[111] bronchial or teratomatous.[62] Acquired pericardial cysts may be neoplastic, parasitic or secondary to hematoma. On the other hand, there may be true pericardial diverticula as distinguished from cysts.[110] Certain pericardial outpouchings or diverticula are chronic, encapsulated pericardial effusions or exudates resulting from pericardial inflammations. True pericardial diverticula and encapsulated effusions are termed pseudocysts.

There are usually no subjective symptoms. Occasionally there are chest pressure or pain or other complaint, which may not be due to the diverticulum as such. Rarely the diverticulum points anteriorly and may present as a non-tender rounded mass on the anterior chest wall near the sternum.[7, 26]

The diagnosis of pericardial diverticulum is made by roentgenologic examination as pointed out by Kienbock and Weiss.[31] The diverticulum appears as a sharply outlined or lobulated semicircular, oval or polygonal area protruding from the cardiac silhouette, usually from its lower right contour, occasionally from its left side. It may or may not pulsate. Pulsations present on one examination may disappear after a period of years. Calcification may develop over many years' observation.[5] The preoperative diagnosis of a pericardial celomic cyst has been made by aspiration and injection of air.[39]

HEMOPERICARDIUM

Hemopericardium denotes the accumulation of blood in the pericardial cavity. It should be distinguished from conditions in which pericardial inflammation produces a hemorrhagic exudate as in tuberculous or malignant pericarditis.

The *etiology* of hemopericardium is varied.[32] Essentially it results from rupture of the wall of a cardiac chamber, a coronary artery, the aorta or rarely the pulmonary artery. These structures are either diseased or torn by trauma. Hemopericardium may also be due to scurvy, leukemia or other hemorrhagic diseases. Neoplasms may cause hemorrhagic pericardial effusions which are almost pure blood.

The commonest cause of acute hemopericardium is *myocardial rupture following acute myocardial infarction*.

Rupture of the aorta in its intrapericardial portion with consequent hemopericardium may be the result of (1) syphilitic aneurysm, (2) degeneration or medionecrosis (so-called spontaneous dissection and rupture of the aorta, see p. 555), (3) adult coarctation of the aorta with rupture just above the aortic valve, and (4) mycotic aneurysms burrowing along the aorta into the pericardial cavity.

Trauma of the heart and pericardium is considered elsewhere (Chapter 44).

The pathologic physiology and clinical picture are essentially those of cardiac tampon-

ade (p 593) The degree and rapidity of bleeding are important Usually bleeding is rapid and cardiac tamponade occurs with as little as 250 cc blood in the pericardium There may be sudden death occurring within one hour after rupture of a ventricle Not infrequently hours or days elapse during which the picture of acute cardiac compression develops (p 594) characterized by high venous pressure a falling arterial pressure and a small quiet heart Shock is frequent Other manifestations are determined by the different causes of hemopericardium

Treatment of the hemopericardium per se consists of relief of acute tamponade by pericardial aspiration or if time permits by surgical removal of the hemorrhagic collection followed by suture of the rupture or closure by graft Transfusions and other measures to combat shock are important (See also cardiac trauma p 1059) Constrictive pericarditis may result from organization of a hemopericardium [89]

HYDROPERICARDIUM

Hydropericardium denotes an excessive quantity of transudate in the pericardial cavity It is probable that the normal amount of pericardial fluid is not more than 30 cc but amounts up to 50 cc are not regarded as excessive Hydropericardium is to be distinguished from pericardial effusions resulting from pericarditis

Hydropericardium is usually part of a generalized anasarca of congestive heart failure or glomerulonephritis It also occurs in myxedema in cases of occidental beriberi in the rare cases of scleredema or Buschke s disease [103] or terminally in wasting diseases such as tuberculosis or carcinomatosis even when there is no direct pericardial involvement It may be part of a nutritional deficiency with hypoproteinemia Hydropericardium may result from local causes which interfere with the venous return from the pericardial circulation such as mediastinal tumors tumors of the lung or heart mediastinal lymphomata or tumors of the thymus or mediastinal lymph nodes

The amount of fluid may vary from 100 to several thousand cubic centimeters As a rule there is no interference with cardiac action and no subjective symptomatology Rarely large effusions occur and may require aspiration to relieve cardiac tamponade

PNEUMOPERICARDIUM

Pneumopericardium or the presence of air in the pericardial cavity is uncommon In 1925 Rigler[85] found 73 reported cases including 1 of his own Often the air is associated with fluid which is usually of a purulent nature—pyopneumopericardium [71]

Pneumopericardium results from (1) traumatic perforation (2) perforation of a neighboring air containing organ into the pericardium[85] or vice versa (3) artificial introduction of air into the pericardium either intentionally or accidentally, and (4) possibly by spontaneous formation of gas when the pericardium is infected by gas producing bacilli

When infection by gas bacilli causes air to be present within the pericardial tissue itself the condition is termed pneumatosis of the pericardium

Usually there are no subjective *symptoms* of the pneumopericardium or they are masked by the more serious consequences of the causative condition Occasionally cardiac compression is produced If there is a large quantity of air there may be tympany on percussion of the precordium and metallic or clinking heart sounds on auscultation If both fluid and air are present characteristic loud gurgling or splashing metallic sounds may be audible (bruit de Moulin) There may also be a pericardial rub

Radiologic examination readily reveals the presence of air which is indicated by a laterally delineated area of increased transparency around the cardiovascular silhouette There is usually striking cardiac activity There may be a horizontal fluid level which moves with cardiac pulsations

Treatment may be unnecessary as small quantities of air are readily absorbed Usually treatment must be directed to the more serious primary or associated conditions When these can be satisfactorily treated it may also be necessary to aspirate the pneumopericardium or to provide surgical drainage of a pyopneumopericardium

Chapter 23

ADHESIVE PERICARDITIS
CHRONIC CONSTRICTIVE PERICARDITIS

Adhesive pericarditis denotes the presence of adhesions between the two pericardial layers, between the pericardium and heart or between the pericardium and various neighboring thoracic structures. Since chronic inflammatory changes are often absent, the term adherent pericardium is sometimes used instead of adhesive pericarditis. The terms fibrous pericarditis or fibrosis of the pericardium may be used when scar tissue with or without active inflammation is present in the pericardium but there are no concomitant adhesions. Adhesive pericarditis of varying degree was found in 1.6 per cent of 8912 necropsies at the Mayo Clinic,[44] in 2.26 per cent of 1000 necropsies at Massachusetts General Hospital,[67] and in 1.4 per cent of 9618 autopsies in the Mount Sinai Hospital, New York.[61]

Concretio cordis (internal adhesive pericarditis) denotes adhesion, usually extensive, between the parietal layer of the pericardium and the visceral layer (epicardium). There may be partial or complete obliteration of the pericardial cavity.

Accretio cordis denotes the adhesion of the pericardium to neighboring extracardiac structures. It is often associated with internal adhesive pericarditis with or without cardiac compression. *Mediastinopericarditis* is a form of external adhesive pericarditis in which there is extensive scarring of the mediastinal structures with adhesion to a thickened pericardium. There is no definite evidence that the adhesions cause either circulatory disturbance or cardiac hypertrophy.

The lesions known as *milk spots* or *soldiers patches* are milky white, occasionally cloudy, irregular or oval flat plaques of hyalinized fibrous tissue. They are usually situated on the anterior surface of the right ventricle where it is not covered by lung.

CONSTRICTIVE PERICARDITIS

(Pericardial Compression Scar)

DEFINITIONS

Chronic constrictive pericarditis[30, 13] is a dense fibrous thickening of the pericardium, usually of uncertain but frequently of tuberculous or other bacterial origin, which causes chronic compression of the heart and interferes with its diastolic relaxation and filling. This results in systemic venous engorgement and a diminished cardiac output, which produce a characteristic clinical picture. Because the disease is due to an external mechanical impediment without significant concomitant myocardial or valvular lesions, surgical removal of the fibrous pericardial encasing membrane is capable of effecting a rapid and sometimes brilliant result.

The term *Pick's disease* or syndrome is sometimes applied to cases of constrictive pericarditis. Pick[55] described a series of cases characterized by recurrent or progressive ascites attended by little or no edema, in which postmortem examination revealed adhesive pericarditis and an atypical cirrhosis of the liver and fibrosis of its capsule. However, it is doubtful whether Pick's cases represent an homogeneous group.

Polyserositis or *Concato's disease*[16] has sometimes been used interchangeably with constrictive pericarditis. Concato referred to cases in which multiple serous cavities were presumed to be involved by tuberculosis. In my opinion it is questionable whether Concato's disease is an entity. Constrictive pericarditis differs essentially from the usual forms of polyserositis in that it is characterized by

cardiac compression whereas inflammation of the serous membranes is usually absent or occurs only secondarily

ETIOLOGY

Causative Diseases

1 In most cases the cause remains uncertain even after microscopic and bacteriologic examination of the compression scar [11, 2]

2 Tuberculosis is the commonest cause in cases of known etiology [11, 8, 1, 46, 77] The resected scar may be negative for tubercle bacilli in a case previously proven to be tuberculous by culture of aspirated pericardial fluid [37]

3 Bacterial pericarditis especially that due to the pneumococcus occasionally results in constrictive pericarditis Constrictive pericarditis has been reported due to P tularensis [38, 47]

4 Rheumatic fever very rarely if ever causes constrictive pericarditis [49]

5 Occasionally there [illegible] a previous history of acute pericarditis usually of undetermined etiology There are reports of constrictive pericarditis appearing many months or years after an acute pericarditis [1, 30] after chest trauma[4] or after traumatic hemopericardium [1, 54]

6 Neoplastic involvement of the pericardium[73, 27] or a foreign body [73] in the pericardium may produce the syndrome of constrictive pericarditis Constrictive pericarditis was reported in a case of chronic pericardial effusion in which the resected specimen revealed chronic cholesterol pericarditis [16]

Age and Sex

Constrictive pericarditis is essentially a disease of youth although it may occur in persons beyond middle life Most of the proven cases occur between the ages of 10 and 40

There is a predominance of males over females in a ratio of about 3 to 1

PATHOLOGY

The essential pathologic feature of constrictive pericarditis is a dense callous thickening of one or both layers of the pericardium Usually it is 3 to 5 mm in thickness but it may be 1 cm or more It has been described as being as hard as shoe leather The thick pericardium forms an inelastic casement of armor composed of cicatrized fibrous tissue which is incapable of stretching during diastole Microscopically it appears as [illegible] non specific dense avascular hyalinized connective tissue except in those cases which reveal the granulation tissue of tuberculosis or pyogenic infection

Usually both layers of the pericardium are involved the pericardial cavity may be completely or almost completely obliterated Occasionally there are small or large usually sacculated collections of fluid or caseous debris especially in the definitely tuberculous forms of chronic cardiac compression The pericardial scar may extend over the entire cardiac surface and even over the great vessels but it may also be relatively localized From the point of view of circulatory disturbance the scar over the ventricles especially the anterior surface is most important because excellent results are usually obtained by pericardial resection without removal of the scar over the atria and great vessels

Calcification of the scar tissue which may be observed roentgenologically at operation or sometimes only by microscopic examination occurs in at least one fourth to one third of the cases [74, 71, 1] Armstrong found calcification in [illegible] of 10 cases of constrictive pericarditis and only in 2 out of 28 cases of nonconstrictive adherent pericardium In one instance there was true bone The calcification may be so extensive as to form a hard complete shell confining the heart (armored heart or Panzer herz)

The Heart

The heart is usually of normal or less than normal size and the individual fibers may be atrophied In 1728 Lancisi[41] had noted the characteristic syndrome of constrictive pericarditis in a young man with engorged jugular veins enlargement of the abdomen and a small pulse whose heart at necropsy was found to be small and surrounded by a thick completely adherent pericardium Chevers[14] in 1842 distinguished cases of adhesive pericarditis with enlarged hearts and valvular disease from those in which the pericardium was obliterated by [illegible] thick almost cartilaginous deposit the valves were normal and the heart of remarkably small size The latter group presented the clinical picture now associated with constrictive pericarditis Wilks[79] also called attention to such cases but the last 3 of his [illegible] reported cases were probably instances

of rheumatic heart disease and not of constrictive pericarditis

The heart is free from valvular lesions or any of the ordinary forms of cardiac disease In 1 of White's[74] cases there was rheumatic cardiovalvular disease and in another congenital heart disease, both being interpreted as coincidences Similarly the presence of rheumatic heart disease in 5 of 18 cases of constrictive pericarditis reported by Kaltman et al[29] was regarded as coincidental However the superficial subepicardial layers of the myocardium may be involved by the cicatrizing process or by tuberculous or other bacterial infection Myocardial atrophy may be severe enough to cause functional disability

The Liver and Other Viscera

The pathology of the organs other than the heart in cases of constrictive pericarditis, is essentially similar to that in (right sided) congestive heart failure

The *liver* was long considered the site of the basic changes in the disease Curschmann[19] noted in cases of polyserositis an inflammatory coating on the liver (perihepatitis) which he termed the Zuckergussleber (sugar icing or frosted liver) because of the resemblance of the exudate to confectioners' sugar icing The relation of hepatic enlargement and ascites to pericardial obliteration was noted by Rosenbach while Hutinel[36] described the occurrence of hypertrophic cardiac cirrhosis of the liver due to adhesive pericarditis Pick[65] first clearly emphasized that the hepatic changes were caused by venous stasis secondary to the adherent pericardium

As a rule the liver is enlarged in cases of constrictive pericarditis due to venous engorgement In later stages the liver may become small because of atrophy and fibrous contraction The typical nutmeg liver of cardiac failure is usually seen Fibrosis occurs and may be extensive There may be an associated congestive splenomegaly Pick[65] described the hepatic changes as a "pseudocirrhosis to distinguish them from the portal cirrhosis of Laennec

Other pathologic abnormalities may be mentioned briefly The abdominal viscera are congested The kidney and spleen as well as the liver may be somewhat cyanotic and firm due to congestion and fibrosis (cyanotic induration) Pleural adhesions and pleural effusions are usual Pulmonary arteriosclerosis presumed to be secondary to sustained pulmonary hypertension, has been observed Large collections of ascitic fluid occur invariably with occasional secondary peritoneal inflammation and even adhesions

PATHOLOGIC PHYSIOLOGY

That the constricting pericardial scar is the basic cause of the physiologic and clinical disturbances was demonstrated by (a) reproducing the clinical picture in dogs, in which Dakin's solution or other foreign irritating material injected into the pericardial cavity had caused an obliterating constricting pericarditis,[6] and (b) eliminating the clinical manifestations in humans with constrictive pericarditis following resection of the pericardial scar However, to a minor, variable degree, myocardial damage may be a contributory factor in producing physiologic disturbances and the clinical picture

Diminished Diastolic Relaxation and Inflow of Blood

The constricting pericardial scar interferes with normal diastolic relaxation of the heart and thereby impairs the venous inflow into the right atrium and ventricle[14] Constriction of the venae cavae at their entrance into the right atrium is not a factor in producing the circulatory disturbances as indicated by cardiac catheterization and measurement of vena caval and right atrial pressures[31] There is no increase in pressure gradient between the vena cava and the right atrium or between the right atrial mean pressure and the diastolic pressure of the right ventricle The latter excludes significant constriction of the atrioventricular groove The compressing effect of the pericardial scar is best demonstrated by the striking bulging of the heart and resumption of active pulsation when the scar is excised Systolic contraction is usually unimpaired for the heart is capable of expelling what blood it receives although occasionally it suffers as a result of myocardial atrophy

Diminished Cardiac Output

There is a diminished stroke output and minute volume output due to the reduction in venous inflow The reduced cardiac output is due entirely to the diminution in output per beat since the basal cardiac rate is either normal or more often accelerated[11] Diastolic restriction of the heart is such that the stroke output cannot be augmented during exercise, a needed increase in cardiac out

put must be effected entirely by an elevation of the cardiac rate[44]

Increased Systemic and Pulmonary Venous Pressure and Venous Stasis

In both experimental and human constrictive pericarditis there is an early rise in systemic and pulmonary venous pressure But maintenance of an elevated venous pressure despite the diminished cardiac output depends on a greatly augmented circulating blood volume[11] The latter like the increased blood volume of chronic cardiac failure is probably secondary to the deficient cardiac output and the consequent renal retention of sodium and water

Measurements by cardiac catheterization disclose that the pulmonary arterial and pulmonary capillary pressure are elevated[46 ...] indicating that there is also pulmonary congestion due to left ventricular involvement (constriction) as well as systemic congestion Right atrial pressure tracings show an M or W shaped contour with an early diastolic dip followed by a rapid rise to form a plateau[43] The ventricular end diastolic pressure exceeds one third the systolic pressure Similar findings are encountered with diffuse myocardial lesions (p 627) and constricting subendocardial fibroelastosis (p 638)

The augmented circulating blood volume and venous return cannot be accepted normally not because of any right heart deficiency but because of the pericardial impediment to ventricular filling The systemic venous pressure rises because of the disparity between venous return and cardiac filling capacity Intravenous saline infusions given experimentally to human subjects with constrictive pericarditis[44] do not increase the cardiac output in contrast to their effect in acute pericardial effusion[17] This may be due to the fact that in the former it is a non distensible scar which prevents further ventricular filling in diastole in the latter it is an elevated pressure which can be partially overcome

The large circulating volume causes stasis and engorgement in the systemic venous tributaries The circulatory disturbances resemble the inflow stasis due to tricuspid stenosis except that the impediment to right ventricular inflow is due to constriction from without Pulmonary congestion similarly results from a compression scar about the left ventricle with consequent impediment to left ventricular filling and contraction Pulmonary congestion may be partially limited by the diminution of right ventricular output into the pulmonary circulation

CLINICAL FEATURES

The *general clinical picture* resembles that of pronounced right-sided heart failure especially that due to tricuspid stenosis However ascites occurs earlier and is a more prominent feature while edema is less pronounced

Symptoms

The *chief complaints* are most often swelling of the abdomen and dyspnea on exertion

Abdominal swelling is due to the accumulation of ascitic fluid It may be associated with various digestive disturbances, anorexia, abdominal fullness or even pain Sometimes the patient's first complaint is an increase in the size of his waistline or a gain in weight despite limited food intake

Dyspnea usually occurs only on exertion This is presumed to be related to the inability of the heart to increase its stroke output and its limited capacity to augment its minute volume by tachycardia *Orthopnea* likewise occurs when there is pulmonary congestion Occasionally there is dyspnea at rest either because of extensive pleural effusions or because of the reduction in vital capacity due to marked elevation of the diaphragm by ascites but it may be due to pulmonary congestion caused by obstruction to inflow into the non distensible left ventricle

Loss of weight is common in the cases associated with active tuberculous pericarditis but it occurs sooner or later in most cases if allowance is made for serous effusions and edema Weakness fatigability epigastric discomfort and anorexia are occasionally prominent symptoms Syncope occurs occasionally presumably due to inability to increase the cardiac output with exercise

Pulsations of the chest wall are minimal or absent The heart is quiet The apical impulse is difficult to see or feel Broadbent's sign[10] and other signs of systolic retraction of the interspaces are absent

Percussion of cardiac dullness usually reveals a small heart or at least one without significant enlargement But in many cases cardiac enlargement has been noted clinically and roentgenologically This may be due

to the thick scar pleuropericardial adhesions, pericardial effusion or associated rheumatic valvular disease There may be little or no depression of the apex on deep inspiration due to pericardiopleural adhesions Shift of the body from right to left lateral position may be accompanied by little or no displacement of the heart

Auscultation discloses no evidence of organic valvular disease except in cases with concomitant rheumatic cardiovalvular disease Systolic murmurs are occasionally heard as in many normal hearts The heart sounds may appear distant and muffled An early diastolic sound related to rapid ventricular filling is common [52] This extra sound is termed a pericardial protodiastolic sound to distinguish it from the third heart sound or a protodiastolic gallop [44]

The *cardiac rhythm* is usually normal However atrial fibrillation was noted in 4 of White's [74] 15 cases and in 2 of the 9 cases of Stewart and Heuer [71] This arrhythmia may be due to atrial involvement by the compression scar The cardiac rate is usually accelerated

Examination of the lungs usually reveals signs of pleural effusions sooner or later in the course of the disease

Signs of Circulatory Disturbance

1 **Prominent Superficial Veins** The cervical veins are extremely engorged There is no diastolic collapse [5] and no systolic engorgement in contrast with cases of tricuspid valvular insufficiency *Inspiratory swelling of the cervical veins* may be noted but this is often obscured by the constant fullness of the veins

2 **Hepatic Enlargement** Enlargement of the liver due to venous engorgement, is often prominent and occurs early Epigastric pain may be a prominent early complaint due to the enlarging liver The liver may be tender but does not pulsate (a differential diagnostic point with respect to tricuspid insufficiency) However it may be difficult or impossible to palpate the liver if there is massive ascites With longstanding venous stasis atrophy and fibrosis, the liver may occasionally become small

3 **Ascites** *Ascites precox* Ascites is a cardinal feature of the disease The ascites is characterized both by its copious quantity and its tendency to recur However, occasionally it may not recur for months or years, even in the absence of surgical therapy Usually the patient requires abdominal paracenteses every few weeks or months to obtain relief In an oft quoted classic case, 301 paracenteses were performed

A feature of the ascites is its predominance over subcutaneous edema and especially its earlier development (ascites precox) This reverses the usual relationship of ascites and edema in cases of congestive heart failure

The *mechanism* which accounts for the copiousness and early appearance of ascites is obscure The older explanations implicated peritonitis,[40] pleural effusions or cirrhosis of the liver[55] as primary causes Obviously, the pericardial scar and its interference with the inflow of blood is the fundamental cause But the consequent elevation of venous pressure in the inferior caval system should result in peripheral edema at least as early as in ascites The possibility of greater interference with the flow of blood from the hepatic veins than from the inferior vena cava has been suggested on the basis of certain inconclusive observations [25] The adherent pericardium on the diaphragmatic surface of the heart may obstruct lymphatic drainage of the peritoneum which converges onto the diaphragm, and thus may increase the tendency to peritoneal effusion by further elevating the capillary pressure

4 **Subcutaneous Edema** This is often minimal or occurs relatively late Usually, it is less prominent than the ascites It is localized chiefly to the lower extremities or sacral region but occasionally edema of the face rarely of the neck arms and chest wall, is observed when the patient arises in the morning or when he is bedridden

5 **Pleural effusions** are usually present at some stage of the disease They may be of minimal size or sufficiently copious to cause dyspnea and require thoracentesis for relief

6 **Cyanosis** of slight or moderate degree is common This may be due to pulmonary congestion caused by resistance to venous inflow in the left atrium and ventricle or to associated pleuropulmonary disease or peripheral venous stasis

7 **Pulsus paradoxus** is almost always observed if carefully sought Its mechanism has been discussed (p 594)

8 **Abnormal Circulatory Measurements** (a) The *venous pressure* in the antecubital veins is sharply and persistently elevated The aver

age values range between 25 and 35 cm, which are higher than those ordinarily seen with congestive heart failure Sodium restriction and diuresis usually have strikingly little influence on the venous pressure Pressure over the right upper quadrant of the abdomen causes a sharp rise in venous pressure (hepatojugular reflux) even when the venous pressure is not much elevated Exercise and intravenous infusions are more likely to elevate the venous pressure and to a greater height than in normal subjects A fall in venous pressure often follows paracentesis Corresponding to the rise in venous pressure there is also an elevation of the spinal fluid pressure and of the pressure in the thoracic duct [5]

(b) The *arterial blood pressure* is usually low The systolic blood pressure ranges between 90 and 110 mm Hg and rarely exceeds 120 Since the diastolic pressure is usually normal *the pulse pressure is reduced* This is an important sign The pulse pressure averages between 15 and 25 mm Hg Corresponding to the pulsus paradoxus the arterial pressure usually falls on inspiration

(c) The *circulation time* is prolonged [71] As in cases of congestive heart failure the arm-to-tongue time is increased to between 20 and 40 seconds or longer The observations of Stewart and Heuer[71] indicate a prolongation of circulation time through both the right heart and the pulmonary circulation

(d) The *circulating blood volume* as determined in 2 cases by Burwell and Blalock [11] was increased from 30 to 45 per cent above normal

(e) The *cardiac output* is diminished

(f) The *vital capacity* was reduced to between 36 and 68 per cent of normal in the cases studied by Stewart and Heuer [71]

Cardiac catheterization disclosed that the right ventricular diastolic pressure is elevated as in right-sided heart failure and ranges between 6 and 32 mm Hg The right ventricular pressure curve is characterized by a slightly elevated normal or slightly lowered systolic pressure a rapid early diastolic dip followed by a high diastolic plateau indicating a high end diastolic pressure [31, 46, 77] The end diastolic pressure is more than one third that of the right ventricular systolic pressure and the pulse pressure is diminished features which are distinctive from those of right heart failure [77] Catheterization studies also revealed an elevation of pulmonary systolic diastolic and mean arterial pressure and of pulmonary wedge (capillary) pressure [60]

Hypoproteinemia

A reduction of the blood protein concentration is frequent in cases with longstanding symptoms of constrictive pericarditis The reduction is limited to the serum albumin the serum globulin remaining normal or even elevated Reduction in serum albumin favors the development of both edema and ascites (p 201)

The cause of hypoproteinemia in these cases is uncertain It has been attributed to malnutrition (i e to an inadequate intake of protein) to loss of protein in the ascitic fluid which is repeatedly drained and to a reduction in liver function due to chronic passive congestion with consequent inability to fabricate serum protein [43] Stadler and Stinger[68] showed that hypoproteinemia persisted in a child with constrictive pericarditis even though the dietary protein intake was sufficiently high protein nitrogen was retained no albumin was lost and the amount of protein lost by paracentesis was far less than that administered by transfusions Although the usual tests of hepatic function were normal these authors concluded that the inability to regenerate serum albumin was due to liver damage caused by passive congestion Impaired liver function as determined by the Bromsulphalein test was found in all 9 cases of constrictive pericarditis reported by Harrington and Barnes [3]

Roentgenology

Whenever possible large pleural or peritoneal effusions which may interfere with interpretation should be removed before roentgenologic examination of the heart is completed The following are the most significant findings

1 Calcification of the pericardium[66] is the most definite evidence of an adhesive pericarditis but does not necessarily denote constriction The latter is usually present however if calcification is extensive (Fig 117)

2 There is an absence or diminution of cardiac pulsation as observed by fluoroscopy and by roentgenkymography [70] *Electrokymography* usually discloses a characteristic series of alternate flat tops and V depressions[17] (Fig 6 p 10)

3 The cardiac silhouette is usually small or of normal size Although it may appear

slightly or moderately enlarged, in some cases the pronounced enlargement associated with right sided congestive heart failure is not observed

4 The vascular shadow on the right, representing the superior vena cava is usually widened due to engorgement of that vessel

5 Pleural effusion and pleural thickening are common

6 Other roentgenologic observations are less significant There may be any or all of the abnormalities listed above as being associated with external adhesions These include limitation of motion of the heart with change in body position and respiration hazy cardiac border tentlike shadows along the cardiac silhouette and diaphragm abnormal or paradoxical motion of the diaphragm with respiration, and obliteration or encroachment on the retrosternal and retrocardiac spaces

Angiocardiography[16] usually shows dilatation of the superior vena cava, and occasional obliteration of the retrosternal space dilatation of the left atrium and main pulmonary artery

The Electrocardiogram

There is usually a low voltage of the QRS complexes T waves are frequently flattened or inverted in lead I or II or both Corresponding T wave alterations may be seen in chest leads The T wave in limb leads may resemble the inverted coronary T wave of myocardial infarction There may be slurring of the QRS complexes in all leads but no notching[20]

Broad, notched P waves were found in 42 6 per cent of one large series[13] The second notch of the P wave is characteristically taller than the first[26] Fixation of the electrical axis may or may not be present[71] Fixation of the electrical axis in cases of valvular disease with large hearts and external adhesions may be distinguished from that due to constrictive pericarditis by the high voltage of the QRS complex in the former group of cases Atrial fibrillation has been reported in a fair percentage of cases of constrictive pericarditis

The ballistocardiogram frequently shows large abnormal early and middiastolic waves and distortion of the initial portion of the systolic complex[6]

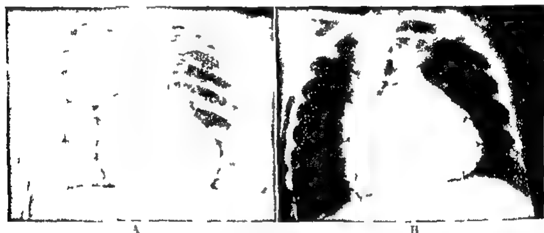

Fig 117 Constrictive pericarditis with dense calcification of pericardium *A* Posteroanterior view *B* Right anterior oblique view

DIAGNOSIS

The diagnosis is usually simple if the condition is borne in mind It is suggested by the presence of signs of congestive heart failure without signs of heart disease Usually the diagnosis is based on the observation of venous engorgement, persistently high venous pressure hepatic enlargement and ascites in a patient without organic valvular murmurs or other evidences of heart disease, and without cardiac enlargement Beck[4] emphasizes the triad of chronic cardiac compression (1) an elevated venous pressure (2) ascites and (3) a small quiet heart Confirmatory signs are a small and usually paradoxical pulse low systolic blood pressure and especially a *low pulse pressure,* roentgenologic finding of diminished cardiac pulsations and occasionally of pericardial calcification, and finally little or

no change in objective signs despite active treatment of congestive heart failure. A history of a pericardial rub or effusion, especially of tuberculous or other bacterial origin, may be helpful. Not infrequently the patient is observed in the febrile phase of acute pericarditis (usually tuberculous) and signs of impaired cardiac filling appear as the acute disease subsides.

In a number of reported cases cardiac enlargement was said to be present.[74, 75] Occasionally elevation of the diaphragm by ascites, the presence of pleural effusions, the haziness of the cardiac borders and the width of the thick pericardium lead to an erroneous roentgenologic interpretation of cardiac enlargement. The differential diagnosis may be difficult when there is coexistent rheumatic cardiovalvular disease.[29]

DIFFERENTIAL DIAGNOSIS

The prominence and early development of ascites may suggest the presence of cirrhosis of the liver or of a chronic (usually) tuberculous peritonitis with or without polyserositis.

Cirrhosis of the liver may be excluded by the finding of venous congestion in the superior caval as well as in the portal system, i.e., by the observation of cervical venous congestion and elevation of the venous pressure in the upper extremities.

I have seen one case which was at first erroneously diagnosed as constrictive pericarditis because of evidences of obstruction of both the superior and inferior vena caval systems without physical signs of cardiac disease. But the correct diagnosis of *multiple venous thrombosis* (of unknown etiology) was made ante mortem chiefly because of the presence of a visible collateral venous circulation on the chest wall, which does not occur in cases of constrictive pericarditis.

Congestive heart failure due to primary cardiovalvular or pulmonary disease is distinguished by the history and by physical, roentgenologic and electrocardiographic evidence of the underlying cardiac or pulmonary disease. *Tricuspid stenosis* is distinguished by the concomitant presence of mitral stenosis and often an atrial venous pulse, while in tricuspid insufficiency there is usually a systolic hepatic pulsation and a positive cervical venous pulse.

TREATMENT

Once the diagnosis of chronic constrictive pericarditis is made, the only satisfactory treatment is surgical—partial pericardiectomy (decortication of the heart). However, signs of cardiac compression due to tuberculous pericarditis may disappear without operation if the tuberculous pericarditis is cured by streptomycin-isoniazid therapy[7] (p. 603).

Preoperative Management

Bed rest for a few weeks, minimal sodium intake, salt-free albumin if there is pronounced hypoproteinemia, mercurial diuretics, removal of large abdominal, pleural or pericardial effusions are important preoperative measures (Chapter 11). Digitalis is not indicated in the classic case with normal or small heart and without myocardial or valvular disease. However, digitalization should be effected rapidly if the atrophic heart is unable to handle the increased inflow after cardiac decortication. Venesection is said to be contraindicated, for the high venous pressure serves the useful purpose of maintaining a desirable pressure head to secure an adequate inflow of blood into the heart despite pericardial compression of the heart.

In the active tuberculous stage, medical therapy with streptomycin, isoniazid and/or para-aminosalicylic acid (*PAS*) is employed. Signs of cardiac tamponade during this phase may be due to pericardial effusion and may be relieved by aspirations. Constriction by scar tissue may be thus avoided. If this develops despite the above treatment, operation is indicated.

Operation

If there is active pericardial infection the operation should be deferred if possible until the tuberculosis or other infection is controlled by antibiotics. However, Blalock and Levy[9] and also Beck[4] have had successful results in some cases in which pericardiectomy had to be performed because this seemed to be the only hope of reversing a downhill course. Blalock and Levy decided on operation for patients with active tuberculous pericarditis and cardiac compression if the patient became sicker and the venous pressure rose even though the pericardiocardiac shadow, by roentgenologic examination, was becoming smaller.

The *operative technique* has been described by various surgeons (see Schmieden[63] Churchill[15], Blalock and Burwell[8] Beck[5] Heuer and Stewart[34], Harrington and Barnes[2, 35]) The operation of decorticating the heart from its confining scar was first suggested by Delorme[21] first carried out successfully by Rehn[56] and in this country by Churchill[15] It is important to provide an adequate exposure of both the left and right ventricles This may be obtained by excision of the left sixth rib from spine to sternum with division of the fourth and fifth costal cartilages close to the sternum Sometimes the sternum is transected transversely As a rule the scar is first dissected from the left ventricle and when this is free to receive a greater amount of blood than previously the right ventricle is decorticated Care must be taken to avoid injury to the coronary arteries and the phrenic nerve The pericardial scar is removed from as much of the anterior surface of the ventricles as possible without too great danger to the patient s general condition and with caution to avoid tearing the myocardium or injuring the anterior descending coronary artery Only occasionally is it possible to resect the pericardium from the posterolateral posterior and diaphragmatic surfaces but this is usually unnecessary However Harrington and Barnes[2] emphasize the need for wide pericardial resection including the apex of the heart and diaphragmatic surface of the right ventricle There is similar difference of opinion as to the need for removal of scar tissue from the thin walled right atrium which tears easily and from the venae cavae Harrington and Barnes believe that when the constricting pericardium is calcified as much of the calcium as possible should be removed from the right atrium the atrioventricular sulcus and the area around the orifices of the venae cavae In most if not all cases removal of the scar from both ventricles is the essential procedure in the operation whereas dissection of the membrane from the venae cavae and atria is unnecessary and involves considerable risk of bleeding The criterion of adequate pericardial resection is the successful release of the heart and visible increase in cardiac pulsation

Postoperative Management

The patient is usually placed in an oxygen tent in semi Fowler s position and kept there for several hours or a few days But some surgeons employ oxygen only if specially indicated Fluids are limited Beck[5] avoids the administration of fluids intravenously because the atrophic heart may not be able to cope with both the additional inflow of blood and the fluids In fact venesection is sometimes indicated if there is a sharp rise in venous pressure Digitalis or quinidine may be required postoperatively to control atrial fibrillation or other cardiac irregularities But these are usually transient and subside spontaneously

Convalescence is usually rapid and the patient is ambulatory in four to six weeks The restriction of sodium and the administration of diuretics should be continued until there is no longer any evidence of edema or serous effusions

PROGNOSIS WITH AND WITHOUT OPERATION

The outlook of patients with constrictive pericarditis is almost uniformly poor if pericardiectomy is not performed The patient is a semi or complete invalid Sooner or later he becomes bedridden, weak and emaciated He suffers extremely from the recurrence of copious ascites and the need for frequent paracentesis But to evaluate operative results it must be noted that occasional unoperated patients survive for many years or decades that sometimes without apparent cause abdominal effusions remain stationary or do not recur for years after aspiration, and finally that in occasional patients fair results may be obtained by active, prolonged, dehydration therapy

In comparison with medical treatment the results of pericardiectomy are brilliant when the operation is properly performed on appropriate cases Between 50 and 75 per cent are cured or greatly improved[5, 15, 34, 8, 53, 13, 46, 2] The mortality has ranged between 15 and 25 per cent but has diminished with increased surgical experience The favorable effects of the operation may be noted early During the operation the heart should enlarge and herniate into the pericardial defect created by resection thus indicating the removal of compression The pulsations become noticeably greater the pulse stronger and the systolic pressure and pulse pressure should increase Cyanosis often disappears The patient usually feels subjectively better when he

becomes conscious and breathing is easier The extremities feel warmer and cervical venous engorgement may be less prominent although still present Sometimes a considerable diuresis occurs within 48 hours after operation, more often it is delayed

Whereas occasional cases show a rapid and progressive improvement immediately after operation most successful cases require three to six months for a cure In particular enlargement of the liver moderate engorgement of the cervical veins and some elevation of venous pressure may persist after other evidences of the disease have disappeared Pulmonary hypertension may not be alleviated when the left ventricle is insufficiently released from its scar[61] Imperfect clinical improvement and incomplete restoration of normal hemodynamics may be due in part to myocardial atrophy and fibrosis but chiefly to inadequate decortication of the ventricular scar When a successful result is obtained not only do the serous effusions and edema disappear but the abnormal circulatory measurements are completely or almost completely restored to normal [9, 71]

CALCIFICATION OF THE PERICARDIUM

Incidence and Etiology

Calcification occurs as a secondary degenerative change complicating chronic inflammation of the pericardium It is observed in cases of rheumatic pericarditis[35] pneumococcus[4] or other bacterial (purulent) pericarditis chronic tuberculous pericarditis traumatic pericarditis [4, 78] and in many cases of constrictive pericarditis of unknown etiology (p 609) Calcification of the pericardium may occur without determinable cause in apparently healthy persons[45] It has been found in individuals with a negative tuberculin but a positive histoplasmin skin test[7]

Pathology

The calcium may form discontinuous plates or bands or it may form almost a complete shell 1 to 2 cm thick (armored heart or Panzerherz) Predominant localization is believed to occur where cardiac pulsation is least The commonest sites of calcification are the coronary sulcus the diaphragmatic surface of the right ventricle the right atrium and the sternal aspect of the right ventricle in the order named

Calcification occurs in the parietal or epicardial layers usually in both As a rule there is an associated adhesive pericarditis with complete or incomplete obliteration of the pericardial cavity or rarely a purulent pericarditis[43] Occasionally ossification is also associated with the deposition of lime[1]

Clinical Features

Calcification of the pericardium, per se usually causes no disturbance in cardiac physiology and no clinical subjective symptoms However in many cases there is a clinical picture of constrictive pericarditis or of congestive heart failure due to associated cardiovalvular disease Calcification of the pericardium may be associated with electrocardiographic abnormalities such as RS T depressions and T wave inversions[45]

Roentgenology and Diagnosis

Calcification of the pericardium is recognized by roentgen ray examination[4] or is first discovered at operation or at necropsy A tabular review of over 70 cases was presented by Rummert[19] Stehr[43] reported 12 of his own cases in 1939 Roentgenologic discovery is most likely if both teleoroentgenographic and fluoroscopic examinations are made,[46] and especially by tomography Calcification is most apt to be seen in the lateral and oblique views especially where the cardiopericardial and sternal shadows fuse The calcium may appear as dense sickle shaped shadows or as massive irregular plates streaks or branched forms Multiple roentgenologic views are often necessary to prove the pericardial site of calcification Pericardial calcification must be distinguished from calcification of the valves which is centrally located in all views and shows extensive motion from calcified thrombi which are oval masses usually near the cardiac apex, and from calcification of the coronary arteries of adjacent lymph nodes or of the costal cartilages

Chapter 24

MYOCARDITIS AND MYOCARDIAL DISEASE OF OBSCURE ORIGIN

Almost every cardiac disease is associated with myocardial involvement The most frequent and most significant types of myocardial disturbance will be presented in the individual chapters devoted to the etiologic forms of cardiac disease This chapter is concerned with those instances of myocarditis and myocardial disease which cannot be classified under the major etiologic forms of heart disease

MYOCARDITIS

The term myocarditis was first employed by Sobernheim[35] to denote inflammation of the myocardium Currently it refers to the myocardial lesions and symptoms associated with infectious diseases infections and intoxications as well as to myocardial inflammatory changes of obscure origin [36, 4, 8] It has been applied also to certain essentially degenerative lesions of the muscle fibers encountered in cases of diphtheria and other infectious diseases On the other hand myocarditis is no longer considered a proper diagnosis in cases of myocardial infarction due to coronary artery occlusion, even though an inflammatory reaction is elicited by injury of the muscle fibers Diffuse and focal fibrosis of the myocardium associated with hypertensive and coronary artery disease should not be classified as chronic myocarditis or fibroid myocarditis since the fibrous scars are due to myocardial ischemia and not to the healing of inflammatory lesions

Myocarditis itself is rarely an adequate diagnosis since it may be due to a variety of causes Whenever possible the etiologic factor should be included such as the causative organism (e g meningococcus myocarditis) or chemical agent (phosphorus poisoning) or the primary disease which either produced the myocarditis (e g rheumatic fever) or of which the myocardial inflammation is a part (e g subacute bacterial endocarditis) Myocarditis is often only a pathologic anatomic diagnosis since the lesions may be insufficient to cause clinical symptoms or the latter may be overshadowed by other clinical features of the primary disease The finding of microscopic lesions of myocarditis in necropsy cases has led to the erroneous conclusion that the clinical diagnosis of myocarditis should be made much more often [36, 43] The clinical significance of the microscopic myocarditis should not be exaggerated This applies also to non specific electrocardiographic changes encountered in many acute infections

Classification

Myocarditis is sometimes classified as acute and chronic The division is often indistinct Myocarditis may be further subdivided into (1) infectious and toxic myocarditis (2) suppurative myocarditis and (3) idiopathic or isolated (Fiedler's) myocarditis Saphir[36] classified myocarditis as (1) myocarditis following infections with or without endocarditis, (2) specific myocarditis e g rheumatic tuberculous, etc , (3) myocarditis due to chemical poisons physical agents or hypersensitive states and (4) isolated myocarditis (without associated disease)

Etiology and Incidence

The *incidence* of myocarditis is discussed with the individual causative diseases in later chapters The available data are unreliable first because the pathologic diagnosis can be made in only a small percentage of cases owing to the relatively low mortality in infectious diseases and second, because these cases, being the most serious, are not representative of the disease On the other hand the incidence based on clinical cases is unreliable because of unsatisfactory and varied criteria employed by different observers for the diag

nosis of clinical myocarditis When routine serial electrocardiograms are made in infections, the incidence of myocarditis has been reported as being much higher than is generally supposed But it is uncertain whether the electrocardiographic changes observed are actually due to inflammatory lesions in the myocardium There is often a lack of correlation between pathologic changes electrocardiographic abnormalities and cardiac symptoms or signs

According to Saphir[96] 240 cases of myocarditis (4 3 per cent) were encountered in 5626 consecutive autopsies on adults 186 of the cases were nonrheumatic In a similar study among children the incidence of myocarditis was 6 8 per cent [97] Gore and Saphir[42] reported 1402 cases of myocarditis among soldiers studied at autopsy 90 per cent of which were rheumatic In the majority of cases the diagnosis was not suspected clinically These observers listed some fifty conditions associated with myocarditis, including bacterial rickettsial viral fungal protozoal and helminthic infections, glomerulonephritis sulfonamide sensitivity carbon monoxide poisoning heat stroke and burns Although they stressed the point that the clinical diagnosis could have been made frequently on the basis of symptoms and signs and electrocardiographic changes many of the signs listed are those of shock probably due to peripheral vascular failure and not to myocarditis while manifestations of myocardial failure are uncommon

Rheumatic fever is the predominant cause of clinically significant myocarditis (Chapter 31) *Diphtheria* may induce a severe myocarditis (p 902) but both the diphtheria and especially the complicating myocarditis are relatively infrequent *Subacute bacterial endocarditis* (Chapter 34) is accompanied by a high incidence or an invariable occurrence of microscopic cardiac lesions The occurrence of unexpected death following an acute tonsillitis or nasopharyngitis presumed to be due to a myocarditis demonstrated at autopsy,[17, 43] is very impressive but still remains a comparative rarity in proportion to the total number of cases of upper respiratory infections or of myocardial disease A large number of other infections and toxic agents which are responsible for occasional instances of clinical myocarditis and for more frequent instances of histologic myocarditis are discussed in Chapter 36

Pathology

Acute myocarditis is often subdivided pathologically into parenchymatous and interstitial forms In the former the predominant or primary changes involve the myocardial fibers themselves, in the latter the inflammatory lesions are situated chiefly or primarily in the interstitial tissue As a rule, however the lesions involve both the parenchyma and interstitial tissue and it is impossible to decide which structures were first affected

Parenchymatous myocarditis is best exemplified by certain cases of diphtheria, but similar though less severe changes are observed in cases of typhoid fever, scarlet fever, pneumonia and other infectious diseases The fundamental lesions are degenerative alterations of the muscle fibers These include cloudy swelling hyaline or vacuolar (hydropic) degeneration, granular degeneration waxy degeneration and fatty degeneration (p 126) Brown et al [16] reported a case of focal necrotizing myocarditis without interstitial infiltration, in which the clinical picture, thought to be that of acute myocardial infarction, was terminated by sudden death The muscle fibers may be only slightly affected or focal or large areas of muscle tissue may be destroyed and replaced by productive inflammation or fibrosis Associated interstitial inflammatory changes appear early or late as a reaction to the muscle injury or as part of a universal myocarditis

Interstitial myocarditis is typified by the myocardial changes in rheumatic fever (p 816) An essentially or primarily interstitial myocarditis is observed also with meningococcic infections, trichinosis so-called isolated (Fiedler s) myocarditis and occasionally in cases of scarlet fever, influenza and typhoid fever The lesions are usually diffuse and consist of varying degrees of edema and infiltrations of neutrophilic or eosinophilic leukocytes lymphocytes, mononuclear cells, occasional plasma cells and of histiocytes and fibroblasts Eosinophilic and giant cell granulomatous myocarditis has been noted, in one case at least, apparently due to penicillin sensitivity [102] Granulomatous arteritis has been observed in the myocardium of a patient with Wegener s granulomatosis [31] In rheumatic myocarditis a characteristic spe-

cific granulomatous lesion the Aschoff body is frequently observed In mild forms of interstitial myocarditis only focal lesions may occur The muscle fibers may be normal or only little affected but as a rule they undergo some degree of degenerative change atrophy or necrosis

Focal myocardial lesions involving the parenchyma the interstitial tissue or both occur in various bacteremias especially those due to pyogenic organisms or to direct extension from suppurative lesions of the pericardium or endocardium In the latter cases and in bacteremias due to staphylococci hemolytic streptococci and less commonly gonococci and pneumococci a *suppurative myocarditis* occurs The bacteria may produce an arteritis with swelling and necrosis of the adjacent musculature and a reactive infiltration of polymorphonuclear leukocytes Similar foci of necrosis and leukocytes may be the result of bacterial toxins Small or large macroscopic abscesses may result by contiguity from suppuration of the pericardium or endocardium by septic embolization of the coronary vessels with local infarction and softening of the myocardial tissue or by direct bacterial infection through the blood stream Rarely large abscesses develop and may rupture a papillary muscle perforate the interventricular septum or heart or break into the pericardium and cause a suppurative pericarditis

The *gross appearance* of the heart usually presents no characteristic change even though surprisingly diffuse and sometimes severe lesions may be discovered microscopically Sometimes the musculature is soft and flabby and may have a dull parboiled or glassy appearance With suppurative myocarditis miliary abscesses may be seen as yellow dots or streaks surrounded by a reddish zone which yield a drop of pus when cut Cardiac dilatation and hypertrophy may be associated with acute myocarditis especially in cases with congestive heart failure Endocardial (mural) thrombi are found in occasional cases of acute myocarditis

Clinical Picture

There are often no clinical features associated with acute myocarditis as seen pathologically Sometimes the clinical features when present are indistinguishable from and overshadowed by those of the primary disease or of an associated endocarditis or pericarditis or by the manifestations of peripheral circulatory failure The evidences of acute myocarditis may be (1) general symptoms (2) cardiac signs (3) electrocardiographic changes (4) congestive heart failure and (5) embolism

1 **General Symptoms.** These are non specific and include fever leukocytosis weakness palpitation precordial pain and tachycardia They may be due to the primary disease as well as to the myocarditis Tachycardia out of proportion to the fever is suggestive of myocarditis especially in cases of rheumatic fever On the other hand the tachycardia may be evidence of peripheral circulatory failure due to toxemia and especially during convalescence it may be evidence of a labile vasomotor system or of an irritable heart Bradycardia may be present with myocarditis especially in some cases of diphtheria with heart block

2 **Cardiac Signs** A softening or diminution of the first sound has been noted as an early sign of myocarditis[34] The first sound may become indistinguishable from the second sound resulting in a tic tac rhythm (embryocardia) An apical systolic murmur occurs frequently Tachycardia is common These are all inconclusive evidences of myocarditis being frequently present in febrile and toxic states without myocardial lesions A gallop rhythm is indicative of cardiac failure and in the absence of preexisting heart disease suggests a myocarditis if it appears in the course of an acute infection Under the same circumstances cardiac enlargement may indicate the presence of acute myocarditis

3 **Electrocardiographic Changes.** As a result of more frequent electrocardiographic examinations of patients with infectious diseases the incidence of myocarditis is believed to be much higher than was formerly thought Fine et al[35] found abnormalities in serial electrocardiograms which they interpreted as denoting myocarditis in one third of 84 patients suffering from a variety of infectious diseases However it is doubtful whether the electrocardiographic changes are caused by the anatomic alterations observed at autopsy It is more probable that the former are due to electrolyte disturbances especially in potassium to changes in acid base balance or to metabolic or enzymatic disturbances in the

myocardium produced by the primary infection or toxic agent

A variety of *electrocardiographic changes* has been described These will be discussed more fully under the individual diseases Most often there are elevation or depression of the RS T interval, flattening or inversion of the T wave prolongation of the P R interval, or more severe grades of heart block Sinus bradycardia occurs occasionally while extrasystoles are common Atrial fibrillation and flutter may occur, but usually in patients with preexisting cardiac disease The electrocardiographic changes are usually transient and of brief duration but not infrequently persist for several weeks after convalescence

4 **Cardiac Failure** The occurrence of acute myocarditis may be accompanied by the symptoms and signs of cardiac failure Congestive heart failure occurs only occasionally as a result of myocarditis alone except in rheumatic fever On the other hand, congestive heart failure is not infrequently precipitated by an acute infection in patients with preexisting heart disease, usually without a superimposed acute myocarditis Thus the development of congestive heart failure during an infection suggests an acute myocarditis only if there is no associated organic heart disease

More often, acute infections, especially when associated with severe toxemia cause peripheral circulatory failure (shock) This may occur without any significant damage to the myocardium Clinically the patient appears pale and faintly cyanotic and the skin has a grayish hue The extremities and nose are cold and often clammy with perspiration The pulse is rapid, weak and thready The blood pressure and usually the venous pressure also are low The superficial veins are often collapsed Respirations may be rapid but dyspnea is usually absent The exact pathogenesis of this type of failure is still uncertain but except in cases of diphtheritic myocarditis it is not usually the result of acute myocarditis Occasionally both congestive heart failure and shock are associated in the same patient Sudden death has been repeatedly noted in cases of myocarditis complicating acute infections, often following a brief period of heart failure or shock

5 **Pulmonary or other embolism** may complicate cases of myocarditis in which mural thrombosis occurs

Prognosis

This is discussed in connection with the *individual causative diseases*

Treatment

Prolongation of bed rest is indicated when myocarditis complicates an infection Other therapeutic measures are determined by symptoms and particularly by the development of congestive heart failure

ACUTE ISOLATED MYOCARDITIS

An acute *interstitial myocarditis*, of unknown etiology, characterized by a distinctive clinical and pathologic picture was described by Fiedler[33] It is often termed Fiedler's myocarditis Because the inflammatory lesions are limited to the myocardium, while the endocardium and pericardium are unaffected it has also been termed acute *isolated* interstitial myocarditis Primary myocarditis denotes that it is not apparently secondary to any other known causative agent or disease Idiopathic is another descriptive adjective applied to this disease because of the unknown etiology The first two cases in the American literature were described by Scott and Saphir[90] and subsequent studies were reported by Marcuse[69] and others It is doubtful whether the cases included in this category form an etiologic pathologic or clinical entity

Etiology

The cause of this form of acute myocarditis is unknown According to strict criteria, no case belongs under this classification if it follows closely upon an infectious disease or if there is evidence of hypertension, coronary disease previous rheumatic fever or any other known cause of heart disease *But a* history of antecedent respiratory infection or a concurrent respiratory infection is common Most cases occur in the third decade, but some have been reported at diverse age levels from childhood to old age A predominance of males has been noted [redacted]

A variety of causative agents or mechanisms have been postulated to account for these cases of idiopathic myocarditis, including a virus[89] and unknown bacterial toxins Recent pathologic and experimental observations have suggested that the myocarditis may represent an allergic reaction, particularly hypersensitivity to the sulfonamide drugs or penicillin[102] Myocarditis has been reported due to the administration of

serum[71, 75] and to arsphenamine sensitivity.[15] French and Weller[22] reported histologically proven interstitial myocarditis in 55 per cent of 227 patients given sulfonamides in their final illness. The lesions were characterized by eosinophilic cellular infiltrations and by the occurrence of large mononuclear cells of the clasmatocyte type. Similar lesions were produced in the experimental animal by the administration of sulfonamides. However, Fawcett[32] observed no difference in the incidence of interstitial myocarditis before or after the advent of sulfonamide drugs. Nor did he find any evidence that the administration of these compounds shortly before a patient's death was associated with either an increase in the total number of myocardial interstitial cells or an excess of a particular type of cell.

Pathology

The heart is usually dilated and hypertrophied, often strikingly so. Heart weights between 500 and 700 gm. are not uncommon, but the heart may be of normal size.[44] The heart muscle often appears pale and is studded with irregular, yellowish or gray streaks or dots. It may be soft and friable. The pericardium and endocardium are not involved, but intramural thrombi are frequently encountered. The coronary arteries are normal.

Microscopically there is a widespread infiltration of cells in the interstitial tissue. The nature of the cells differs somewhat in the various cases, but they are usually neutrophilic or eosinophilic leukocytes or lymphocytes. Endothelial cells, plasma cells and fibroblasts are also observed, and may predominate. Sometimes the inflammatory changes are characterized by granulomatous infiltrates with giant cells (giant cell myocarditis). There may be evidence of granulation tissue and early reparative changes. The muscle fibers may disclose edema and degenerative alterations, but these are relatively slight. Although the interstitial changes are far more prominent, they may represent a reaction to metabolic, allergic or toxic disturbances in the muscle fibers.

Clinical Features

Often there are no significant symptoms and the diagnosis is made on histologic examination.[49] When cardiac symptoms are manifested, the characteristic clinical picture is one of rapidly progressive congestive heart failure. The onset may be gradual or acute. As a rule, in the beginning fever is absent or only slight. The remainder of the course is one of low fever alternating with afebrile periods. Moderate or high fever may occur toward the end of the disease, less commonly at the outset. Rarely there is a septic febrile course resembling that of bacterial endocarditis. Blood cultures are negative. In a few cases the onset and course resemble those of myocardial infarction,[3, 44] but there is much doubt in at least some of these cases whether they properly belong to the group under discussion.

The outstanding symptoms are dyspnea and weakness. Mild precordial oppression and palpitation are not uncommon. The patient is often apprehensive. There may be a grayish cyanosis of the skin. Eventually there are classic signs of congestive heart failure, including gallop rhythm, enlargement of the liver, peripheral subcutaneous edema, congestion of the superficial veins and occasionally effusions in the serous cavities. Sudden death may occur. The clinical picture may begin with or be complicated by embolization of the pulmonary or cerebral vessels. Hemiplegia and cough with bloody expectoration have been observed.[10] Emboli probably arise in the intramural cardiac thrombi mentioned above. Infarcts of the kidney and lungs have been found at postmortem examination.

The heart is usually enlarged, often considerably so. The heart sounds may be muffled and there may be an apical systolic murmur. Freundlich[33] found the circulation time considerably prolonged and the venous pressure extremely elevated. Extrasystoles are not uncommon and atrial fibrillation has been reported.

The electrocardiogram may reveal no significant abnormalities. Occasionally, as first noted by de la Chapelle and Graef,[19] conduction defects may be disclosed by a prolonged P-R interval and intraventricular block.

The leukocyte count is often normal, especially in the cases with little or no fever, but leukocytosis is not uncommon at some stage of the disease.

Course and Prognosis

The course is unfavorable: cardiac failure is progressively more severe and almost always there is a fatal outcome within a period of weeks or months. In the cases of isolated myocarditis studied by Jaffé[34] in Venezuela, the heart failure followed a

chronic course lasting months or years Idiopathic isolated myocarditis with progressive fatal course but of subacute or chronic duration has also been reported by Boikan[13] and by Franz[37] About 15 per cent of the patients die suddenly[43] the clinical picture being that of acute cardiac failure with pulmonary edema When an occasional patient is said to have survived there is always uncertainty as to the diagnosis since definite proof of the diagnosis requires pathologic examination

Diagnosis

The clinical diagnosis should be suspected when congestive heart failure occurs in a person without evidence of congenital valvular, hypertensive or coronary (atherosclerotic) heart disease and without a history of rheumatic fever or a preceding infection in whom no other known cause of cardiac disease can be discovered A rapidly fatal course is confirmatory evidence

The *treatment* is that of congestive heart failure and is symptomatic Corticosteroid hormones (e g prednisone) should be given a therapeutic trial[40]

IDIOPATHIC HYPERTPOPHY OF THE HEART

A variety of cases of cardiac hypertrophy of obscure origin have been classified under the heading of idiopathic cardiac hypertrophy As our knowledge has increased cases of so-called idiopathic cardiac hypertrophy have been separated from this category and assigned to definite causes such as hypertension congenital lesions (p 784) and glycogen cardiomegaly (p 786) Chronic severe anemia beriberi pulmonary lesions and congenital anomalies of the coronary arteries are among other causes of cardiac hypertrophy which have sometimes been overlooked in the past

Congenital Idiopathic Hypertrophy (p 784)

Idiopathic Cardiac Hypertrophy in Adults

There is a motley group of cases characterized by cardiac hypertrophy and eventually by progressive congestive heart failure not due to any of the known causes of cardiac disease or cardiac hypertrophy[11] These are presently classified as idiopathic cardiac hypertrophy There are many resemblances to some of the cases described under congenital cardiac hypertrophy (p 784) but these cases occurring in adults are not regarded as of congenital origin They differ from the cases of idiopathic myocarditis with hypertrophy by the absence of inflammatory changes except focal reactions to necrotic muscle (See also glycogen storage disease of the heart p 786)

Pathology The outstanding pathologic finding is cardiac hypertrophy, but mural thrombi in either or both ventricles endocardial fibrosis degenerative necrotic and fibrotic myocardial changes are frequent associated findings In addition pulmonary emboli and infarcts and visceral congestion due to heart failure are commonly observed Cases of this type have been described under varying headings depending on the outstanding feature e g, cardiac hypertrophy of uncertain etiology in young adults,[67, 93, 28] myocardial hypertrophy of unknown etiology associated with congestive heart failure,[54] myocardial disease of obscure origin[100, 19] fibrosis of the endocardium and the myocardium with mural thrombosis[94] cardiovascular collagenosis with parietal endocardial fibrosis[8] Some of these cases appear to represent an adult form of endocardial fibroelastosis (p 637)

Etiology As indicated, the etiology is unknown The disease has been attributed in some cases to thiamine deficiency, i e, it has been interpreted as a form of beriberi heart[94] but the nutritional history, the high cardiac output the associated neurologic features and the response to thiamine administration seen in beriberi heart disease are not observed in idiopathic cardiac hypertrophy Idiopathic hypertrophy in this country presents many of the features of a common disease in Africans kwashiorkor (p 1037) thought to be due to malnutrition and/or vitamin deficiency[9, 49, 4]

Clinical Features The cases of idiopathic hypertrophy that I have observed concerned young or middle aged adults usually Negroes The outstanding clinical features were cardiac enlargement progressive and usually intractable heart failure and pulmonary embolization

Diagnosis The diagnosis was suggested by the inability to find evidence of the usual forms of heart disease in a patient with a very large heart and relatively recent and intractable heart failure There was no history of hypertension, the systolic blood pressure was relatively low and the pulse pressure often considerably reduced In other cases there was

a tendency to diagnose coronary heart disease but there was no history of angina pectoris or myocardial infarction and no distinctive electrocardiographic changes to suggest previous *myocardial infarction* In younger adults rheumatic heart disease was usually suggested and sometimes this was supported by the presence of a systolic murmur But there was neither history of a previous cardiac murmur nor evidence of the usual distinctive lesions of rheumatic valvular disease and the cardiac configuration was not that of mitral insufficiency In the absence of these or other distinctive types of cardiac disease idiopathic hypertrophy was suggested In the group of 9 cases reported by Davies et al [19] the problem was one of differentiation from pericardial disease because of the marked cardiac enlargement low pulse pressure paradoxical pulse and distant heart sounds Palpitation associated with arrhythmias was a major complaint in 2 cases and left bundle branch block was present in 4

In cases of congestive heart failure and cardiomegaly without apparent cause one must consider a variety of causes before a diagnosis of idiopathic hypertrophy is made viz hyperthyroidism periarteritis nodosa scleroderma amyloidosis sarcoidosis lupus erythematosus hemochromatosis myocarditis neoplasm

Levy and von Glahn[55] reported 10 instances in young adults of cardiac hypertrophy of unknown etiology In all there were symptoms of cardiac failure The heart sounds were weak and gallop rhythm was frequently present There were no murmurs of valvular disease In some there was electrocardiographic evidence of myocardial damage *and arrhythmias Infarction of the lungs* kidneys or spleen was frequent Death was due to progressive or recurrent cardiac failure in 7 patients and occurred suddenly in 3 At necropsy there was striking cardiac hypertrophy the average heart weight being 563 gm There was no significant coronary artery disease *or arteriolar sclerosis In 4 cases* microscopic examination of the heart revealed only hypertrophy in 2 a slight increase in connective tissue but in the remaining 4 there was extensive scarring with or without recent necrosis There were mural thrombi in six of the hearts In the cases of Flynn and Mann[26] which were characterized by endocardial and subendocardial degeneration mural thrombi and heart failure were associated with well known etiologic causes of heart disease In 8 cases of cardiac hypertrophy of obscure cause reported by Ware and Chapman [101] there was a chronic fibroplastic myocarditis characterized by extensive replacement of myocardial fibers by fibrous tissue Norris and Pote[76] reported 4 fatal cases of heart failure associated with unexplained hypertrophy of the heart in young men *Evans[23] described a familial type of cardiomegaly* in young adults not unlike the cases described by Levy and von Glahn Three similar cases of familial cardiomegaly were reported by Gaunt and Lecutier [30] In 10 *cases from the postmortem files of* The Mount Sinai Hospital New York [4] there were 7 *males and 3 females with ages ranging from 24* to 53 The clinical course was characterized by right and left sided heart failure with cardiomegaly and hepatomegaly in all pulmonary infarction with hemoptysis in 6 hydrothorax in 6 gallop rhythm in 6 and loud systolic murmurs in 4

Right Cardiac Hypertrophy and Endocardial Thrombosis of Obscure Origin (Primary Pulmonary Hypertension?)

Recent interest has been attracted to cases of idiopathic hypertrophy confined to or affecting *predominantly the right cardiac* chambers All known causes of right cardiac hypertrophy had been excluded in these cases by both clinical and microscopic examination Reports of cases of idiopathic hypertrophy of the right heart have been made by Oppenheimer [78] de Navasquez et al East [4] Armstrong[2] and Rosenbaum[81] *among others* The patients were predominantly females of all ages There was a *history of progressive* dyspnea later associated with cough cyanosis and advanced right sided heart failure In some cases there was a systolic pulsation and a systolic murmur over the pulmonic area and an accentuated second pulmonic sound *Roentgenologic examination* disclosed dilatation *of the pulmonary arteries and right* ventricular enlargement The *electrocardiogram* disclosed evidence of right ventricular strain and in some instances right atrial enlargement and right bundle branch block In almost all cases death occurred from congestive heart failure At autopsy there was predominant *or isolated hypertrophy of the right atrium*

chronic course lasting months or years. Idiopathic isolated myocarditis with progressive fatal course but of subacute or chronic duration has also been reported by Boikan[13] and by Franz.[37] About 15 per cent of the patients die suddenly,[41] the clinical picture being that of acute cardiac failure with pulmonary edema. When an occasional patient is said to have survived, there is always uncertainty as to the diagnosis, since definite proof of the diagnosis requires pathologic examination.

Diagnosis

The clinical diagnosis should be suspected when congestive heart failure occurs in a person without evidence of congenital, valvular, hypertensive or coronary (atherosclerotic) heart disease and without a history of rheumatic fever or a preceding infection, in whom no other known cause of cardiac disease can be discovered. A rapidly fatal course is confirmatory evidence.

The *treatment* is that of congestive heart failure and is symptomatic. Corticosteroid hormones (e.g., prednisone) should be given a therapeutic trial.[83]

IDIOPATHIC HYPERTPOPHY OF THE HEART

A variety of cases of cardiac hypertrophy of obscure origin have been classified under the heading of idiopathic cardiac hypertrophy. As our knowledge has increased, cases of so-called idiopathic cardiac hypertrophy have been separated from this category and assigned to definite causes such as hypertension, congenital lesions (p. 784) and glycogen cardiomegaly (p. 786). Chronic severe anemia, beriberi, pulmonary lesions and congenital anomalies of the coronary arteries are among other causes of cardiac hypertrophy which have sometimes been overlooked in the past.

Congenital Idiopathic Hypertrophy (p. 784)

Idiopathic Cardiac Hypertrophy in Adults

There is a motley group of cases characterized by cardiac hypertrophy and eventually by progressive congestive heart failure not due to any of the known causes of cardiac disease or cardiac hypertrophy.[91] These are presently classified as idiopathic cardiac hypertrophy. There are many resemblances to some of the cases described under congenital cardiac hypertrophy (p. 784), but these cases occurring in adults are not regarded as of congenital origin. They differ from the cases of idiopathic myocarditis with hypertrophy by the absence of inflammatory changes except focal reactions to necrotic muscle. (See also glycogen storage disease of the heart, p. 786.)

Pathology. The outstanding pathologic finding is cardiac hypertrophy, but mural thrombi in either or both ventricles, endocardial fibrosis, degenerative, necrotic and fibrotic myocardial changes are frequent associated findings. In addition, pulmonary emboli and infarcts and visceral congestion due to heart failure are commonly observed. Cases of this type have been described under varying headings depending on the outstanding feature, e.g., cardiac hypertrophy of uncertain etiology in young adults,[4, 93] myocardial hypertrophy of unknown etiology associated with congestive heart failure,[8] myocardial disease of obscure origin,[109, 11] fibrosis of the endocardium and the myocardium with mural thrombosis,[94] cardiovascular collagenosis with parietal endocardial fibrosis.[5] Some of these cases appear to represent an adult form of endocardial fibroelastosis (p. 637).

Etiology. As indicated, the etiology is unknown. The disease has been attributed in some cases to thiamine deficiency, i.e., it has been interpreted as a form of beriberi heart,[98] but the nutritional history, the high cardiac output, the associated neurologic features and the response to thiamine administration seen in beriberi heart disease are not observed in idiopathic cardiac hypertrophy. Idiopathic hypertrophy in this country presents many of the features of a common disease in Africans, kwashiorkor (p. 1037), thought to be due to malnutrition and/or vitamin deficiency.[2, 43, 4]

Clinical Features. The cases of idiopathic hypertrophy that I have observed concerned young or middle-aged adults, usually Negroes. The outstanding clinical features were cardiac enlargement, progressive and usually intractable heart failure, and pulmonary embolization.

Diagnosis. The diagnosis was suggested by the inability to find evidence of the usual forms of heart disease in a patient with a very large heart and relatively recent and intractable heart failure. There was no history of hypertension, the systolic blood pressure was relatively low and the pulse pressure often considerably reduced. In other cases there was

be subcutaneous edema hydrothorax and ascites Loss of ventricular distensibility with consequent limitation in diastolic volume may lead to hemodynamic disturbances and clinical features similar to those of constrictive pericarditis[45, 70]

The *electrocardiogram* usually discloses abnormalities but none that are specific for amyloidosis The most frequent changes include atrial fibrillation low voltage of the QRS and T waves and prolongation of the P R interval or complete atrioventricular dissociation[105, 33] QS complexes in right precordial leads suggestive of old anteroseptal infarction and electrical alternation of the *P waves were observed in one case of cardiac* amyloidosis[9b]

Pathologically the amyloid forms grayish nodules or diffuse thickening which causes a leathery rigidity and enlargement of the walls of the ventricles and atria[11] Frequently the amyloid affects the valves and may produce nodules and rigid thickening which interfere with valvular function[98] The coronary arteries as well as smaller vessels may be affected occasionally amyloid infiltration contributes to the coronary narrowing

Congestive heart failure is due chiefly and *most commonly to extensive myocardial in*volvement by amyloid which compresses and damages the muscle fibers and interferes with contraction and relaxation However coronary artery involvement with narrowing of these vessels valvular infiltration with consequent insufficiency and stenosis or extreme infiltration and narrowing of the small pulmonary arteries with secondary chronic cor pulmonale[33] are among occasional causes of congestive heart failure in primary amyloidosis

The *diagnosis* of amyloid disease of the *heart is to be considered in the presence of* cardiac enlargement or heart failure without apparent cause A supporting clue may be found in associated amyloid deposits proven by biopsy e g in the skin simulating scleroderma in the tongue causing macroglossia or tumor formation in the muscle simulating myotonia or occasionally in the *tissues about the joints larynx and other* sites or in the presence of multiple myeloma A Congo red test may be helpful but this may be negative in the primary type of amyloidosis in which the liver is not involved Gum biopsies frequently disclose the presence of amyloid In a patient known to have amyloidosis but none of the common cardiac diseases the presence of low voltage of QRS and T conduction disturbance or atrial fibrillation suggests cardiac involvement by the amyloid

Treatment of primary amyloidosis involving the heart is unsatisfactory In the presence of congestive heart failure the usual therapeutic measures should be employed (p 234)

SARCOIDOSIS

Sarcoidosis is a chronic granulomatous disease whose lesions resemble those of noncaseating tuberculosis but is usually as*sociated with a negative tuberculin reaction* It may affect the heart by causing right heart strain secondary to extensive pulmonary involvement (p 978) or rarely by direct myocardial involvement

Sarcoidosis produces yellowish circumscribed or diffuse tumor like infiltrations of the heart which consist of granulomata containing very large giant cells as well as epithelioid and plasma cells and lymphocytes but no polymorphonuclear leukocytes Diffuse extensive fibrosis may predominate over scattered giant cell granulomata[1] Myocardial damage may be caused by *the active granulo*mata or by subsequent scarring and replacement of muscle fibers

Sarcoidosis of the myocardium may be asymptomatic but congestive heart failure is not unusual[62] In 6 of a series of 31 patients studied by Longcope and Fisher[63] there was evidence of myocardial insufficiency during life or sarcoidosis of the heart was discovered at autopsy In 5 of the cases with heart failure there were also enlargement of the heart arrhythmia and electrocardiographic changes In the cases reported by Bates and Walsh[7] *there was extensive myocardial sarcoidosis* but tachycardia was the only clinical symptom Sudden death may occur[98]

Electrocardiographic abnormalities[62, 88] consist of prolonged P R interval bundle branch block prolonged QRS ST segment depressions flat or inverted T waves and occasional prominent P waves

The *diagnosis* of cardiac sarcoidosis is suggested by heart failure of obscure origin in a patient proven to have sarcoidosis (lymph node biopsy positive Nickerson Kveim test) but with insufficient pulmonary lesions to account for the heart failure

LUPUS ERYTHEMATOSUS (See p 633)

Although the epicardium and endocardium are most strikingly involved the myocardium also contains microscopic lesions in many cases[11] The lesions consist of fibrinoid necrosis of the supporting structures and of the blood vessels with secondary myocardial degeneration and fibrosis Occasionally there is a clinical picture of angina pectoris and there may be electrocardiographic changes simulating acute myocardial infarction[99] More commonly there are non specific T wave changes and changing P R interval or RS T and T wave changes due to an associated pericarditis Congestive heart failure may occur in one quarter of the cases of lupus erythematosus[3] but usually only toward the end of the clinical course Gallop rhythm occurs commonly before there is overt evidence of congestive heart failure

NECROTIZING ANGIITIS

Myocardial lesions occur in periarteritis nodosa and in related forms of necrotizing angiitis Myocardial infarction secondary to necrotizing arteritis of the coronary arteries has been mentioned (p 440) Cardiac enlargement and heart failure may be secondary to severe or malignant hypertension which occurs in many cases of periarteritis nodosa Necrotizing angiitis (hypersensitivity angiitis) with involvement of the small coronary vessels and secondary miliary infarcts may result from the administration of drugs or foreign proteins The occurrence of another variant allergic granulomatous angiitis with giant cell granulomatous myocarditis has been mentioned (p 620)

MYOTONIA ATROPHICA

This is a familial disease characterized by increased muscle tone atrophy of muscles (face neck, thigh forearm hand), dimpling of tongue when the lower teeth are struck by a hammer cataract formation premature baldness, testicular atrophy and impotence It may represent a later stage of myotonia congenita of Oppenheim[88]

Maas and Zondek[67] first called attention to cardiac involvement in this disease Mondon and Pasquet[73] and Romano and Michael[80] emphasized the frequency of cardiovascular abnormalities especially coronary atherosclerosis but the electrocardiographic abnormalities to be described are probably not due to coincident coronary disease[3] Evans[7] described the cardiac findings in 13 cases of myotonia atrophica The electrocardiogram disclosed a prolonged P R interval, low voltage of the P waves slurring of the QRS left axis deviation and bundle branch block In two cases there were breathlessness and cardiac enlargement but no other signs of heart failure Atrioventricular dissociation with Adams-Stokes syndrome has been described[6] Conduction defects and cardiac arrhythmias are the commonest electrocardiographic abnormalities[85] The first sound at the apex may be split In other cases bradycardia hypotension, depression of ST segments and inversion of T waves with little or no cardiac enlargement have been noted[79] In the case studied by Black and Ravin[1] the R T segment was elevated in leads I and II There may be a triple rhythm Quinine may afford some relief to the myotonia, but does not alter the progress of the disease

FRIEDREICH'S ATAXIA

Attention has been called in the French and British literature to the finding of cardiac lesions and electrocardiographic changes in individuals suffering from Friedreich's hereditary ataxia Russell[83] and Manning[65] described pronounced cardiac hypertrophy, fatty and eosinophilic degeneration and lymphocytic interstitial myocarditis in children and young adults with Friedreich's disease some of whom died of heart failure Evans and Wright[28] observed complete heart block and bundle branch block or RS-T and T wave changes resembling those seen in cases of myocardial infarction Lorenz et al[64] described the cases of 5 siblings with similar cardiac findings Angina pectoris has been reported[97]

PROGRESSIVE MUSCULAR DYSTROPHY

Myocardial fibrosis and mild degenerative and inflammatory changes somewhat similar to those in the skeletal muscle have been observed in the hearts of individuals with progressive muscular dystrophy[10, 77] There is usually an increase in fatty and fibrous tissue with hypertrophy or atrophy of the myocardial fibers and vacuolar and other degenerative changes in these fibers[98] The incidence of cardiac involvement has been reported to vary between 50 and 85 per cent[9]

In many cases tachycardia arrhythmia or heart failure had been present [82, 85, 78] Sudden death may occur [3] There may be a shortening of the P R interval and abnomal Q waves P wave abnormalities are frequent The occurrence of electrocardiographic changes in a case of progressive muscular dystrophy suggests involvement of the heart by the same histologic changes found in the skeletal muscle [103] However according to Grandell [43] dystrophic myocardial involvement is uncommon in progressive muscular dystrophy and electrocardiographic and ballistocardiographic abnormalities are usually due to other causes

GARGOYLISM (LIPOCHONDRODYSTROPHY)

This is a rare generalized storage disease of infancy and childhood characterized by the deposition of a macromolecular glycoprotein In the majority of autopsies in gargoylism there is gross or microscopic evidence of cardiovascular disease [80] There is diffuse involvement of the myocardial connective tissue especially that of the valves and coronary arteries Cardiac failure is the common cause of death [58]

FATTY INFILTRATION OF THE HEART (FATTY HEART LIPOMATOSIS CORDIS)

Fatty heart denotes an excessive deposition (infiltration) of normal fat chiefly in the subepicardium of the anterior wall of the right ventricle with extension into and replacement of the subjacent myocardium Occasionally the left ventricle atria and bundle of His may be involved Fatty heart occurs in the markedly obese and was said to occur in heavy beer drinkers Occasionally clinical heart disease e g angina pectoris is found in the absence of any significant cardiac finding except severe fatty infiltration [13]

ATROPHY OF THE HEART

Atrophy of the heart[47] denotes an acquired reduction in size and weight of the heart This occurs with inanition particularly in association with malignant neoplasms and chronic infections In addition to its small size and diminished weight the heart is characterized by increased pigmentation of the muscle fibers decreased size of the fibers with a relative increase in the nuclei wrinkling of the pericardium with serous atrophy of the subepicardial fat and tortuosity of the coronary arteries Although apical systolic murmurs are frequently associated and the electrocardiogram may show low voltage of the QRS complex and T wave and prolongation of the P R and Q T intervals the atrophic heart is competent for the needs of the individual concerned Atrophy of the heart is a reversible pathologic change not a clinical disease

Chapter 25

ENDOCARDITIS AND ENDOCARDIAL DISEASE

DEFINITION

Endocarditis in its narrowest sense refers to exudative and proliferative inflammatory alterations of the inner lining of the heart. The term was first introduced by Bouillaud.[4] Sometimes the term endocarditis is applied rather loosely to a number of simple thrombotic or degenerative lesions of the endocardium. *Endocarditis most frequently involves* the valvular endocardium but it may also affect the inner lining of the cardiac chambers (parietal or mural endocarditis) or the endocardium of the chordae tendineae papillary muscles or trabeculae carneae.

CLASSIFICATION

Endocarditis is merely a general pathologic anatomic diagnosis which does not reveal the different etiologic factors concerned. A complete diagnosis should also include the causative bacterial agent or the general disease of which the endocarditis is a part. According to the studies of Libman[35] and of Friedberg and Gross[15] endocarditis may be classified as

1. Acute and subacute bacterial endocarditis
2. Rheumatic endocarditis
3. Atypical verrucous endocarditis of Libman Sacks disease (lupus erythematosus)
4. Non bacterial thrombotic endocarditis (terminal or cachectic endocarditis thromboendocarditis or non bacterial thrombosis of the endocardium)
5. Syphilitic endocarditis
6. Tuberculous endocarditis
7. Unclassified

In addition there are a number of degenerative alterations of the endocardium which may be primary or superimposed on a pre existing endocarditis. These degenerative changes include endocardial fibroelastosis or sclerosis calcification or rarely ossification fatty degeneration mucoid softening and amyloidosis.

Endocarditis may be one element of a more extensive cardiac disease in which the myocardium pericardium or both are simultaneously involved. Sometimes the endocarditis is only one feature of a generalized disease in which it may be the primary factor determining the clinical picture or merely a secondary element with or without significant *clinical manifestations. For these reasons the* main forms of endocarditis such as the bacterial and rheumatic are discussed separately and in detail in connection with etiologic diseases of which they are a part. Syphilitic and tuberculous endocarditis are rare and unimportant and are considered briefly in connection with other syphilitic and tuberculous lesions of the heart. The purpose of this chapter is to provide an orientation to the different forms of endocarditis.

It is important to distinguish endocarditis itself from the end results or complications of endocarditis. The latter include valvular defects and emboli. Valvular defects arise because of the thickening shortening fixation and deformity of the cusps and chordae tendineae resulting from organization fibrosis contraction and adhesions which represent healing of the inflammatory process. These by preventing proper apposition opening and closing of the valve cusps produce valvular stenosis or insufficiency. Emboli result from the detachment of particles of friable verrucae (usually containing bacteria) or of parietal endocardial thrombi which may develop at the site of parietal endocarditis. The formation of atrial or ventricular mural thrombi is facilitated by the presence of endocarditis at the sites involved.

GENERAL PATHOLOGY OF ENDOCARDITIS

The pathology of endocarditis is characterized by the presence of verrucae on the surface of the endocardium and by changes in the endocardium itself.

1 Verrucae

Superficial excrescences or vegetations termed *verrucae* (Laennec) situated usually on the surface of the valvular endocardium but occasionally also on the parietal endocardium, constitute the most obvious feature of endocarditis The examination of slides containing stained crushings of the verrucae divides the endocarditides into two major groups the bacterial and the non bacterial The vegetations of bacterial endocarditis reveal *numerous* organisms in such spreads except in the healed stages Cultures from the vegetations may help to identify the causative organism but postmortem cultures are not always reliable [14] If there are no bacteria in the vegetations they are due to rheumatic endocarditis healed bacterial endocarditis atypical verrucous endocarditis (Libman Sacks disease) or non bacterial thrombotic endocarditis

The *size of the vegetation* is not a reliable means of differentiating the various forms of endocarditis Minute yellowish soft vegetations about 0 5 to 2 mm in diameter situated in beadlike fashion along the closure line of the cusps are usually rheumatic But terminal acute bacterial endocarditis or terminal non-bacterial thrombotic endocarditis may produce vegetations of similar size and location Usually the bacterial vegetations are larger than the rheumatic averaging about 5 mm in size When multiple they may be as small as 1 or 2 mm, while occasionally there are isolated vegetations 1 to 2 cm in diameter or even larger The non bacterial thrombotic verrucae may be as small as the usual rheumatic vegetation or may form larger conglomerate masses or stalked polyps The huge irregular ulcerated or purulent cauliflower vegetations which are occasionally observed generally represent acute bacterial endocarditis Sometimes the bacterial vegetations are greatly enlarged by the accretion of currant jelly clot to their ulcerated surface When situated on the mitral valvular endocardium they may enhance or produce a mitral stenosis or act as a ball valve thrombus to occlude completely the mitral orifice The vegetations in atypical verrucous endocarditis may be indistinguishable in size from rheumatic verrucae they may form massive conglomerate lesions or they may be of the flat spreading variety which covers a considerable portion of the valvular surface

The *location and distribution* of the vegetations may be diagnostically suggestive Definite elevated verrucae on the posterior wall of the left ventricle are usually bacterial, mostly of the subacute variety The presence of mural endocardial lesions (except minute ones in the left atrium) practically excludes a rheumatic etiology and suggests bacterial endocarditis or atypical verrucous endocarditis Verrucae situated exclusively or chiefly on the tricuspid leaflets without simultaneous lesions on the aortic leaflet usually represent atypical verrucous or bacterial endocarditis Verrucae which are situated only or predominantly in the pockets of the atrioventricular valves and the adjacent ventricular myocardium are almost always due to atypical verrucous endocarditis Vegetations which are associated with ulceration and aneurysm of the cusps and rupture of the chordae tendineae are bacterial in origin If there is complete perforation of a cusp it is more likely due to acute than to subacute bacterial endocarditis The non bacterial thrombotic vegetations, like the rheumatic, are limited essentially to the atrial surface of the atrioventricular cusp and to the ventricular surface of the semilunar cusps they affect the mitral aortic tricuspid and pulmonic valves in that order of frequency individually or in combination

Bacterial vegetations may occur simultaneously with non bacterial vegetations in the same heart and even on the same cusps Thus subacute bacterial endocarditis is frequently superimposed on an active rheumatic endocarditis and an acute terminal bacterial endocarditis is a common complication of the atypical verrucous endocarditis of Libman Sacks disease (disseminated lupus erythematosus)

2 Changes in the Endocardial Substance

The inflammatory changes in the endocardium itself are often the essential feature of endocarditis although their macroscopic appearance is less striking than that of the verrucae Valvular endocarditis especially in rheumatic fever, but occasionally also in Libman Sacks disease, may occur without the formation of verrucae Even when verrucae are present on one or more of the valves a valvulitis without verrucae may be found on the others An atrial endocarditis is almost always found in association with acute rheumatic heart disease but overlying ver

rucae are usually absent or barely visible

The most intense inflammatory reaction is found in rheumatic endocarditis (see below) Beginning in the ring of the cusp it extends a short way or more often to the closure line or tip The inflammatory reaction is both proliferative and exudative the valve is vascularized and organization occurs early Necrosis is absent On the other hand, in the acute bacterial endocarditis valvular necrosis is a prominent feature while inflammatory reaction is scant except for polymorphonuclear leukocytes within the vegetation and in the immediate vicinity of necrotic areas Subacute bacterial endocarditis produces a lesser degree of necrosis and a greater degree of inflammatory reaction the latter being characterized by the infiltration and proliferation of mononuclear cells The valves in atypical verrucous endocarditis may or may not suffer some necrosis An inflammatory reaction tends to be located near both surfaces of the cusps and near the pocket of the valve Plasma cells large mononuclear cells and endothelial bud capillaries are prominent features In nonbacterial *thrombotic endocarditis* the cusps are strikingly free from acute inflammatory change but in most instances they are thickened and deformed by considerable fibrous tissue representing chronic healed rheumatic endocarditis

General Pathogenesis of Endocarditis

The etiology and pathogenesis of endocarditis are discussed in connection with the individual forms of endocarditis

CHARACTERIZATION OF INDIVIDUAL FORMS OF ENDOCARDITIS

Bacterial Endocarditis (Chapter 34)
Rheumatic Endocarditis (Chapters 31–33)

ATYPICAL VERRUCOUS ENDOCARDITIS (LIBMAN SACKS DISEASE) (ACUTE DISSEMINATED LUPUS ERYTHEMATOSUS)

This is a form of endocarditis with nonbacterial verrucae which are usually macroscopically different from rheumatic verrucae and which were first described in 4 cases of a fatal febrile disease reported by Libman and Sacks[36] The latter is a clinical pathologic entity which is now generally termed acute disseminated *lupus erythematosus*[35] The endocardial verrucae are frequently absent and are not significant for the clinical picture[14] Endocardial lesions were found by Humphreys[27] in 12 of 21 cases of acute disseminated lupus erythematosus Like rheumatic endocarditis atypical verrucous endocarditis is only one part of a general febrile disease in which blood cultures are negative and in which serous membranes the skin the blood vessels and other structures may be affected But unlike rheumatic fever the cardiac lesions including the endocarditis, are usually clinically unimportant except toward the end of the clinical course

Etiology

The cause of the disease *is unknown A remarkable* feature is its predominant occurrence in young women of childbearing age Like periarteritis nodosa and rheumatic fever Libman-Sacks disease has been interpreted as an allergic (hypersensitive) tissue reaction chiefly on the basis of the pathologic findings[40] [45] However there is no definite clinical evidence to support this interpretation[2] although several cases have appeared among student nurses following the injection of Dick toxin[1] Lupus erythematosus is classified as a collagen disease[20] [3] [18] *a misnomer* which is difficult to dislodge because it provides a useful catchbasket for a variety of diseases of unknown etiology

Endocardial Lesions

The verrucae are usually *broader and more* massive than in rheumatic endocarditis and have a great tendency to involve the mural endocardium the endocardium of the valve pockets both sides of the cusps and the right side of the heart[11] The tricuspid valve is more often affected than the mitral and the pulmonic more often than the aortic The verrucae consist of areas of proliferating and degenerated valve substance mixed with fibrin and platelet thrombi The cusps contain large mononuclear and plasma cells macrophages fibroblasts capillaries of the endothelial bud type and necrotic cells forming characteristic *hematoxylin stained bodies*[19] These are believed to represent the histologic analogue of the lupus erythematosus cells (L E cells)[22] [a] [14] *found in the bone marrow* and blood Histochemical studies indicate that the hematoxylin stained bodies (blue-cell lesions) represent depolymerized desoxyribosenucleic acids formed by the *necrosis of cell nuclei*[31] Not uncommonly there is a terminal bacterial invasion of the blood stream with the production of an acute bacterial endocarditis A nonbacterial ter

minal thrombotic endocarditis (see below) may also be associated with atypical verrucous endocarditis or it may occur as the only macroscopic endocardial lesion in Libman Sacks disease

Myocardial Lesions

In the myocardium the lesions include foci of round cells atrophy of fat or interstitial edema fibrinoid necrosis, thickening and stenosis of small arteries and fine scars suggestive of small infarcts Aschoff bodies are absent The heart is usually of normal size but may be slightly hypertrophied The visible myocardial lesions do not appear sufficient to account for the frequent occurrence of heart failure in advanced stages of the disease

Pericardial Lesions

Adhesive pericarditis is frequent and a serofibrinous pericarditis is not uncommon In 5 of the 21 cases analyzed by Humphreys[7] there were effusions of 600 to 950 cc

The changes in the heart appear to be part of a widespread alteration of the ground substance[8, 80] The serous membranes vasculature (especially the glomerular capillaries) lymph node skin and mediastinal and retroperitoneal areas are affected Fibrinoid metamorphosis and fragmentation of collagen swelling and increased density of the interfibrillar ground substance wire-loop lesions and focal necrosis of the glomerular capillaries sclerosis of the collagen fibers around the follicular arteries of the spleen and the endocardial lesions are the most conspicuous diagnostic features Although similarities to periarteritis nodosa rheumatic fever and scleroderma have been stressed the pathologic and clinical features of each are usually easily distinguishable Some confusion has arisen because Libman Sacks disease may be associated with necrotizing arteritis or occasionally with scleroderma

Clinical Features[4, 5, 41]

Although Libman Sacks disease is not usually a clinical cardiac ailment its chief clinical features merit brief discussion because it is often confused with rheumatic fever or bacterial endocarditis

Fever is an essential feature The onset is usually characterized by diffuse arthralgias and stiffness of the small and large joints of the extremities Occasionally there are joint changes resembling those of rheumatoid arthritis Not infrequently the patient is first treated for arthritis for which he goes to the seashore where exposure to the sun is followed by distinctive cutaneous lesions However, the onset may be characterized by a 'butterfly' or other eruption, by Raynaud's phenomenon hemolytic anemia, thrombocytopenic purpura, pleurisy or pericarditis[11]

The acute disseminated lesions of lupus erythematosus are most often suggestive of the diagnosis but these lesions may be absent or develop late in the disease The lesions consist of a characteristic, slightly raised erythematous butterfly eruption across the bridge of the nose and extending to the cheeks Papular and erythematous lesions of a bluish red cast also affect other parts of the face, the forehead the ears the manubrium sterni the volar surface of the fingers the thenar and hypothenar eminences and other parts of the upper and lower extremities Telangiectatic and petechial lesions also occur The skin of the face may become scaly and edematous, and the lesion may resemble that of seborrheic dermatitis or erysipelas Erythematous or ulcerative lesions may appear on the hard palate or other parts of the oral mucosa

Albuminuria, microscopic hematuria or the presence of clumped leukocytes in the urine often appears early and may suggest a diagnosis of glomerulonephritis or pyelonephritis The fundi may disclose cotton wool 'exudates' (retinal cytoid bodies) but the blood pressure is almost always normal Fleeting or persistent pleuropneumonic lesions pleurisy with effusion which may be eosinophilic, or evidence of serofibrinous pericarditis is commonly observed Lymphadenopathy and splenomegaly, Raynaud like phenomena scleroderma and cerebral manifestations notably convulsions occur occasionally and evidence of impaired renal function bronchopneumonia and bacterial endocarditis appear late in the disease or preterminally The liver may be enlarged owing to fatty infiltration Dyspnea abdominal pain and chest pain are among the more common subjective symptoms, after fever and joint pains Ascites occurs eventually in about one quarter of the cases Renal insufficiency and uremia are common occurrences toward the end of the disease

Leukopenia anemia occasional thrombocytopenia a reduction in plasma albumin hyperglobulinemia (especially alpha 2 and

gamma globulins) and an occasional false positive Wassermann test[25] are additional features Thrombocytopenia purpura may be an early manifestation Splenectomy may then first reveal the typical onion skin lesions (periarterial fibrosis) of lupus erythematosus A severe hemolytic anemia occurs frequently Leukocytosis is common toward the end of the disease chiefly due to intercurrent infection

Clinical evidence of cardiac involvement is less striking than the pathologic changes in the heart Pericardial effusion and less commonly fibrinous pericarditis are the most frequent manifestations An apical systolic murmur may be audible in almost half the cases but this cannot be correlated with the verrucous endocardial lesions Clinical evidence of heart failure is common in the end stages of the disease Gallop rhythm is frequent under these circumstances The heart failure may be due to myocardial disease or may be secondary to pericardial effusion with cardiac tamponade Hypertension is unusual except in advanced stages of renal insufficiency with azotemia

The electrocardiogram discloses no characteristic changes but occasionally there may be low voltage of the QRS complexes an increased P R interval low or inverted T waves and a tendency to a prolonged Q T interval[32] There may be classic RT elevations characteristic of pericarditis

Diagnosis

Most often Libman Sacks disease is confused with rheumatic fever rheumatoid arthritis or subacute bacterial endocarditis but also with glomerulonephritis or pyelonephritis pleuropericarditis or rarely Hodgkin s disease if there is a prominent lymphadenopathy

The combination of fever arthralgia lupus erythematosus and leukopenia in a young woman is usually adequate for diagnosis The blood culture should be negative except in the terminal stage Rheumatic fever and periarteritis nodosa are associated with a polynuclear leukocytosis as a rule A definitive diagnosis is made by finding the L E cells in bone marrow or blood[27 28 ...] Rarely a positive L E finding is reported in other conditions

In the absence of characteristic cutaneous lesions Libman Sacks disease may be suspected in cases resembling rheumatic fever in which there is evidence of acute glomerulonephritis and azotemia but with a normal blood pressure Similarly the association of thrombocytopenic purpura or of leukopenia or both in cases resembling rheumatic fever should suggest Libman Sacks disease The combination of azotemia fever and normal blood pressure may also be due to this disease It has also masqueraded as a subacute polyserositis with fever with or without arthritis and glomerulonephritis[31] In cases resembling bacterial endocarditis but in which the blood cultures are persistently negative Libman Sacks disease should be suspected especially if there is no organic cardiac murmur

Treatment consists in administration of adrenocortical drugs[... ...] In acute episodes fever and associated symptoms may be best controlled by 100 units or more of corticotropin daily administered by slow intravenous drip As soon as the symptoms are controlled the patient is given 60 to 100 mg of oral prednisone daily in divided doses In milder cases control may be effected by oral medication from the beginning The dose is gradually and progressively reduced if the clinical response is maintained Frequently a prolonged maintenance dose of 15 to 20 mg of prednisone suffices Dubois[1] reported beneficial effects from the use of quinacrine (Atabrine) in the treatment of both systemic and discoid lupus erythematosus He administered 300 mg daily the first week and increased or diminished the dose according to the clinical response and the presence of toxicity Thoracentesis is occasionally required if there are respiratory symptoms due to large pleural effusions Salicylates may ameliorate the joint pains and fevers Transfusions are indicated if there is pronounced anemia and hypoproteinemia Penicillin or streptomycin may be required to control complicating infections Death usually occurs within a period of six months to two years but I have seen many patients who have thus far survived four years or longer

NON BACTERIAL THROMBOTIC ENDOCARDITIS

This refers to the verrucous endocardial lesions which are associated with a variety of infections and chronic wasting diseases The term cachectic endocarditis was applied by Harbitz[21] to these lesions but because they occur toward the end of the disease they have

also been classified as terminal endocarditis. Many of the lesions diagnosed as terminal endocarditis prove on careful bacteriologic and microscopic examination to be examples of active rheumatic verrucous endocarditis or terminal bacterial endocarditis.[9] The latter two forms should be distinguished from the cases under consideration. The term thromboendocarditis was introduced by Ziegler[54] to emphasize the essential thrombotic nature of the lesions. Koniger[32] in his extensive study of endocarditis referred to this group as simple thromboendocarditis. It is preferable to avoid this term which according to recent usage has come to be applied to all types of non-bacterial verrucous endocarditis including rheumatic endocarditis. Gross and Friedberg[9] introduced the term non bacterial thrombotic endocarditis to denote the essential descriptive features. But it is questionable whether the term endocarditis may be properly employed in these cases since there is little or no inflammatory reaction in the cusps. Perhaps non bacterial thrombosis of the endocardium would be a more accurate term although it is probable that the deposition of thrombus is secondary to a toxic damage to the cusp itself.[33, 9]

The essential feature in these cases is the presence of non-specific valvular vegetations which may resemble those of rheumatic endocarditis. Sometimes they are minute and arranged in rows on the closure line of the cusps. But they may be much larger than rheumatic verrucae and appear as a pyramidal ridge or a massive solitary sessile or pedunculated lesion. The mitral, aortic and tricuspid valves are affected in that order as in rheumatic endocarditis. Neither the mural endocardium nor the chordae are involved. Valvular deformities do not result from the lesions.

Microscopically the vegetations consist essentially of agglutinated blood platelet thrombi. Superficially there is a small or large cap of fresh thrombus often overlying an amorphous irregular area of valve substance which has undergone eosinophilic or fibrinoid degeneration. There are no bacteria in the vegetation. A striking feature which contrasts with the findings in active rheumatic endocarditis is the absence or paucity of inflammatory reaction in the cusp despite the freshness of the verrucous lesion. When cells are present they are usually fibroblasts and histiocytes which participate in early organization of the base of the verrucae. There are no Aschoff bodies in the heart. In a preponderant majority of cases the verrucous lesions are superimposed on thickened, fibrotic deformed valves usually the result of chronic rheumatic endocarditis.

Non bacterial endocarditis is an accidental occurrence in a variety of infections and chronic wasting diseases which, as a rule, has no clinical significance except that it may facilitate a superimposed bacterial endocarditis. However, the non bacterial vegetations give rise to systemic emboli especially to the brain.[7] The non bacterial verrucous lesions appear most often in association with carcinomatosis, glomerulonephritis, chronic pulmonary disease including tuberculosis, uremia, lobar pneumonia, leukemia, osteomyelitis, cirrhosis of the liver and Libman-Sacks disease. The possibility that metabolic or bacterial toxins may contribute to valvular injury and subsequent endocardial thrombosis has been mentioned. Previous valvular deformity by rheumatic endocarditis favors secondary deposition of non bacterial thrombi. Friedberg and Gross[13] observed 3 cases of non bacterial thrombotic endocarditis associated with fever, essential (thrombocytopenic) purpura hemorrhagica and vascular lesions (thrombotic thrombocytopenic purpura). The endocarditis was not related to the clinical picture. Friedberg, Gross and Wallach[14] also reported 4 cases of this form of endocarditis associated with prolonged fever, arthritis, inflammation of serous membranes and vascular lesions. The latter may now be classified as examples of Libman-Sacks disease (lupus erythematosus). The non specific non bacterial thrombotic endocarditis as well as the characteristic atypical verrucous endocarditis (and a terminal bacterial endocarditis) may occur in Libman Sacks disease.

SYPHILITIC ENDOCARDITIS

This is rarely if ever a primary endocarditis, but results from the contiguous spread of the syphilitic aortic lesion to the commissures and bases of the aortic cusps (p 895). Rarely the aortic leaflet of the mitral valve is involved by contiguous spread of syphilitic inflammation from the aorta.[47]

TUBERCULOUS ENDOCARDITIS

This occurs very rarely. The endocardium

may be involved by extension of a tuberculous perimyocarditis or by miliary tubercles in instances of generalized miliary tuberculosis (pp 602 and 913)

ENDOCARDIAL FIBROELASTOSIS LOEFFLER'S FIBROPLASTIC ENDOCARDITIS CONSTRICTIVE ENDOCARDITIS

A variety of cases of heart disease of unknown etiology are characterized pathologically by thickening of the endocardium One large group in which there is a prominent proliferation of endocardial and subendocardial fibrous and elastic tissue is termed endocardial fibroelastosis and less frequently endocardial fibrosis or sclerosis Endocardial fibroelastosis in the first two years of life is a congenital and possibly hereditary disease which is the commonest cause of congenital idiopathic cardiac hypertrophy (see p 786) In addition there are cases of fibroelastosis in childhood (ages 2 to 16) which are probably identical with those in the younger group except for the later age of onset[10]

Finally endocardial fibroelastosis of similar pathologic nature is encountered in adults[10, 11] in cases of idiopathic hypertrophy and heart failure (p 624) In these mural thrombosis with resultant emboli is a frequent finding There are case reports of endocardial fibroelastosis in patients aged 53 and 71 with cardiac symptoms for 6 and 15 years respectively[12] Despite the long interval between birth and the development of symptoms the adult form of endocardial fibroelastosis like the infantile may be congenital Since endocardial fibroelastosis is seen to varying extent in other conditions associated with cardiac hypertrophy and heart failure the fibroelastosis may be a non-specific reaction to some undetermined factor such as myocardial anoxia[23] or more probably to altered fetal pressure relations with increased tension in the affected chamber The clinical features of the adult cases of endocardial fibroelastosis are those described under the heading idiopathic cardiac hypertrophy (p 624) Congestive heart failure embolization conduction disturbances and cardiac arrhythmias and a syndrome resembling that of constrictive pericarditis are most frequently observed

The cases of heart disease occurring frequently in East Africans known as East African endomyocardial necrosis[17, 3] resemble clinically those of endocardial fibroelastosis with respect to the presence of congestive heart failure of undetermined origin But pathologically they differ distinctly in that (1) the patchy endocardial thickening shows only irregular masses of endocardial elastic tissue instead of proliferating elastic tissue and (2) the thickened areas show destruction of the original endocardium and adjacent myocardium with replacement by vascular fibrous tissue[20] Mitral or tricuspid insufficiency may occur The cases from South Africa described as cardiovascular collagenosis with parietal endocardial thrombosis[3] may be identical with East African endomyocardial necrosis A review of the various types of endocardial fibrosis indicated to Davies and Ball[8] that virus infection some antigen antibody reaction and malnutrition were the possible etiologic factors in the endocardial fibrosis observed in Uganda The clinical picture is dominated by progressive congestive heart failure and death is due to the heart failure bacterial endocarditis or intercurrent infection[3]

Certain inflammatory lesions of the endocardium still cannot be accurately classified Among these are the cases of isolated parietal endocarditis such as those reported by Baumler[4] and by Loeffler[31] Baumler described an extensive whitening and thickening of the left ventricular endocardium especially near its apex associated with mural thrombi and cardiac dilatation but without valvular lesions The patients suffered from chronic congestive cardiac failure especially from attacks of nocturnal dyspnea and sometimes from an anginal syndrome The resemblance to some of the cases of idiopathic hypertrophy and heart failure is noted

Loeffler[31] reported 2 cases of an afebrile parietal fibroplastic endocarditis of both ventricles There was an insignificant mitral valvulitis and insufficiency The clinical picture which resembled that of constrictive pericarditis was characterized by persistent tachycardia progressive evidences of visceral congestion including enlargement of liver and spleen serous effusions in the pleural cavity subcutaneous edema of the lower extremities and finally ascites and edema of the upper extremities The clinical manifestations were attributed to interference of the thickened retracted endocardium with the inflow of

blood into the right ventricle A remarkable feature was the presence of an eosinophilia which in one case reached 70 per cent with a leukocytosis of 18 000 Hoffman et al[26] reported a case of Loeffler s fibroplastic endocarditis with eosinophilia and reviewed the literature

Cases pathologically similar to Loeffler s endocarditis parietalis have been described under the heading of *constrictive endocarditis*[39] or constrictive endocardial sclerosis because the thickened endocardium was thought to restrict the diastolic expansion and perhaps the systolic contraction of the ventricles The clinical picture was precisely that of constrictive pericarditis (p 611) Cases of 'recurrent parietal thromboendocarditis simulating coronary disease and associated with hypotension and disturbances in cardiac rhythm have been observed in young adults[40]

OTHER ENDOCARDIAL LESIONS

A number of non inflammatory and degenerative endocardial lesions especially of the valves must not be confused with endocarditis Certain hair like *endocardial tags* such as the Lamblian excrescences from the nodulus aurantii may occasionally simulate endocardial vegetations[18] They are composed of myxomatous or hyaline connective tissue without thrombus or associated valvular inflammation

Yellow flecks or plaques of *atheromatous degeneration* are common on the ventricular surface of the anterior (aortic) cusp of the mitral valve They are most frequent and prominent in the hearts of elderly and anemic subjects They consist of collections of lipoid material sometimes with calcium

Valvular sclerosis is common There may be only whitish plaques of valvular thickening occupying the distal portion of the leaflets especially of the mitral valve They consist of fibrous tissue The atheromatous areas in the anterior mitral cusp may undergo fibrous replacement or occasionally calcification These changes do not interfere with valvular function for they are not extensive Occasionally the ring of the mitral or aortic valve or both is infiltrated by a rigid incomplete collar of calcium (sclerosis annularis fibrosi—Dewitzky[10]) Ossification may occur Calcification of the mitral or aortic ring may be denoted clinically by the presence of a loud very harsh or musical systolic murmur Histologically there is evidence that extensive fibrosis, hyalinization and occasionally elastification precede the deposition of calcium

Calcification of valve cusps occurs usually when there is longstanding chronic rheumatic endocarditis But occasionally calcification and consequent stenosis of the aortic valve may occur as a primary degenerative process[43 17] (p 698) In these cases fibrosis and calcification begin in the arterial portion of the aortic valve near its base and extend from there to the sinuses of Valsalva (Monckeberg's ascending sclerosis) or up the aortic leaflets until the whole valve is a hard, rigid mass with irregular calcific nodules and spicules which penetrate the ventricular surface (p 698) In the fully developed stage it is indistinguishable from the much more common calcific aortic stenosis of rheumatic origin The roentgenologic diagnosis of calcification of the annulus fibrosus, mitral and aortic cusps is discussed elsewhere (p 704)

Endocardial pockets also known as accessory leaflets regurgitant pockets or birds' nests are sclerotic thickenings of the mural endocardium seen most often on the left ventricular septum below an insufficient aortic valve They are believed to be due to tension of the regurgitant stream Their openings are directed toward the aortic valve Similar pockets directed toward the apex, are found in the left atrium just above the mitral valve

Among other regressive lesions are occasional instances of *mucoid* or *amyloid degeneration*

Not uncommonly in the hearts of newborn or young infants, occasionally in those of children and rarely in the hearts of adults, are found single or multiple *endocardial blood cysts* or *tumors* These are pink or dark red circumscribed nodules, chiefly on the leaflets of the mitral or tricuspid valves and composed of endothelial lined lacunae of blood They have been interpreted as hemangiomata or as hematomata

Mural Thrombosis Mural endocardial thrombi involving chiefly the left ventricle occur in cases of myocardial infarction With extensive septal infarction mural thrombi may also develop in the right ventricle Right and left ventricular mural thrombi have been described in certain cases of cardiac hypertrophy of obscure origin In cases of advanced congestive heart failure, especially with atrial

fibrillation, mural thrombi may occur in any chamber but predominantly in the atria and the atrial appendages. An underlying rheumatic atrial endocardial lesion may favor the development of mural thrombi. The thrombi may be of clinical importance because they are sometimes the source of systemic or pulmonary emboli.

Chapter 26

MITRAL VALVULAR DISEASE

Valvular heart disease is a major cardiac ailment which corresponds in incidence with its chief cause rheumatic fever Mitral valvular disease is most common aortic stenosis or insufficiency next while tricuspid disease occurs occasionally and pulmonic valvular disease rarely Combined mitral and aortic disease is common in the rheumatic cases, in about 10 per cent the tricuspid valve is also affected The frequency of aortic insufficiency is increased in regions where syphilis is common

Valvular heart disease is presented as a separate subject because it is often encountered when there are neither symptoms nor a history of the causative disease Certain clinical features of valvular disease are identical and may be described in common whatever the cause Finally, the disturbances in circulatory dynamics the symptomatology and the type of heart failure are determined more often by the valvular lesion than by the disease which produced it This is not to obscure the fact, however that the presence of active rheumatic inflammation, the severity and extent of myocardial damage the association of hypertension and the interference with coronary blood flow by atherosclerosis or syphilitic ostial stenosis are vital factors which reduce the ability of the heart to tolerate the strain of valvular disease, and which may lead to heart failure

ETIOLOGY OF MITRAL VALVULAR DISEASE

Rheumatic endocarditis is responsible for the great majority of cases of mitral valvular disease It may produce mitral stenosis or mitral insufficiency, but usually mitral stenosis is combined with some degree of insufficiency However as a rule the physical signs and the cardiac disturbances are determined by the predominant mitral insufficiency or by predominant mitral stenosis

Occasionally there is pure organic *mitral insufficiency* Brigden and Leatham[41] studied a series of 30 cases of mitral insufficiency, which they thought might not be rheumatic because in contrast with mitral stenosis which affects females predominantly, these occurred chiefly among males Furthermore there was rarely a history of rheumatic fever

Other rare causes of organic mitral insufficiency are bacterial endocarditis, traumatic rupture of a cusp or of the chordae tendineae spontaneous rupture of the chordae and rupture of a papillary muscle secondary to bacterial endocarditis or coronary occlusion The occasional occurrence of severe mitral insufficiency in children below the age of 5 and without a history of rheumatic fever suggests that there are rare instances of congenital mitral insufficiency Congenital mitral insufficiency may be due to perforations in the valve leaflets or to a congenital cleft in the septal leaflet of the mitral valve Traumatic mitral insufficiency is now due in most instances to injury of the valve in the course of mitral valve surgery

Relative or functional mitral insufficiency occurs commonly as a result of pronounced dilatation of the left ventricle due to hypertensive, coronary or aortic valvular disease, usually in association with left ventricular failure Imperfect valvular closure under such circumstances is due to dilatation of the mitral ring and to retraction of the cusps by chordae and papillary muscles as the ventricular chamber elongates

Mitral stenosis is almost always due to rheumatic endocarditis Occasionally it is a congential lesion[87] due either to anomalous development or to fetal endocarditis e g in the cases of Lutembacher s syndrome (p 735) Functional mitral stenosis may result from obstruction of the valvular orifice by bacterial vegetations atrial thrombi or tumors Congenital mitral atresia has been reported (p 791)

Rheumatic mitral valvular disease occurs two or three times as frequently among females as among males

PATHOLOGY OF MITRAL VALVULAR DISEASE

Rheumatic Mitral Disease

The rheumatic valvulitis and verrucae lead to scarring thickening shortening and deformity of the cusps and retraction of their free margins[■ 134] At the same time similar inflammatory changes and fibrosis cause thickening fusion and shortening of the chordae tendineae

Mitral Insufficiency characterized by incomplete closure of the mitral orifice with consequent systolic regurgitation of blood into the left atrium results from the following

1 Imperfect coaptation of the valve cusps because of their rigidity deformity and retraction Retraction and contraction of the scarred cusps may so reduce their cross sectional area as to produce a significant loss of substance The regurgitation is virtually always at the posterior (posteromedial) commissure the mural or posterior leaflet being drawn down into the left ventricle or becoming adherent to the mural endocardium in its posterolateral corner

2 *Fusion and shortening of the chordae* which fix the cusps and restrain their apposition to each other thus preventing closure of the valvular orifice in systole

The contracted shortened chordae affect particularly the posterior leaflet which is held down in the ventricle and prevented from effecting valvular closure during ventricular systole

3 Inflammation and scarring of the mitral ring which dilate the orifice and interfere with the muscular systolic reduction in its circumference an important factor in its normal closure The orifice of the valve may become so large that the cusps are incapable of closing it Dilatation of the ring may be intensified by enlargement of the left ventricle due to associated aortic valvular disease or hypertension especially when complicated by left ventricular failure The enlargement of the left ventricle which results from mitral insufficiency further increases the degree of regurgitation by dilating the ring

Serious mitral insufficiency may be associated with some degree of stenosis in as many as 75 per cent of the cases but the stenosis is rarely significant Conversely some degree of insufficiency accompanies most cases of mitral stenosis but the degree of insufficiency becomes insignificant when the stenosis is very severe In a number of cases there is a high degree of stenosis due to fusion and calcification of the leaflets at the anterior commissure while shortening loss of substance or adhesion at the posterior commissure causes significant regurgitation in that region

Mitral stenosis results from repeated rheumatic inflammation and healing It is probable that at least two years are required for the development of mitral stenosis after the initial attack of rheumatic valvulitis Mitral stenosis results from the following valvular abnormalities

1 Fusion of adjacent leaflets at their commissures to form a single circular curtain The mitral opening may be further narrowed by continued contraction of the scar tissue and by subsequent calcification of the mitral ring and cusps

2 Rigidity of the valve cusps due to fibrosis *This keeps them fixed in a position* which narrows the mitral orifice

3 Fusion and shortening of the chordae tendineae and their absorption into the mitral *cusps resulting in a funnel shaped structure* which accentuates the narrowing of the orifice In other instances adhesion and shortening of the cusps produces a diaphragmatic slit *described as the button hole or fish* mouth type of mitral stenosis

As a result of these changes two major types of mitral stenosis have been described[131 14] In about 80 to 90 per cent of operated cases the leaflets have undergone fibrous contraction are rigid and form a stenotic opening with little thickening or fusion of the chordae tendineae In this type calcification is very common In the second relatively infrequent type the scarred leaflets form an elastic funnel and in addition the chordae tendineae are shortened fused and often firmly adherent across the valvular opening[4] Whereas the results of surgery are usually good in the first type they are relatively poor in the second In the latter the elastic valve does not yield readily to finger fracture and even when the fused cusps are incised the fused interlacing chordae tend to maintain the stenosis of the mitral orifice

The normal area of the fixed orifice of the

mitral valve is 5 sq cm Narrowing to between 1 and 2 sq cm is associated with only mild mitral stenosis from the clinical view point since normal blood flows may be attained with moderate elevations in left atrial pressure In moderate to severe cases of mitral stenosis the mitral orifice has an area of less than 1 sq cm and even less than 0 5 sq cm The term "tight" mitral stenosis is applied to those cases in which the mitral orifice admits only a probe

Atherosclerotic (Calcific) Mitral Disease

Isolated white collagenous plaques of thickening and yellow atheromatous patches are almost always found in normal valves even in those of children More extensive degenerative changes occur with increasing age especially on the ventricular surface of the anterior (aortic) mitral cusp These lesions are of no clinical significance

Calcification of the annulus fibrosus or ring of the mitral valve has been found in 10 per cent of hearts at necropsy, with greatest frequency among the aged and among women [85] This lesion is clinically unimportant but may cause a loud rough or musical apical systolic murmur and may be discovered by careful fluoroscopic examination [9] Usually calcification of the mitral ring is of degenerative origin [III 193] and is not accompanied by calcification of the cusps On the other hand, calcification of the valve cusps is almost always secondary to rheumatic inflammation and occurs commonly in advanced mitral stenosis and/or insufficiency Calcification of inflammatory origin may also involve the mitral ring Calcification of the mitral ring or cusps may be associated with calcific aortic stenosis and occasionally with calcific deposits in the fibrous septum The latter may damage the bundle of His and produce complete heart block or other disturbances in conduction [40] The frequency of congestive heart failure angina pectoris or conduction disturbances in cases of calcification of the mitral ring or cusps is due to associated rheumatic cardio valvular disease or to coronary atherosclerosis and not to the direct effects of the calcium deposits

Rarer Forms of Mitral Disease

Bacterial endocarditis (Chapter 34) may produce mitral insufficiency by perforation of a cusp, by formation of a valvular aneurysm or by rupture of chordae tendineae or a papillary muscle The severity of clinical mitral insufficiency due to rupture of chordae tendineae or of a papillary muscle attests to the importance of these structures in the closure of the mitral orifice Functional mitral stenosis rarely results from obstruction of the orifice by cauliflower like vegetations I have seen an infected ball thrombus in the left atrium cause intermittent complete obstruction with shock and peripheral gangrene [208] Syphilis (Chapter 35) rarely involves the mitral valve either as a gumma or by contiguous extension from a luetic aortitis [14] The syphilitic myocarditis may simultaneously involve the bundle of His and produce heart block Mitral stenosis due to tumors is discussed in Chapter 45

Rupture of the mitral valve[19] may cause mitral insufficiency by perforation or tear of a cusp or by rupture of chordae or a papillary muscle Spontaneous rupture of chordae tendineae usually of previously diseased valves has also been noted [14]

The Heart in Mitral Valvular Disease

The *left atrium* is considerably dilated and hypertrophied in both mitral insufficiency and stenosis Sometimes it enlarges to giant proportions (aneurysmal dilatation of the left atrium), rarely attaining a volume of 2 or 3 liters [191] This is usually associated with severe mitral insufficiency occasionally with mitral stenosis Rarely a giant left atrium erodes the spine at the level between D5 and D9 [7] The variable degree of left atrial enlargement independent of the degree of mitral stenosis or insufficiency appears to be related to intrinsic differences in the atrial muscle, but the exact factors responsible are unknown

The *left ventricle* is dilated and hypertrophied in cases of predominant mitral insufficiency, or when prolonged mitral insufficiency precedes stenosis In hearts with predominant mitral stenosis the left ventricle may be of normal size But with pronounced and longstanding mitral stenosis the left ventricle may become smaller than normal and even atrophic The decreased size of the chamber is particularly confined to the posterior half or the so called inflow tract [152] An associated aortic valvular disease may produce enlargement of the left ventricle

The *right ventricle* usually enlarges and becomes hypertrophied, especially after the development of pulmonary hypertension due to

left atrial failure The *right atrium* also becomes dilated with progressive right heart failure

The Lungs in Mitral Valvular Disease

As a result of prolonged congestion and fibrosis the lungs become reddish brown firm dense and dry (brown induration of Virchow)[111] Infarcts due to pulmonary embolism hemorrhagic areas due to rupture of small vessels and atherosclerosis of the pulmonary arteries are also observed on gross examination The hemorrhages may give rise to nodular accumulations of granular hemosiderin chiefly within the alveoli[180, 95, 278]

The microscopic changes have been described by zu Jeddeloh[144] and by Parker and Weiss[191] and others[137, 180, 110, 95, 77, 278] The alveolar walls are markedly thickened by interstitial edema increased collagen and widening of the capillary basement membrane The width of the alveolar wall may increase from a normal of 1 to 3 micra to 30 to 50 micra Heart failure cells which arise from alveolar epithelium or reticuloendothelial cells and which contain brownish iron pigment derived from hemorrhage are observed in the alveolar lumina These cells are often extruded into the sputum The capillaries become congested wider than normal elongated and beaded and project into the alveolar lumina and the arterioles or small arteries undergo thickening of their wall and narrowing of their lumina[131, 106] These various changes interfere with pulmonary ventilation by making the lung rigid and inelastic and with diffusion and oxygenation of the blood by widening the alveolar-capillary wall The increased resistance in the congested capillaries and the narrowed pulmonary arterioles or small arteries impose a strain on the right ventricle

MITRAL INSUFFICIENCY

PATHOLOGIC PHYSIOLOGY

Magnitude and Dynamics of the Leak[110]

The magnitude of the regurgitant stream is determined by the area of the mitral orifice which is not closed during ventricular systole and by the pressure relations in the left ventricle left atrium and the aorta A serious degree of insufficiency may be represented by regurgitation of 10 to 30 cc per beat while leaks of 30 to 100 cc or more may be encountered in the most severe cases of mitral insufficiency Leaks of less than 10 cc per stroke are regarded as small and those below 5 cc as virtually insignificant

The pressure gradient between the left ventricle and the left atrium during systole is much higher than that between the left ventricle and the aorta Therefore there is a large reflux into the left atrium during ventricular systole even if the mitral opening is much smaller than that into the aorta Even moderate incompleteness of closure of the valve orifice may cause a sharp reduction in cardiac output which is the major physiologic defect in mitral insufficiency[107, 106] It has been estimated that regurgitation through an extent of one fifth of the cross-sectional area of the mitral orifice may reduce the cardiac output 50 per cent

Compensation of the Left Atrium

Experimental studies[226, 176] indicate that the normal ventricular output can be restored despite regurgitation into the left atrium of 50 per cent of the total stroke volume The volume of blood in the left atrium during its diastole is greater than normal because of the regurgitant stream it receives from the left ventricle in addition to the usual inflow from the pulmonary veins This results in increased left atrial pressure and increased stretch of the atrial musculature The increased atrial pressure promotes the left atrial output during atrial diastasis The increased stretch results in a stronger atrial contraction according to Starling's law of the heart Thus the left atrium compensates for the mitral insufficiency by a greater output But the greater diastolic volume and pressure in the left atrium lead to dilatation and hypertrophy of that chamber

The augmented blood flow from the left atrium into the left ventricle is favored by bradycardia with prolongation of diastole Conversely compensation for mitral insufficiency may be seriously impaired by tachycardia and shortening of the diastolic period

Compensation of the Left Ventricle

The enlarged output of the left atrium increases the diastolic volume and pressure of the left ventricle This leads to a more forceful contraction and an augmented ventricular discharge of blood In this manner the normal effective output into the aorta is restored but the actual output is equal to the output into the aorta plus the regurgitant outflow into the

left atrium An essential feature in left ventricular compensation is the speedy elevation of pressure during its isometric contraction, before there is any ejection or regurgitation of blood[44] The increased diastolic volume and pressure in the left ventricle lead to dilatation and hypertrophy of this chamber Thus compensation of mitral insufficiency is effected by dilatation and hypertrophy of both the left atrium and ventricle, but only at the expense of increased work for these chambers Furthermore as the left ventricle enlarges it leads to or enhances dilatation of the mitral ring thereby increasing the degree of mitral regurgitation Eventually the hypertrophied left ventricle may maintain an adequate output only at rest, but not with exercise When the left ventricle fails its output is inadequate and the left ventricular diastolic pressure rises

The Lungs and Right Heart

In pure rheumatic mitral insufficiency compensation may be effective if the magnitude of the leak is small or moderate and the left atrial and ventricular musculature is not seriously damaged But with large leaks left atrial compensation is rarely effective and there is some degree of pulmonary congestion Pulmonary hypertension gradually develops and the right ventricle becomes hypertrophied Eventually the right ventricle fails and right ventricular diastolic and right atrial pressure rise When mitral insufficiency appears suddenly as a result of trauma or spontaneous rupture of the chordae tendineae there is a rapid development of pulmonary congestion hypertension of the pulmonary circulation and right ventricular enlargement associated with heart failure

CLINICAL FEATURES OF MITRAL INSUFFICIENCY

Clinical Varieties

Clinical manifestations and course vary considerably according to the severity of the lesion Some patients are virtually asymptomatic and, except for the presence of an apical systolic murmur and perhaps some evidence of left ventricular hypertrophy, present no important manifestations of cardiac disease In a second group of patients there is more definite evidence of left atrial and left ventricular enlargement and there may be annoying palpitation due to multiple ventricular or atrial premature beats and dyspnea on more than moderate exertion There are many cases of pure organic mitral insufficiency in which the course is relatively long and benign but in which heart failure, when it develops, is severe and rapidly progressive[98] The importance of the cases with relatively benign and asymptomatic mitral insufficiency is that bacterial endocarditis may complicate and shorten their course Finally, there are the cases with large leaks, disabling symptoms and unfavorable course and which are often difficult to distinguish from mitral stenosis These are the cases which are to be considered for surgical correction as soon as a satisfactory operation becomes fairly standardized and generally acceptable

Symptoms and Signs

Palpitation and dyspnea are the earliest symptoms of mitral regurgitation But in the more severe cases dyspnea on slight exertion or even at rest orthopnea and fatigability are outstanding symptoms Gorlin et al[107] stressed that fatigue or weakness is more prominent than dyspnea in mitral regurgitation in contrast with mitral stenosis But this finding varies in different patients and with the stage of the disease, and cannot be used in differentiating the two conditions In some patients analysis of the fatigability indicates that it is definitely due to dyspnea and fatigue of respiratory muscles, but in others the fatigue is related to the legs, suggesting that it is due to inadequate cardiac output at rest or with exertion Right ventricular failure is relatively infrequent until late in the course but when it develops it is usually progressive and intractable Hepatic enlargement and tenderness marked venous engorgement peripheral edema and ascites are common In several patients the development of right heart failure was associated with atrial flutter or flutter fibrillation Not only was this difficult or impossible to convert to normal sinus rhythm with quinidine, but the rapid ventricular rate could not even be slowed adequately by either quinidine or large doses of digitalis Atrial thrombosis and peripheral emboli are much less common than in cases of pure mitral stenosis

Cardiac Findings

The outstanding finding is the presence of an apical systolic murmur, which is loud and prolonged, often replaces the first heart sound or starts immediately after it, and occupies most of systole (holosystolic) Occasionally is occurs late in systole It may be decrescendo

i e diminishing in intensity from the beginning to the end of systole or crescendo [41] High pitched musical murmurs are common in mitral insufficiency The murmur is usually loudest at or near the apex and radiates to the axilla and not infrequently toward the base of the heart and to the back in the left subscapular region Unlike the systolic murmur of tricuspid insufficiency it becomes softer on inspiration A systolic thrill accompanies the very loud murmurs especially in cases of mitral regurgitation due to ruptured chordae tendineae or papillary muscle There may be no systolic murmur in proven cases of significant mitral regurgitation when accompanied by mitral stenosis but this is exceptional [184 114] Elkin and associates[72] reported the absence of a systolic murmur in 5 patients submitted to operation for mitral stenosis but found to have a significant mitral regurgitant jet at operation

The second pulmonic sound is usually accentuated and may be split The second sound at the apex may be faint or inaudible being included in the systolic murmur A third heart sound occurs frequently but no opening snap [41] The apex beat may be displaced downward and outward and may be palpable as a heaving thrust in the sixth interspace lateral to the midclavicular line In cases of giant left atrium extending beyond the right border of the heart there may be a systolic propulsion of the right chest [99] Evidence of enlargement of the left atrium and ventricle often requires roentgen ray examination

Roentgenologic Examination of the Heart in Mitral Insufficiency

In the anteroposterior view the lower left cardiac border representing the left ventricle extends abnormally outward and downward and may be unusually rounded Posterior enlargement of the left ventricle is best seen in the left anterior oblique view There may be a slight prominence due to a large left atrium or atrial appendage where the left ventricle approaches the junction to the pulmonary artery The barium-containing esophagus is displaced to the right in anteroposterior views and posteriorly in the right oblique view by the curve of the enlarged left atrium When failure supervenes the pulmonary markings are increased because of vascular congestion and the right cardiac contour is greatly widened because of right atrial and ventricular dilatation

Fluoroscopic examination often discloses systolic expansion of the left atrium [7 1] but this may be absent with small leaks marked enlargement of the left atrium tachycardia or an atrial arrhythmia or when the atrial border cannot be distinctly visualized Pulsation of the left atrium in mitral regurgitation has also been observed by roentgenkymography or electrokymography [63 111 178] and is recorded as an early rise in systole with a flat top (plateau) A similar systolic plateau occurring late in systole is said to suggest mitral stenosis [189]

If the left atrium is of unusual proportions its shadow may appear along the right border Then the right lower arch is due to the right atrium and the right middle arch to the overlapping left atrium These two arches may show pulsations in opposite directions giving a see-saw effect The upper pulsation (left atrium) expands laterally in systole owing to the regurgitation of blood from the left ventricle the lower (right atrium) moves medially in systole due to the transmitted pulsation of the right ventricle

Electrocardiogram in Mitral Insufficiency

In contrast with the electrocardiogram of mitral stenosis that of insufficiency shows a tendency to left axis deviation In the majority of cases of significant mitral regurgitation there is evidence suggesting left ventricular hypertrophy best seen in precordial leads The P waves may be tall but are more likely to be normal than in mitral stenosis [41]

Ballistocardiogram

A consistent abnormal headward wave was found preceding the J wave [184] But Izak and Braun[184a] could not confirm its specificity

Pulmonary capillary and left atrial pressure curves[134 136 15 151 193] usually show an a wave of atrial contraction and a gradually rising V wave in systole In mitral insufficiency there is often a single large positive wave (plateau) throughout systole due to regurgitation of blood from the left ventricle

DIAGNOSIS

The diagnosis of mitral insufficiency is based primarily on the presence of a loud prolonged apical systolic murmur and enlargement of the left atrium and ventricle A history of rheumatic fever is supporting evidence Demonstration of systolic expansion of the left atrium is also diagnostically important but not conclusive Pulse tracings of

the pulmonary capillary[7,8] (by a catheter wedged into a small pulmonary artery) or of the left atrium by needle puncture through the chest wall[150] or bronchoscope[3] or by a balloon in the esophagus,[158] may disclose a systolic plateau due to the regurgitant jet, but this is not reliable in individual cases[249]. For differential diagnosis from mitral stenosis, see page 666

The *diagnosis of mitral insufficiency due to non rheumatic causes* is based on the sudden development of a loud apical systolic murmur in the course of bacterial endocarditis or myocardial infarction after penetrating or non penetrating chest injury or after an unusual, severe exertion Spontaneous rupture of mitral chordae is suggested by the development in a middle aged or elderly person without striking cause of a loud apical murmur and thrill followed in a few days weeks or months by enlargement of the left atrium and ventricle and by congestive heart failure Rupture of a papillary muscle is more likely to be followed by rapid heart failure, shock, acute pulmonary edema and death Rupture of a congenital aneurysm of the sinus of Valsalva must also be differentiated (p 773) Aortic stenosis may be associated with a systolic murmur which is loudest at the mitral area

Relative or functional mitral insufficiency is suggested by the presence of an apical systolic murmur in a patient with hypertension or coronary heart disease and heart failure If the mitral murmur disappears with improvement of the circulatory status, the functional nature of the disturbance is confirmed

Calcification of the mitral ring may be disclosed by a harsh or musical apical systolic murmur and by fluoroscopic visualization of a U or J shaped calcification in the region of the annulus fibrosus (Fig 118)

Calcification of the mitral leaflets can be dif

Fig. 118 Calcification of mitral ring J shaped density (arrow) Fluoroscopy and kymography revealed wide pulsations toward apex Al a calcification of pericardium

ferentiated from calcification of the ring and almost always denotes organic rheumatic mitral insufficiency or stenosis[2,9] Calcification in the cusps appears fluoroscopically as groups of irregular nodular masses in the posterior third of the heart moving downward toward the apex with ventricular systole[13]

The Functional Systolic Murmur

The greatest problem in the differential diagnosis of mitral insufficiency is to distinguish an organic mitral murmur from a so called *functional* one[1,4] A non significant physiologic or functional systolic murmur has been described in 30 to 90 per cent of children or adolescents[9,131,172] Often the murmur may be heard after exercise when it is absent during rest[214] The incidence of functional systolic murmurs diminishes rapidly in adult life That systolic murmurs often appear with anemia fever and hyperthyroidism suggests that they result in these conditions from the increased velocity of blood flow Many functional murmurs are of cardiorespiratory origin arising as a result of compression of the overlying lobule of lung when the heart contracts Chisholm[50] suggested that functional pulmonic systolic murmurs may occasionally be due to unequal stretching of the pulmonary artery with change of position forced inspiration or as a result of pleural adhesions Under these circumstances the valve cusps are apposed in such a way (trigonoidation of the semilunar cusps) as to act as an obstruction to the outflow of blood

Although there is no certain method of differentiating organic from functional murmurs the following points are helpful Functional murmurs are often loudest in the pulmonic area radiate little and are faint in intensity A close relation between the intensity of a systolic murmur and the presence of organic heart disease has been indicated by the studies of Freeman and Levine[84] Baker et al[17] Boone and Levine[25] and of Kuttner and Markowitz[156] Functional murmurs usually disappear when the breath is held in inspiration These differences permit a statistical differentiation of organic from functional murmurs when dealing with large numbers of persons but are not decisive in the individual case

The association of cardiac enlargement with an apical systolic murmur usually denotes that the murmur is organic (in the absence of left ventricular failure) But organic mitral insufficiency may be characterized by an apical systolic murmur without demonstrable cardiac enlargement Thus Boone and Levine[25] observed 225 individuals with a history of rheumatic fever with faint or distinct systolic murmurs but without cardiac enlargement During an average observation period of 9 6 years 42 per cent of those with a distinct systolic murmur developed mitral stenosis aortic insufficiency or both in contrast with 4 8 per cent of those with soft poorly transmitted murmurs Similarly Kuttner and Markowitz[156] after an eight year follow up period observed the development of definite organic heart disease in 48 per cent of 144 rheumatic children with a loud blowing apical systolic murmur but without cardiac enlargement and in 13 per cent of 171 cases of potential or possible heart disease in which the murmur was soft and poorly transmitted For practical purposes it is important to view all systolic murmurs with suspicion and to attempt to determine their cause This viewpoint often leads to the discovery of rheumatic mitral valvular disease or calcific aortic stenosis sickle cell or other anemia hyperthyroidism or hypertension Not infrequently especially in older individuals the finding of an apparently insignificant systolic murmur suggests the possibility of subacute bacterial endocarditis when the diagnosis otherwise appears obscure In young persons without a history of rheumatic fever and without cardiac enlargement or other evidences of cardiovascular disease care must be taken not to make a diagnosis of organic heart disease lest cardiac invalidism or cardiac neurosis be initiated even though a certain percentage of such individuals will eventually disclose unmistakable valvular heart disease Under the circumstances mentioned restriction of activity [redacted] rarely indicated On the other hand the realization that many individuals with apparently non significant systolic murmurs have organic valvular disease poses a different problem when deciding whether to accept such applicants for life insurance or military service

SURGICAL TREATMENT OF MITRAL INSUFFICIENCY

A variety of surgical techniques have been used to correct mitral insufficiency[10,12,58,147,161] but there is currently no uniform procedure which has gained general acceptance The

the pulmonary capillary [78, 3] (by a catheter wedged into a small pulmonary artery) or of the left atrium by needle puncture through the chest wall [56, 8, a] or bronchoscope[3] or by a balloon in the esophagus [68] may disclose a systolic plateau due to the regurgitant jet but this is not reliable in individual cases [249, 1] For differential diagnosis from mitral stenosis see page 666

The *diagnosis of mitral insufficiency due to non rheumatic causes* is based on the sudden development of a loud apical systolic murmur in the course of bacterial endocarditis or myocardial infarction after penetrating or non penetrating chest injury or after an unusual severe exertion Spontaneous rupture of mitral chordae is suggested by the development in a middle aged or elderly person without striking cause of a loud apical murmur and thrill followed in a few days weeks or months by enlargement of the left atrium and ventricle and by congestive heart failure Rupture of a papillary muscle is more likely to be followed by rapid heart failure shock acute pulmonary edema and death Rupture of a congenital aneurysm of the sinus of Valsalva must also be differentiated (p 773) Aortic stenosis may be associated with a systolic murmur which is loudest at the mitral area

Relative or functional mitral insufficiency is suggested by the presence of an apical systolic murmur in a patient with hypertension or coronary heart disease and heart failure If the mitral murmur disappears with improvement of the circulatory status the functional nature of the disturbance is confirmed

Calcification of the mitral ring may be disclosed by a harsh or musical apical systolic murmur and by fluoroscopic visualization of a *U* or *J* shaped calcification in the region of the annulus fibrosus (Fig 118)

Calcification of the mitral leaflets can be dif

Fig 118 Calcification of mitral ring J shaped density (arrow) Fluoroscopy and kymography revealed wide pulsations toward apex Also calcification of pericardium

ferentiated from calcification of the ring and almost always denotes organic rheumatic mitral insufficiency or stenosis [9] Calcification in the cusps appears fluoroscopically as groups of irregular nodular masses in the posterior third of the heart moving downward toward the apex with ventricular systole [12]

The Functional Systolic Murmur

The greatest problem in the differential diagnosis of mitral insufficiency is to distinguish an organic mitral murmur from a so-called functional one [3,4] A non significant physiologic or functional systolic murmur has been described in 30 to 90 per cent of children or adolescents [9,181,172] Often the murmur may be heard after exercise when it is absent during rest [214] The incidence of functional systolic murmurs diminishes rapidly in adult life That systolic murmurs often appear with anemia fever and hyperthyroidism suggests that they result in these conditions from the increased velocity of blood flow Many functional murmurs are of cardiorespiratory origin arising as a result of compression of the overlying lobule of lung when the heart contracts Chisholm[10] suggested that functional pulmonic systolic murmurs may occasionally be due to unequal stretching of the pulmonary artery with change of position forced inspiration or as a result of pleural adhesions Under these circumstances the valve cusps are apposed in such a way (trigonoidation of the semilunar cusps) as to act as an obstruction to the outflow of blood

Although there is no certain method of differentiating organic from functional murmurs the following points are helpful Functional murmurs are often loudest in the pulmonic area radiate little and are faint in intensity A close relation between the intensity of a systolic murmur and the presence of organic heart disease has been indicated by the studies of Freeman and Levine[94] Baker et al [17] Boone and Levine[38] and of Kuttner and Markowitz [153] Functional murmurs usually disappear when the breath is held in inspiration These differences permit a statistical differentiation of organic from functional murmurs when dealing with large numbers of persons but are not decisive in the individual case

The association of cardiac enlargement with an apical systolic murmur usually denotes that the murmur is organic (in the absence of left ventricular failure) But organic mitral insufficiency may be characterized by an apical systolic murmur without demonstrable cardiac enlargement Thus Boone and Levine[38] observed 225 individuals with a history of rheumatic fever with faint or distinct systolic murmurs but without cardiac enlargement During an average observation period of 9 6 years 42 per cent of those with a distinct systolic murmur developed mitral stenosis aortic insufficiency or both in contrast with 4 8 per cent of those with soft poorly transmitted murmurs Similarly Kuttner and Markowitz [153] after an eight year follow up period observed the development of definite organic heart disease in 48 per cent of 144 rheumatic children with a loud blowing apical systolic murmur but without cardiac enlargement and in 13 per cent of 171 cases of potential or possible heart disease in which the murmur was soft and poorly transmitted For practical purposes it is important to view all systolic murmurs with suspicion and to attempt to determine their cause This view point often leads to the discovery of rheumatic mitral valvular disease or calcific aortic stenosis sickle cell or other anemia hyperthyroidism or hypertension Not infrequently especially in older individuals the finding of an apparently insignificant systolic murmur suggests the possibility of subacute bacterial endocarditis when the diagnosis otherwise appears obscure In young persons without a history of rheumatic fever and without cardiac enlargement or other evidences of cardiovascular disease care must be taken not to make a diagnosis of organic heart disease lest cardiac invalidism or cardiac neurosis be initiated even though a certain percentage of such individuals will eventually disclose unmistakable valvular heart disease Under the circumstances mentioned restriction of activity is rarely indicated On the other hand the realization that many individuals with apparently non significant systolic murmurs have organic valvular disease poses a different problem when deciding whether to accept such applicants for life insurance or military service

SURGICAL TREATMENT OF MITRAL INSUFFICIENCY

A variety of surgical techniques have been used to correct mitral insufficiency [19,3, 49,147,101] but there is currently no uniform procedure which has gained general acceptance The

procedure employed differs with the pathologic disturbance responsible for the regurgitation[89] In the cases of predominant mitral stenosis with rigid, fused cusps and a small regurgitant jet separation of the fused cusps with restoration of their mobility usually corrects not only the stenosis but also the regurgitation

The more severe forms of mitral insufficiency are usually of two types (1) There is a loss of valve substance, preventing the normal overlapping or even the coaptation of the cusps to close the mitral orifice As a rule it is the posterior (mural) leaflet which is responsible and the regurgitant leak is at the posteromedial commissure (tear drop opening) or occasionally in the center of the orifice (crescent-shaped opening between the cusps) The rigid narrowed cusps form a flat diaphragm with a crescentic or buttonhole opening In these cases division of the commissures usually increases the regurgitation Surgical procedures attempt to correct this type of insufficiency by suturing together the lips of the valve at its incompetent portion or by the insertion of a graft or prosthesis to substitute for or reinforce the defective portion of the cusps

(2) A common cause of large regurgitant leaks is an enlarged stretched or malfunctioning mitral annulus which is too large to be occluded Consequently the cusps, even when freely mobile do not approximate in ventricular systole In fact the cusps may become more widely separated and the regurgitation increased during systole Attempts have been made to reduce the circumference of the annulus (and therefore the cross section of the mitral orifice) by suturing the annulus or by inserting grafts or prostheses

Occasionally mitral insufficiency is due in large measure to adherence of the cusps to shortened chordae tendineae which keep the cusps, especially the mural cusp fixed in the ventricular cavity and prevent closure of the mitral orifice In such cases the finger passed through the atrial appendage and mitral orifice (p 673) draws the affected cusp upward to free it of its adhesions If this is impossible the cusp is mobilized by severing the shortened chordae and scar tissue by a flexible or right angle neurectomy knife introduced through the left ventricular wall while the finger in the mitral valve guides it[147]

Detailed description of the operative procedures is unwarranted until one of those presently available, or some other technique is generally accepted as most satisfactory In general any significant mitral stenosis is corrected first and an effort is then made to free the posterior (mural) leaflet from any adhesions to the shortened chordae or mural endocardium and elevate it to its proper position Bailey et al[12] employed pericardial grafts in a series of 150 patients operated on for mitral insufficiency, and a similar procedure was used by Logan and Turner[168] The creation of a transventricular "hammock" by means of a pedicled pericardial graft was associated with improper placement and occlusion of the orifice, hemolysis of blood eventual atrophy of the graft and a high mortality[184] Harken and associates used various synthetic prostheses in operations on 51 patients with mitral insufficiency most recently a lucite spindle baffle which substitutes for the loss of valve tissue[10] The teardrop shaped spindle is anchored at one end beneath the leaflets and annulus in the left ventricle, and the larger end is fixed above the annulus posteriorly There has been general objection to the use of foreign substances in the heart because of the danger of their becoming free and the relatively high mortality rate associated with the operation

Davila and associates[69] employed a constricting (circumferential) suture to decrease the size of the atrioventricular annulus and recently reported satisfactory results in 12 clinical cases of mitral insufficiency[101] By means of suturing Hurwitt et al[134] corrected experimental mitral insufficiency by plicating the annulus from the epicardial surface of the left ventricle without compromising the coronary circulation Kay and Cross[147] noted that anterior displacement of the posterior wall of the atrium at the level of the mitral orifice obliterated the regurgitant jet Accordingly they devised a technique to reduce the size of the mitral ring at the posteromedial commissure Nichols has devised a technique whereby limited apposed portions of the mitral valve ring over either or both valve poles, are approximated by mattress suture[191] In 17 patients thus operated on there was a striking immediate reduction in the size of the digitally palpable regurgitant stream There were 3 postoperative deaths In all but one case there was auscultatory improvement and striking clinical benefit

MITRAL STENOSIS

PATHOLOGIC PHYSIOLOGY

Alterations in Hemodynamics[48, 88, 142, 111]

Size of the Mitral Orifice In animal experiments[3] significant circulatory disturbances occur only when the mitral orifice is narrowed to less than one quarter of its normal size In man the normal area of the mitral orifice ranges between 4 and 6 sq cm Serious circulatory disturbances and consequent clinical symptoms arise only when this area is reduced to less than 1 sq cm In symptomatic mitral stenosis the mitral orifice usually measures between 0 5 and 1 1 sq cm[142]

Left Atrial and Pulmonary Capillary Pressures[104, 104a, 104] The resistance afforded by a narrowed mitral orifice results in an increased left atrial pressure Since there are no valves between the atrium and the pulmonary veins the rise in left atrial pressure is reflected by that in the pulmonary veins and capillary The pulmonary capillary pressure is measured preoperatively by wedging the cardiac catheter into the extreme periphery of a branch of the pulmonary artery[229] Whether this pressure actually represents pulmonary capillary pulmonary venous or even pulmonary arteriolar pressure, it is an approximation of the left atrial pressure and of the resistance offered by the narrowed mitral valve Left atrial pressures have been measured by venous catheterization[48] (when there was an associated atrial septal defect) by needle puncture through the bronchoscope[8] suprasternal notch[20a] or chest wall[30, 247] or by direct puncture during cardiac operations[5] The greater the blood flow the higher the left atrial and pulmonary capillary pressure for a given degree of mitral stenosis i e for a given mitral resistance Therefore the left atrial and pulmonary capillary pressures rise with the increased flows usually associated with exercise

The normal mitral orifice permits not only normal flows at rest but greatly increased flows with exercise without a rise in left atrial pressure When the mitral orifice is moderately reduced in area to about 1 5 sq cm there may be only a slight increase in left atrial pressure at rest but a marked rise with exercise In moderately severe cases of mitral stenosis with an orificial area of about 1 sq cm the mean pressure in the left atrium and pulmonary capillaries may be 15 to 25 mm Hg at rest (normal below 10 mm Hg) but with exercise this may increase to levels of 35 mm Hg or more at which pulmonary edema is likely to occur When there is more extreme mitral stenosis with a mitral orificial area of 0 5 sq cm or less such elevations of left atrial and pulmonary capillary pressures may be attained with very slight exertion since the mean *resting* left atrial pressure ranges up to 35 mm Hg and that in the pulmonary capillaries may likewise be elevated up to 35 mm Hg

The Mitral Atrioventricular Gradient Maintenance of blood flow through the narrowed mitral orifice is determined by the excess of left atrial over left ventricular pressure in diastole This diastolic atrioventricular pressure difference is termed the mitral gradient Normally there is a minimal gradient of 1 mm Hg or less Since the left ventricular diastolic pressure is usually 10 mm Hg or less and the left atrial pressure in mitral stenosis is 11 to 40 mm Hg the gradient in mitral stenosis usually varies between 5 and 30 mm Hg at rest depending on the severity of the stenosis[48, 104, 104a] Since the gradient is a direct measure of the degree of mitral stenosis successful surgical relief of the obstruction should be followed by marked reduction or virtual abolition of this gradient

Pulmonary Artery Pressure The pulmonary artery pressure for a given flow is determined by the pressure in the pulmonary capillaries and by the resistance in the pulmonary arterioles Increased blood flows up to 2 5 to 3 times the normal do not usually raise pulmonary artery pressure unless there is pulmonary vascular disease or an abnormal cardiovascular shunt Arteriosclerosis with narrowing of the pulmonary arterioles develops after prolonged increase in pulmonary capillary pressure This results in a variable increase in pulmonary arteriolar resistance which is added to the resistance represented by the high pulmonary capillary pressure The pulmonary arteriolar resistance increases from a normal of less than 50 up to 500 in moderately severe cases and up to 1500 or more dynes/second/cm^{-5} in very severe cases Pulmonary artery hypertension appears secondary to the increased pulmonary capillary and pulmonary arteriolar resistance[88] Instead of a normal pulmonary artery pressure of 30/10 with a mean of 15 mm Hg patients with severe mitral stenosis have pul

monary artery pressures of 40 to 120 systolic, 15 to 50 diastolic and 20 to 85 mm Hg mean pressure at rest.[16, 84] Furthermore, whereas the pulmonary artery pressure does not normally rise with exercise, it increases considerably in cases of mitral stenosis.

Cardiac Output (Blood Flow). Various compensatory mechanisms (infra) maintain a normal cardiac output despite the mechanical obstruction at the stenotic mitral valve. With the severer degrees of stenosis the cardiac output falls below normal at rest. In cases selected for mitral commissurotomy the cardiac index at rest is usually 1.5 to 2.5 liters per minute per square meter of body surface area, instead of the normal of 3.2. Furthermore, there is an inability to increase this output with exercise as occurs normally, or there is no increase whatever, i.e., the blood flow through the mitral orifice is maximal at rest. Occasionally, during exercise, a reduction in cardiac output is found.

Oxygen Consumption and Arteriovenous Oxygen Difference. The oxygen consumption (normally 130 cc. per minute) is usually normal or slightly elevated at rest, the latter increasing with the degree of heart failure. The rise in oxygen consumption with exercise is relatively limited compared to normal, and a large oxygen debt may be sustained. Of significance is the fact that the increased oxygen consumed during exercise is delivered to the tissues not by an increase in blood flow as is the major factor normally, but by increased extraction from the blood as indicated by an increased arteriovenous oxygen difference. Even at rest, the patient with severe mitral stenosis and diminished cardiac output obtains an adequate tissue oxygen supply by an abnormally large arteriovenous oxygen difference (5 to [redacted] instead of 4.2 vol. per cent).

Compensation by the Left Atrium

Mitral stenosis tends to diminish the inflow of blood from the left atrium into the left ventricle and the left ventricular stroke output, but with moderate degrees of stenosis the normal output is restored by the following mechanisms:

1. The residual blood in the left atrium plus the normal inflow from the pulmonary veins increases the diastolic volume and diastolic pressure in that chamber.

2. The elevated pressure in the distended left atrium and the consequent diastolic atrioventricular gradient increase the ventricular inflow during early diastole.

3. In late ventricular diastole the heightened diastolic tension in the left atrium leads to a more forceful atrial contraction and [redacted] greater discharge into the left ventricle (Starling's Law of the Heart).

The effectiveness of left atrial compensation is limited because of its relatively weak musculature, by the frequent active or inactive lesions of rheumatic fever in this chamber and often by the development of atrial fibrillation. Tachycardia and the abbreviation of diastole greatly impair these compensations. With extreme narrowing of the mitral orifice (0.5 sq. cm. or less), these compensations can no longer maintain [redacted] normal cardiac output at rest, and the normal ability to increase blood flow through the mitral orifice with exercise is diminished or completely lost.

Compensations in Pulmonary Circulation and Right Ventricle

The obstruction at the mitral orifice results in a rise in pressure and increased resistance in the pulmonary veins and capillaries. The right ventricle maintains its normal output despite this increased resistance by a more forceful contraction according to Starling's Law, and consequently the pulmonary arterial pressure and right ventricular systolic pressure rise. The right ventricle becomes hypertrophied. The subsequent increase in pulmonary arteriolar resistance, due to sclerosis and narrowing of these vessels, on the one hand imposes an additional strain on the right ventricle, but on the other hand may protect the pulmonary capillaries from dangerous rises in pressure with consequent pulmonary edema. By imposing a barrier in front of the congested capillaries, the narrowed arterioles buffer the effects of a sudden increase in right ventricular output, e.g., with exercise. Eventually, the right ventricle cannot maintain a normal cardiac output against marked increases in total pulmonary resistance or can maintain it only at rest but not with exercise. The right ventricle then fails and the right ventricular diastolic as well as the right atrial and systemic venous pressures rise.

Pulmonary Function in Mitral Stenosis

The occurrence of dyspnea and associated pulmonary symptoms in mitral stenosis [redacted] re-

lated to changes in structure and function of the lungs. Certain differences in reported findings are due largely to differences in severity of the mitral stenosis, the presence or absence of heart failure, and the type and severity of the latter.

Lung Volumes (p. 971). In asymptomatic and mild cases of mitral stenosis total and timed vital capacity, maximal breathing capacity, breathing reserve, residual volume and intrapulmonary mixing were found to be normal [illegible] West et al[141] found no appreciable alterations in lung volume even with considerable pulmonary congestion if there was no pulmonary edema or hydrothorax. With increased severity of symptoms there is a progressive reduction in total and timed vital capacity and in maximal breathing capacity and a symmetrical reduction in inspiratory capacity and expiratory reserve. The symptomatic disability is disproportionate to the ventilatory effects observed and much greater than the disability in patients with pulmonary disease with similar degrees of ventilatory disturbance. The disturbances in pulmonary function are attributed to pulmonary vascular engorgement and hypertension which reduce pulmonary compliance (elasticity) and interfere with maximal air flow velocity during respiration[20,64] In severe mitral stenosis reduction in total lung capacity may be due to increasing blood volume and enlargement of the left atrium, and with heart failure to the mechanical effects of hydrothorax and ascites. Determination of the pulmonary blood volume is of uncertain accuracy. Studies with the Hamilton dye method or with Cr^{51} tagged erythrocytes[176] have shown no consistent increase in pulmonary blood volume in mitral stenosis[37, 133, 18, 141] However, an increased blood volume is present in the enlarged left atrium, and in the right ventricle when that chamber becomes enlarged.

Pulmonary Compliance and Resistance. Work of Breathing. The occurrence of dyspnea, a subjective symptom, is related to fatigue of the muscles of respiration due to the work of breathing. The force exerted by the respiratory muscles is used to overcome the elastic resistance of the lung and the resistance offered by pulmonary tissue viscance and air turbulence and viscance. Pulmonary compliance, which denotes the distensibility of the lung, is a measurement which varies inversely as the elastic resistance of the lung. Pulmonary compliance which may be measured by new techniques[119] (p. 976) is significantly reduced in mitral stenosis[119, 174] i.e., its distensibility is decreased and its elastic resistance increased. This is an early abnormality and may be present in the absence of significant ventilatory disturbance or symptoms. The reduction in pulmonary compliance is intensified during exercise[174, 5, 6] and with increasing pulmonary congestion and heart failure. All other pulmonary resistance (besides that due to elastic resistance) is increased only slightly unless there is heart failure. The work of breathing can be calculated from pressure-volume diagrams made from tracings of intraesophageal pressure and tidal volume. The work of breathing for a given alveolar ventilation is increased in mitral stenosis owing chiefly to pulmonary rigidity as measured by diminished pulmonary compliance[174] Furthermore the occurrence and degree of dyspnea and orthopnea is correlated closely with the diminished pulmonary compliance and increased work of breathing. More recent studies[1, 3] suggest that dyspnea in mitral stenosis is conditioned not by the *work* of breathing but by the *force* which has to be applied to satisfy the ventilatory demands at rest or with exercise. This force is indicated by the magnitude of the negative pleural pressure swing during inspiration.

A slight degree of hyperventilation is common in mitral stenosis[4] Normally there is an optimum respiratory rate to accomplish a given alveolar ventilation with the minimum work. In mitral stenosis this optimum frequency of respiration is significantly augmented, accounting for the rapid shallow respirations in the dyspneic patient with mitral stenosis. With exercise the oxygen consumption per liter of ventilation falls.

Alveolar Capillary Diffusion in Mitral Stenosis

The thickening of the pulmonary alveolar capillary interface commonly observed in advanced mitral stenosis appears to be associated with impaired diffusion of oxygen from the alveoli to the pulmonary capillaries[18] Carroll and Riley[49] and Fowler et al[50] found a good correlation between the impairment of diffusion and the severity of exertional dyspnea. Carroll, Cohn and Riley[48] determined that the distribution of alveolar aeration and pulmonary circulation, and the alveolar-capillary diffusion (p. 975), were normal

in 7 of 29 patients with mitral stenosis In the remaining patients they discovered either disturbances in distribution resulting in a diminished vital capacity and maximal breathing capacity or disturbances in diffusion resulting from pulmonary capillary congestion fibrosis and thickening of the alveolar capillary membrane and minimal pulmonary edema Dyspnea is not related directly to impaired alveolar capillary oxygen diffusion even though the two may be empirically correlated Increased pulmonary rigidity and increased effort of breathing which result in dyspnea, and alveolar capillary thickening with impaired diffusion both tend to appear concurrently as pulmonary consequences of severe and prolonged mitral stenosis

Arterial Oxygen Saturation and Tension[111]

The arterial oxygen saturation and tension are usually normal in mitral stenosis even in patients with dyspnea In some cases, however the oxygen saturation is reduced slightly below the normal of 95 to 98 per cent and this reduction may be intensified with exercise[4] However even slight reductions in the arterial oxygen saturation may denote more significant reductions in arterial oxygen tension, as seen in the dissociation curve of oxyhemoglobin (Fig 56 p 229) Reductions in arterial saturation in mitral stenosis particularly with heart failure are due to improper pulmonary alveolar ventilation or alveolar capillary diffusion (L factor) but sometimes also to venous admixtures (α factor)[48, 90] Finally in some patients with mitral stenosis the oxygen saturation is definitely diminished to 90 per cent or less, especially in the presence of pulmonary edema, infarction or pneumonia However, dyspnea cannot be related to diminished oxygen saturation or tension in most patients with mitral stenosis, since these are usually normal The reduction in arterial oxygen saturation is, however causally related to cyanosis when the former is definitely reduced

Blount and associates in a study of 18 subjects with mitral stenosis found the alveolar oxygen tension normal, but the arterial oxygen tension was diminished and there was consequently an increased oxygen gradient between the alveoli and arterial blood The increased gradient was interpreted as being due to an increased venous admixture (p 975) rather than to impaired diffusion

CLINICAL FEATURES OF MITRAL STENOSIS

1 Stage of Complete Compensation

Cardiac symptoms may be completely absent in patients with physical signs of mitral stenosis In these patients the mitral obstruction is of slight or moderate degree and compensation is perfect

The perfectly compensated, asymptomatic patient with mitral stenosis may live a normal life span and engage in normal physical activities But he is subject to the same complications as patients with severer mitral lesions Repeated rheumatic infections progressive contraction and adhesion of a scarred valve, or secondary calcification may intensify the obstruction and produce circulatory disturbances in a patient hitherto asymptomatic A patient with mitral stenosis may suddenly develop symptoms of pulmonary congestion or right heart failure after a prolonged period of perfect compensation Bacterial endocarditis atrial fibrillation, embolization, pulmonary infections and acute pulmonary edema may suddenly abbreviate a previously uneventful course

2 Stage of Left Atrial Failure

The majority of clinically significant cases of mitral stenosis are those in which compensation is imperfect and there are evidences of pulmonary congestion In these cases we may speak of failure of the left atrium for this chamber, although dilated and hypertrophied, is no longer able to eject or accommodate the excess of blood dammed up behind the mitral obstruction The lungs undergo alterations which interfere with the mechanics of respiration and increase the force and work of breathing (p 651) When this occurs the disease is no longer asymptomatic Some degree of decompensation is a common and early development in patients with mitral stenosis because the weak left atrium can rarely prevent pulmonary congestion for long When this congestion is slight or moderate, the patient may suffer hardly any discomfort unless he attempts some unusual physical task Thus the degree of left atrial failure and consequent pulmonary congestion is very variable and the distinction between compensation and decompensation in mitral stenosis may not be a sharp one

The following are the chief manifestations of mitral stenosis in the stage of left atrial failure but some of them may occur when the

lesion is seemingly well compensated or at any stage of the disease

Dyspnea and cyanosis are the major symptoms of mitral stenosis They result from pulmonary congestion due to failure of the left atrium A mild degree of cyanosis produces early the so-called mitral facies This is characterized by a cyanotic flush over the cheek bones and a dusky cyanosis of the lips which may be more striking following exertion Severe degrees of cyanosis are seen in long standing cases of mitral stenosis and pulmonary congestion with marked alterations in pulmonary structure

Shortness of breath is the commonest complaint in mitral stenosis and the one most disturbing to the patient Almost invariably the dyspnea is induced by exertion Rarely is it of the paroxysmal nocturnal variety encountered in the left ventricular failure of aortic hypertensive or coronary heart disease Many patients with mitral stenosis become so accustomed to a mild degree of chronic exertion dyspnea that they are hardly aware of its existence Occasionally shortness of breath is precipitated acutely perhaps by arduous exertion an infection pregnancy or the onset of atrial fibrillation Eventually dyspnea may be present even at rest At this stage *orthopnea* is generally associated

The occurrence of dyspnea and related symptoms has been correlated empirically with the height of the capillary pressure the pulmonary resistance and the pulmonary arterial pressure [35, [illegible], 35, 118, 210, [illegible]] Actually it is more directly related to the pulmonary congestion and rigidity of the lung and the consequently greater strain and work imposed on the muscles of respiration (p 654) Paroxysmal dyspnea has been particularly related to the pulmonary capillary pressure (p 649) Dyspnea on exertion or at rest is usually mild with slightly elevated mean pulmonary arterial pressures (20 to 35 mm Hg) and moderate or severe with higher mean pressures between 35 and 75 mm Hg Dyspnea may be correlated even more closely with the rise in pulmonary artery pressure on exercise Similarly mild dyspnea has been associated with moderate increases in pulmonary arterial resistance (75 to 140 dynes/second/cm^{-5}) moderate dyspnea with resistances between 150 and 500 and severe dyspnea with pulmonary arteriolar resistances between 500 and 1500 dynes/second/cm^{-5} There are however frequently examples of a disparity between the degree of dyspnea and the increase in pulmonary arteriolar resistance

Palpitation and precordial distress are early symptoms which occur almost as frequently as dyspnea They are not directly due to the pulmonary engorgement Palpitation is especially disturbing at night when the patient may be unable to fall asleep or may be awakened suddenly to become aware of forceful or rapid heart beats which occasionally skip Palpitation may be due to extracardiac factors such as indigestion excessive coffee alcohol or tobacco exertion or excitement but it appears to be induced by these causes much more readily in the heart with mitral disease than in the normal one The onset of atrial fibrillation may be heralded subjectively by palpitation and precordial distress but when the fibrillation is established and associated with a slow ventricular rate many patients are either unaware of or undisturbed by its presence

Hemoptysis has been encountered in 10 per cent of cases of mitral stenosis [347] and Thompson and Stewart[330] reported frank hemoptysis in 29 (17 per cent) of 168 cases of mitral stenosis It may occur late in the disease or it may be the initial and only subjective complaint Usually it denotes advanced mitral stenosis It may occur suddenly and be of considerable severity In 3 cases reported by Oppenheimer and Schwartz[196] and in 6 by Guizetti and Dinkler [117] the volume of a given hemorrhage amounted to between 200 and 300 cc I have seen repeated brisk hemoptysis produce a marked secondary anemia in a woman with mitral stenosis who was otherwise asymptomatic Other possible causes of hemoptysis and of secondary anemia had been thoroughly excluded In one patient with advanced mitral stenosis repeated exsanguinating hemoptyses of 500 to 1000 cc were erroneously attributed to pulmonary infarctions The bleeding was found to be due to bronchiectasis of the left lower lobe secondary to bronchostenosis caused by the pressure of a huge left atrium

Hemoptysis may occur repeatedly with moderate pulmonary engorgement and be absent when pulmonary stasis is severe Usually however it is more likely to occur with increasing pulmonary congestion In the cases reported by Oppenheimer and Schwartz

the attacks of hemoptysis were preceded by aura with psychogenic manifestations and pain between the shoulder blades The hemoptyses are not in themselves fatal and subside within a few days but the ultimate prognosis in these cases is usually poor Hemoptysis has been attributed to the rupture of small congested capillaries or small vessels in the lung (pulmonary "apoplexy") But according to Ferguson et al [8] the bleeding arises from the rupture of varices of the bronchial veins These varices result from pulmonary congestion and consequent enlargement of the communications between the pulmonary and bronchial veins Hemoptysis may also be due to pulmonary embolization and infarction This usually occurs in patients with severe pulmonary stasis right heart failure and atrial fibrillation

Cough is a frequent symptom It is usually worse at night and after physical exertion As a rule it is due to pulmonary congestion and occasionally in part to pressure of a large left atrium on the bronchial tree Occasionally cough is the most prominent symptom of the disease Most often the cough is non productive, but sometimes there is an associated mucoid or mucopurulent expectoration due to secondary bronchial and pulmonary infections which are prone to complicate pulmonary congestion in mitral stenosis The sputum frequently contains numerous "heart failure" cells

Acute pulmonary congestion or edema occurs in mitral stenosis but it is much less frequent than in aortic valvular lesions Nevertheless it is characteristic for patients with tight mitral stenosis to suffer from recurrent attacks of acute pulmonary edema with severe dyspnea orthopnea and the expectoration of frothy, blood stained sputum [27, 15] Pulmonary edema may occur in patients with atrial fibrillation or with sinus rhythm The occurrence of the attack is less sharply limited to the night and the horizontal position than in cardiac "asthma" due to left ventricular failure As a rule it follows sudden or severe *exertion emotional excitement, sexual intercourse* or bathing and may develop during operations, pregnancy, childbirth or after rapid digitalization It has also been precipitated by attacks of paroxysmal tachycardia or atrial fibrillation or by the intravenous administration of salt solution, premenstrual fluid retention infections of the upper respiratory tract, pulmonary embolism, hyperthyroidism or acute anemia

The most plausible explanation for its occurrence is the sudden intensification of pulmonary stasis in an already congested lung owing to an increase in venous return to and output from the right heart This serves to increase the pulmonary capillary pressure which rises significantly above the colloid osmotic pressure and results in transudation of plasma fluid into the pulmonary alveoli [4] A relatively competent right heart appears essential to its development The development of pulmonary edema due to a rise in pulmonary capillary pressure is favored also by factors increasing the resistance to flow in the left atrium, notably tachycardia, which shortens diastole during which the left atrium must be emptied The occurrence of paroxysmal dyspnea and pulmonary edema has been correlated with the height of the pulmonary capillary pressure, in those subject to these attacks the pressure is usually between 25 and 35 mm Hg at rest and higher with exercise [106] Occasionally a very elevated pulmonary capillary pressure has been found in patients who do not suffer from pulmonary edema This may be due to an inability of the right ventricle to increase its output with exercise, to a high pulmonary arteriolar resistance, which bears the brunt of the increased right ventricular output and "protects" the pulmonary capillaries, or to thickening of the pulmonary capillary alveolar membrane which impairs permeability and inhibits transudation of plasma despite a high capillary pressure [5] That acute pulmonary edema occurs so much less frequently in the pulmonary congestion of mitral stenosis than in that of left ventricular failure may be due to the more gradual development of pulmonary congestion in the former and consequently to differences in pulmonary accommodation Diminished permeability of thick capillaries may be a factor

Angina Pectoris Vague precordial sticking or aching sensations occur occasionally in *mitral stenosis Most often they are due to* extracardiac causes or to a superimposed neurosis Definite angina pectoris with typical precordial and arm radiations occurs occasionally and is probably due to associated aortic or coronary artery disease [131] Cardiac pain was present in 34 (8 5%) of 400 patients with mitral stenosis [2]

Hoarseness and paralysis of the left recurrent (laryngeal) nerve were first described by Ortner[196] in two cases of mitral stenosis The hoarseness may be intermittent at first Later it becomes constant and may progress to complete aphonia The most plausible explanation of this symptom appears to be that of Fetterolf and Norris [■] who concluded from detailed anatomic studies that the left recurrent nerve is compressed between the dilated left pulmonary artery and the aorta or aortic ligament Paralysis of the laryngeal nerve and left vocal cord also occurs in other cardiac conditions associated with dilatation of the pulmonary artery[66] The paralysis of the vocal cord is reversible since it may disappear following mitral commissurotomy[6]

Dysphagia is an uncommon symptom resulting from pressure of a dilated left atrium on the esophagus[231]

Weakness ■ a common complaint in mitral stenosis with failure just as it ■ in other forms of valvular disease It may be related to the excessive work of respiration or to an inadequate cardiac output *Menstrual disturbances* especially irregularity oligomenorrhea or amenorrhea are frequently encountered in women with mitral disease

Arrhythmias occur frequently both in this stage and when the right ventricle fails *Atrial fibrillation* is the most important of these De Graff and Lingg[68] encountered it in 43 per cent of 644 patients with mitral stenosis who were followed to their termination It was present in 42 per cent of 200 cases operated on for mitral stenosis[233] Its development ■ denoted symptomatically by palpitation less often by precordial distress and dyspnea It may be preceded by other irregularities such as extrasystoles or atrial flutter The fibrillation may be paroxysmal or persistent Usually paroxysmal fibrillation is converted into the permanent form It may herald the onset of right heart failure or it may actually precipitate it There is evidence that the cardiac output is diminished 20 to 25 per cent when atrial fibrillation occurs in patients with mitral stenosis[150] On the other hand clinical experience indicates that usually cardiac efficiency is not appreciably better with normal rhythm than with atrial fibrillation provided the ventricular rate can be kept slow Atrial fibrillation like right heart failure is a late stage in mitral stenosis Atrial fibrillation with slow ventricular rate is compatible with five or more years of life

Paroxysmal tachycardia and extrasystoles are seen frequently in patients with mitral stenosis but they are not characteristic of this lesion as is atrial fibrillation

3 Stage of Right Sided Heart Failure

Right heart failure is a common termination of mitral stenosis The longstanding increase of pressure in the pulmonary circulation as indicated anatomically by severe sclerosis of the pulmonary vessels leads to dilatation and hypertrophy of the right ventricle Failure of this chamber results in part from the mechanical effect of the increased strain and in part from the myocardial disease which is generally of rheumatic origin The precipitating causes have been discussed elsewhere (p 137)

The symptoms of right heart failure may develop gradually or suddenly Usually they follow a period dominated by symptoms of pulmonary engorgement Exertional dyspnea becomes more severe and breathlessness ■ present even at rest Orthopnea may be a prominent symptom Not infrequently when right sided failure is well developed the dyspnea and orthopnea are alleviated owing to the diminished right ventricular output into the pulmonary circulation But when severe changes in the lungs are fully established as a result of longstanding mitral stenosis the dyspnea and orthopnea may remain unabated even when the right ventricle fails Cyanosis similarly persists with the development of right-sided heart failure

Certain additional symptoms are intrinsic in right sided heart failure and result from engorgement of the systemic venous system (Chapter 7) These include engorgement of the cervical and other superficial veins enlargement of the liver peripheral subcutaneous edema and transudates in the serous cavities

Atrial Thrombosis Atrial (mural) thrombi may occur at any stage of mitral stenosis but they are especially frequent after right heart failure and atrial fibrillation develop[144, 28] These antemortem clots depend chiefly on the stagnation of blood in a very large atrium but rheumatic endocardial lesions may predispose to their formation[109] The thrombi are found in either atrium and especially in the atrial appendages In the absence of right heart failure and consequent dilatation of the right

atrium, the thrombi are usually confined to the left atrium They occur as small brownish-red ovoid masses of organized platelet thrombi attached to the pectinate muscles and endocardium Occasionally they are large spherical or polypoid purplish masses with smooth surface and gelatinous structure which partially or completely fill the atrial chamber At operation thrombi were found much more frequently in cases of pure mitral stenosis (86 of 200) than in cases of mitral stenosis with significant regurgitation (4 of 47 cases)[133] Perhaps the regurgitant jet inhibits stasis and thrombus formation Correspondingly arterial embolism was encountered in only 6 4 per cent of 47 cases of mitral stenosis and regurgitation as compared with 23 [illegible] per cent of 200 operated cases of pure mitral stenosis Actis Dato et al[14] reported the occurrence of thrombi in the left atrium in 56 (11 2 per cent) of 500 patients with mitral stenosis in whom valvulotomy was performed They were found in 35 3 per cent of the 133 patients with atrial fibrillation and in only 2 4 per cent of the 367 patients with sinus rhythm The left atrial appendage was thrombosed in 30 per cent of 1200 patients operated on by Bailey s group for mitral stenosis and in 53 per cent of those with persistent atrial fibrillation

Clinical symptoms are not an invariable consequence of the atrial thrombi which may be accidentally discovered post mortem Frequently however they produce serious clinical disturbances either by (1) embolic closure of distant vessels or (2) local obstruction of the stenotic mitral orifice

1 Embolization[144, illegible] Fragmentation or erosion of atrial thrombi results in dissemination of small particles which produce embolic closure of pulmonary cerebral, visceral or peripheral arteries De Graff and Lingg[65] found that embolism and infarction were somewhat more frequent among patients with atrial fibrillation Among 194 patients with rheumatic heart disease complicated by systemic emboli Daley et al [illegible] found a mitral lesion in 97 per cent atrial fibrillation in 90 per cent and either a mitral lesion, atrial fibrillation or both in 100 per cent About half of systemic emboli are cerebral[145] Pulmonary emboli with infarction of the lung occurred in almost half of the patients I have seen with mitral stenosis and right heart failure In these cases the source of the emboli may be thrombi either in the right atrium or in the peripheral deep veins of the lower extremity Pulmonary infarction is one of the complications to be considered when cardiac failure does not yield to treatment Systemic arterial emboli arise in left atrial thrombi Such emboli had occurred preoperatively in one quarter of 56 patients who were found to have left atrial thrombi at the time of mitral valvulotomy[14]

Several times I have observed the sudden occurrence of cerebral emboli in well compensated patients with mitral stenosis I have also seen cerebral embolization as the first clue to the presence of mitral stenosis Frequently the right middle cerebral artery is occluded with resultant aphasia and crossed hemiplegia Sometimes these hemiplegias are relatively benign in that they clear up with only slight disability in the patient But they are usually forerunners of further embolization A small cerebral artery may be occluded and only a focal paralysis or isolated aphasia is observed

Visceral embolization is not infrequent especially in the kidney and spleen Infarcts in these organs are most often discovered accidentally post mortem but clinical symptoms may occur I have also seen embolization of the hepatic artery with infarction of a lobe of the liver Of greater clinical importance is embolization of a mesenteric artery with infarction of the intestinal wall I have twice seen patients with infarction of the ileum operated upon for suspected acute appendicitis

Embolization of peripheral arteries is not rare Usually it produces dramatic clinical symptoms because of the abruptness of the occlusion and the absence of adequate collateral circulation Embolization of the aorta with formation of a pantaloon thrombus at its bifurcation may cause sudden sharp pain in the abdomen, lower back and extremities loss of pulsation and warmth of the lower extremities and shock More localized symptoms occur with embolization of the popliteal femoral or brachial arteries Gangrene may result and amputation may be necessary Occasionally recovery follows such amputation, but usually the general condition of the patient or subsequent emboli in other parts of the body cause death I have frequently seen spontaneous recovery from peripheral embolization without the development of gangrene

2 Ball Valve Thrombus The large ball shaped thrombi may completely occlude the

mitral orifice[60, 61] and produce sudden death I have also seen occlusion occur more gradually and lead to distinctive clinical features which make possible an antemortem (usually preterminal) diagnosis of this complication The patient develops a cadaveric mottled cyanotic discoloration of the hands and feet The ends of the extremities the tip of the nose and the ear lobes become cold and streaked with blue and undergo local necrosis The pulse may be weak or absent Within a few days the patient goes into shock and dies I have seen the identical clinical picture preterminally in patients with extremely tight mitral stenosis without the association of a ball valve thrombus All the patients with surface of the precordium in the region of the apex

A palpable *shock* may accompany the first sound at the apex and the second sound in the pulmonic area A systolic lift is often felt in the third left interspace over the outflow tract especially when pulmonary hypertension is moderate or severe [69] A similar systolic heaving pulsation in the left sternal and central precordial region[70] and sometimes in the epigastrium[71] is associated with right ventricular hypertrophy and clockwise rotation of the heart on its longitudinal axis In addition one can sometimes feel a *tap* in the apical region immediately after the second sound This is the palpable equivalent of the

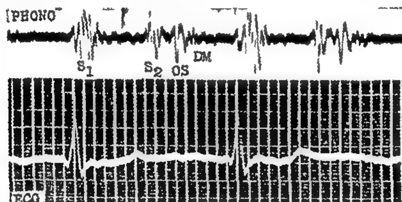

Fig 110 Mitral stenosis Opening snap (OS) with diastolic murmur (DM) Absence of presystolic murmur related to atrial fibrillation

ball valve thrombus studied by Schwartz and Biloon [68] had atrial fibrillation with rapid ventricular rate and were refractory to digitalis

Occasionally there is intermittent occlusion as the thrombosis is floated away from the orifice either by the blood stream or by change in the patient's position With recurrent occlusion there is an exacerbation of symptoms especially dyspnea and cyanosis syncope and sometimes disorientation convulsions or transient shock Relief may occur spontaneously Sometimes the patient learns to obtain relief by sitting up and leaning forward

Physical Signs in the Heart

Inspection In children the precordium may bulge There may be a visible pulsation in the epigastrium and to the right of the sternum if right ventricular hypertrophy has occurred

Palpation A characteristic *presystolic thrill* may be felt as a purring sensation on the sound produced by the opening snap of the rigid stenotic mitral valve (see below)

The apical impulse is usually felt at its normal site as a hurried slapping stroke A tentative diagnosis of mitral stenosis can sometimes be made on palpation which may reveal a rapid slapping apical impulse a presystolic thrill a diffuse precordial heaving pulsation and a palpable shock over the pulmonary region and apex

Percussion Prominence of the pulmonary artery and left atrial appendage may cause increased cardiac dullness along the left border at the level of the third interspace and fourth rib

Auscultation The auscultatory signs of mitral stenosis are frequently confusing because they vary greatly with the severity of the lesion at different stages of the disease Over long periods of time they may alter considerably even in the same patient because

the valve may be undergoing progressive change as a result of recurrent inflammation and healing

The characteristic sign is a localized apical *diastolic murmur* (Fig 120)[181] This may be entirely presystolic in time or it may fill most or all of diastole, with accentuation in presystole (Fig 120) or it may occur in the early or middle period of diastole and completely lack a presystolic element Most often it is predominantly mid-diastolic or predominantly presystolic in time The presystolic accentuation may disappear with atrial fibrillation or heart failure (Fig 119) The diastolic murmur arise as a result of an extremely rapid blood flow past the mitral obstruction into the left ventricle It occurs during those portions of diastole when the pressure difference between the left atrium and left ventricle becomes especially high This pressure difference is accentuated by atrial contraction, especially when the left atrium undergoes compensatory dilatation and hypertrophy

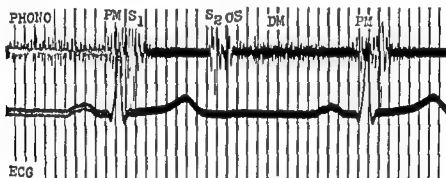

Fig 120 Mitral stenosis Opening snap (OS) and decrescendo diastolic murmur (DM) followed by crescendo presystolic murmur (PM)

The *presystolic murmur* which in itself suggests the diagnosis of mitral stenosis, is low pitched and rumbling or rolling in quality, with a characteristic crescendo accentuation which merges into a "snappy" or booming first sound This murmur is sometimes described as a mid diastolic roll with presystolic accentuation Graphic registration of the heart sounds indicates that the crescendo effect is not part of the murmur itself but only an auditory illusion created by the proximity of the murmur to the subsequent sharp first sound[163] The murmur is usually well localized just within the apex in an area which is not much larger than the bell of a Bowles stethoscope Thus it can be easily overlooked unless the region of the apex is completely examined Its small area of audibility corresponds to the small portion of left ventricle applied to the chest wall, while its radiation toward the left atrium is not heard, since that chamber is situated posteriorly deep in the chest wall Often the presystolic murmur is heard only if the patient is in the left lateral position Sometimes it is demonstrable only if the cardiac rate is quickened by exercise, emotion or the administration of amyl nitrite

The characteristic presystolic murmur is often absent in mitral stenosis On the other hand its presence does not always signify that lesion[170]

1 It is absent in mild cases, or early in the disease when the obstruction is relatively insignificant It disappears in the late stages of mitral stenosis if atrial fibrillation sets in or when the left atrium becomes extremely dilated The early diastolic murmur however, remains and occupies a variable part of diastole The diastolic murmur may be misinterpreted as presystolic in cases with atrial fibrillation if the ventricular rate is rapid and the murmur is close to the first heart sound

2 A typical presystolic murmur may be encountered in aortic insufficiency with a normal mitral valve[91] (Austin Flint murmur, p 689) Bland White and Jones[8] noted that a rumbling mid diastolic or presystolic murmur occurred in children and young adults with recent severe active rheumatic carditis and ventricular dilatation in whom post mortem examination revealed no mitral stenosis A presystolic murmur has been described also in some cases of severe secondary anemia and cardiac dilatation due to ancylostoma (hookworm) infection[113] and in cases of pernicious anemia and sickle cell anemia (Chapter 43) A transient mid

diastolic apical murmur has been noted in some cases of acute nephritis with hypertension and left heart failure[204] An apical diastolic murmur may occur in atrial or ventricular septal defect or patent ductus arteriosus[139]

A *systolic murmur* is commonly heard in cases of mitral stenosis[39, 18] and occasionally is the only murmur It may be due to an associated significant mitral insufficiency but it may be heard in pure mitral stenosis perhaps as a result of calcification of the cusps[43] It may also be due to an associated tricuspid insufficiency

The *first sound* at the apex is almost as characteristic as the presystolic murmur It is short somewhat delayed snapping (or snappy), loud and booming and accompanied by a palpable apical shock The first sound normally occurs within 0 06 second of the onset of the QRS In mitral stenosis it is usually delayed to 0 07 second or more[119] It is usually an early sign and may be noted before there is any diastolic murmur Its shortness and loudness have been explained as being due in part to the fibrotic changes in the valve cusps and chordae tendineae but especially to the rapid contraction of the left ventricle (as a result of the abbreviation of systole) A similar booming first sound may be heard in Graves' disease where there is diminished ventricular filling due to tachycardia When the mitral valve becomes completely rigid and immobile the sharp first sound disappears (as does the opening snap)

The time interval between the onset of the QRS of the electrocardiogram and the first sound in the phonocardiogram was found to vary according to the duration of the preceding cycles[18] Wells[39] devised a method whereby the severity of the mitral stenosis could be estimated from a logarithmic phonocardiogram and a synchronous electrocardiogram He measured the Q 1 interval (onset of QRS to onset maximal vibration of first heart sound) the 2 O S interval (onset of second sound to opening snap) and the R R interval The Q 1 and 2 O S intervals were corrected to correspond to a cycle length of 0 8 second The severity of mitral stenosis was estimated from the difference between these intervals. The more rigid the mitral cusps the more the delay between the onset of QRS and the first sound the higher the atrioventricular gradient the less the interval between the second sound and the opening snap Therefore, the more severe the mitral stenosis the greater the difference between these two intervals (Q 1)-(2 O S)

The *second sound* heard over the pulmonic area is accentuated regardless of the degree of pulmonary hypertension Like the first sound at the apex it may be accompanied by a palpable shock usually only in cases with moderate or severe pulmonary hypertension (i e mean pulmonary artery pressure over 40 mm Hg)[43] The accentuated pulmonic second sound is due partly to the rise of pressure in the pulmonary artery and partly to the rotation of the pulmonary artery and conus, which brings them closer to the chest wall The pulmonic second sound may be *reduplicated* as well as accentuated The pathogenesis of this reduplication is uncertain but may be the change in the relative pressures in the pulmonary artery and aorta with resulting asynchronous closure of the semilunar valves Reduplication of the second pulmonic sound with accentuation of the second element of the split sound has been correlated with severe pulmonary hypertension[43]

The *second sound at the apex* may appear reduplicated since it is often followed immediately by a click which is palpable as well as audible This is caused by the sudden recoil of the resistant mitral cusps as they are opened by the strong atrial stream It has been termed the "opening snap or the claquement d ouverture of the mitral valve (Figs 119 120)[167] While it has long been recognized by continental writers its frequent occurrence was emphasized in this country by Margolies and Wolferth[172] who made detailed phonocardiographic studies They demonstrated that this third apical sound (opening snap) occurred usually between 0 08 and 0 11 second after the beginning of the second sound which confirms the concept that it is connected with the opening of the mitral valve The opening snap occurs at the peak of the V wave in the venous pulse tracing The briefer the interval between the second sound and the opening snap the higher the atrioventricular gradient and the more severe the stenosis In the presence of atrial fibrillation the interval between the second heart sound and the opening snap of the mitral valve varies with the preceding cycle length But when mitral regurgitation is associated, the interval may remain fixed[154] This extra click may be

quite loud and produce an echo effect which the French have termed "bruit de rappel" The opening snap may be misinterpreted as a normal third heart sound as a gallop rhythm or as a split second sound

The second component of the split second sound occurs earlier than the opening snap, whereas a third heart sound occurs later The opening snap is high pitched and sharp, the third heart sound is low pitched and dull The occurrence of an extra sound at the apex in a young individual without failure and especially with a history of rheumatic fever should always suggest the possibility of mitral stenosis

Functional Pulmonic Insufficiency In addition to the apical diastolic murmur in mitral stenosis described above a soft, blowing high pitched diastolic murmur is heard over the pulmonic area in cases with severe pulmonary hypertension This was described in 1889 by Graham Steell as "the murmur of high pressure in the pulmonic artery" and is known as the Graham Steell murmur[2 3] It is probably the result of a functional insufficiency of the pulmonic valve due to pulmonary artery hypertension and consequent dilatation of that vessel and of the pulmonic orifice Rheumatic inflammation of the base of the pulmonary artery and valve and athero sclerotic changes in the vessel may play an accessory role in its dilatation While relative pulmonic insufficiency and the Graham Steell murmur are encountered most often in mitral stenosis, they may also occur in various chronic pulmonary diseases associated with increased pressure in the pulmonary circuit The Graham Steell murmur must be distinguished from the diastolic murmur of aortic insufficiency The latter is characterized by differences in the roentgenologic appearance of the heart the associated electrocardiographic findings of left ventricular hypertrophy, and sometimes by distinctive peripheral signs (p 690)

Pulse and Blood Pressure in Mitral Stenosis

In compensated mitral stenosis the *pulse* is generally normal In extreme stenosis, the pulse may become soft and small, corresponding to a diminished stroke output Late in the disease especially during the stage of right sided heart failure the pulse is often completely irregular due to atrial fibrillation Extrasystoles and dropped beats are not infrequent at various stages of mitral stenosis

The *blood pressure* in mitral stenosis is e normal or slightly diminished The pulse p sure may also be somewhat less than nor The occasional reduction in blood pres and pulse pressure probably reflects slightly diminished stroke output Main ance of blood pressure despite a dimini cardiac output has been ascribed to a c pensatory vasoconstriction

With advancing age, patients with m stenosis were said to develop *hyperten* more frequently than control groups[24] H ever, this alleged relationship has b doubted[206 113] Hypertension was noted 16 5 per cent of 200 patients with m stenosis[113] The hypertension modified cardiac signs and electrocardiographic f ings usually associated with mitral steno

The Pulmonary Blood Pressure Pulmon Hypertension This has been discussed 649) The presence and degree of pulmon hypertension are important in the selectio patients for mitral commissurotomy a favorable results are not likely in patients w little or no pulmonary hypertension Since t can be determined directly only by card catheterization attempts have been made estimate it by correlation with clin phenomena[243] A Graham Steell murmur, *palpable* second pulmonic heart soun prominent atrial 'a' waves in the jugu venous pulse, very prominent pulmon arteries on roentgen ray examination of t chest and electrocardiographic evidence right ventricular hypertrophy are associat with moderate or severe pulmonary hyp tension Nocturnal dyspnea and hemopty occur more commonly with moderate or seve pulmonary hypertension than with mild h pertension but cannot be used to ass ess t degree of pulmonary hypertension in a given patient

Roentgenologic Appearance of the Heart Mitral Stenosis

The roentgenologic appearance of the hea in mitral stenosis varies with the stage severity of the lesion

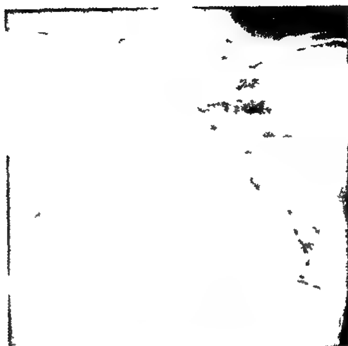
1 In cases of early or mild mitral stenos the cardiac size and outlines are often no mal[198] If some left atrial dilatation a hypertrophy are present they are difficult demonstrate

2 More advanced cases reveal evidence enlargement of the left atrium and o casionally of the right ventricle[148]

(a) Left atrial enlargement (p 103) is characterized by encroachment on the retrocardiac space and posterior displacement of the barium containing esophagus as seen in the right anterior oblique view (Fig 41*B* p 104) Recent studies suggest that the size of the left atrium is estimated best by a left lateral teleoroentgenogram with barium in the esophagus [135]

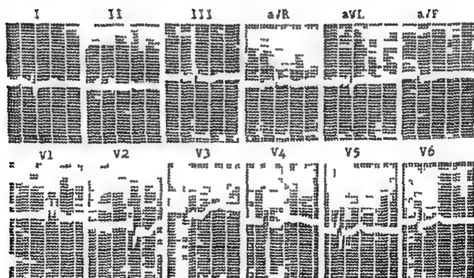
(b) In the posteroanterior view the left *sided waist of the heart is filled out there is a* straightening or convexity of the left middle cardiac contour due to enlargment of the left atrial appendage and increased prominence of the pulmonary artery and its left main branch (Figs 41*A* p 101 and 122) The latter results chiefly from elevation and elongation of the pulmonary artery [114] by the left atrium and enlarged right ventricle and slightly from dilatation of the artery The prominence of the atrial appendage is below that of the pulmonary artery This straightened or convex left border gives the cardiac silhouette its so-called mitralized configuration But a similar appearance may be encountered in other conditions associated with pulmonary hypertension When the left atrium is extremely large it may form a second bulge on the right border just above the right atrial segment or it may rarely form the entire right cardiac border (Fig 43 p 105) The enlarged hypertrophied left atrium may appear as an increased density within the shadow of the heart In the posteroanterior view the barium containing esophagus is seen to be displaced to the right (Fig 42 p 104) The left main bronchus is elevated toward the horizontal position (Figs 42 and 43 pp 104 and 105)

(c) In the left oblique view the enlargement of the left atrium causes upward and backward displacement of the upper posterior cardiac contour and may splay the main bronchus and compress and elevate the left one Displacement of the right chambers by the large left atrium may cause an enlargement of the cardiac shadow to the right and anteriorly in this view



Right ventricular enlargement is not prominent and may be revealed by anterior encroachment on the retrosternal space in the right lateral view The aortic knob is small in contrast with the prominent pulmonary artery

3 With advanced mitral stenosis and heart failure the above alterations become accentuated In addition the right cardiac border is displaced to the right by enlargement of the right atrium or by displacement of this chamber by the enlarged right ventricle and left atrium The left cardiac border may also be displaced to the left by enlargement and rotation of the right ventricle which may come to form the apex of the heart (Fig 121) The transverse diameter of the heart is enlarged



4 Calcification of the mitral valve may be demonstrated on a slightly overpenetrated film of the chest preferably by spot films after fluoroscopy to localize the site of calcification Genovese and Levine[47] thus demonstrated calcification of the mitral valve in 15 or 50 patients with mitral valvular disease All but 3 of these 15 with mitral calcification were admitted for congestive heart failure In 10 of the 15 there was atrial fibrillation In general there was good correlation between mitral calcification and the severity of mitral valvular disease A similar correlation was not associated with aortic valvular calcification Valvular calcification may also be demonstrated by planigraphy [119] Janton and associates[186] reported the finding of calcification of the mitral valve in 65 per cent of 47 patients in whom there was mitral stenosis with associated regurgitation and in [illegible] per cent of those with pure mitral stenosis Calcification of the left atrium may also be observed roentgenologically [45, 130]

5 The pulmonary vessels especially at the hilum become more prominent and the pulmonary fields congested (Fig 122) Prominence of the main pulmonary arteries is a striking feature in tight mitral stenosis with severe pulmonary hypertension In such cases the radiologic appearance may resemble that of interatrial or interventricular septal defect with severe pulmonary hypertension The prominent perihilar vessels contrast with the narrow peripheral arteries

The pulmonary veins become enlarged especially the right inferior pulmonary vein Costophrenic septal lines [46] also termed lines B of Kerley [1] are horizontal lines hair line to 2 mm thick and about 2 or 2 5 cm long 5 to 10 cm above the costophrenic angle occurring in patients with pulmonary hypertension secondary to mitral stenosis usually when the mean pulmonary artery pressure is 39 mm Hg or higher[47] (normal 20 mm Hg)

A

B

Fig 191 *A* Pure mitral stenosis in 57 year old man Prominent pulmonary artery and left atrial appendage on left Large pulmonary vessels on right Enlarged lower left contour with elevated apex formed by hypertrophied and rotated right ventricle but misinterpreted as enlarged left ventricle because of basal diastolic murmur (due to pulmonary insufficiency but attributed to aortic insufficiency) and apical and lower sternal systolic murmur (due to tricuspid insufficiency but attributed to mitral insufficiency)

B Electrocardiogram of same patient showing right ventricular hypertrophy with incomplete right bundle branch block No evidence of associated left ventricular hypertrophy

They are better seen on the right than on the left side, and there may be only 2 or 3 lines or as many as 10 to 15 spaced 0.5 to 1.0 cm apart. The lines are thought to represent widening of the interlobular septa by edema fluid.[III] Occasionally there is an acute increase in the degree of pulmonary congestion with consequent pulmonary edema (Fig. 123). Pulmonary infarction occurs commonly (Fig. 121). In longstanding cases of

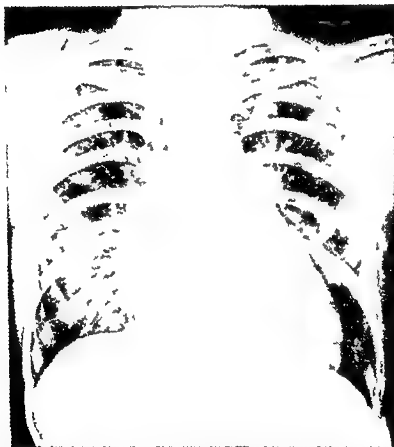


Fig. 122 Mitral stenosis. Prominent left pulmonary segment. Large hilar and pulmonary vessels. Chronic pulmonary congestion with finely mottled or nodular densities in both lung fields. Limited cardiac reserve but no overt physical or other signs of heart failure.

mitral stenosis and pulmonary congestion hemosiderin deposits produce nodular densities or reticular areas resembling miliary tuberculosis, sarcoidosis, pneumoconiosis or carcinomatosis[160, 95, 7, 8, 79] (Fig. 125). Sometimes these disseminated nodules are calcified or even ossified.[71]

The above configurations may be modified by associated lesions, notably by left ventricular enlargement in aortic insufficiency or to a lesser extent in mitral insufficiency.

Angiocardiography

Normally the left atrium is not clearly demarcated from the left ventricle. In mitral stenosis the opaque material is held up in the left atrium, which becomes sharply outlined for comparatively long periods.[50, 8] Angiocardiograms in patients with severe mitral regurgitation show enlargement of both the left atrium and ventricle without a sharp difference in opacification. However, other studies have failed to disclose angiocardiographic patterns which distinguished between mitral stenosis and mitral regurgitation.[219] The angiocardiographic diagnosis of left atrial thrombosis has been reported.[249a]

Cardiac Tomography (Planigraphy)

Section radiography may aid in distinguishing between mitral stenosis and mitral insufficiency by distinguishing right ventricular from left ventricular enlargement, since the right ventricle enlarges an

Fig. 123 Mitral stenosis with pulmonary edema. Diffuse haziness of lung fields with prominent pulmonary vessels and radiating streaks. Tendency to involve medial fields with clearing at periphery.

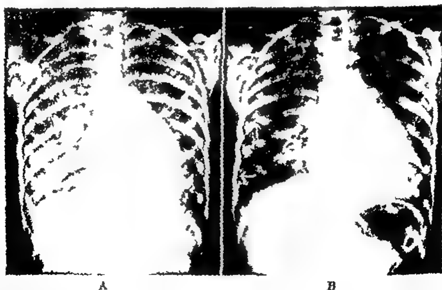

Fig. 124 *A* Mitral stenosis. Pulmonary infarction in right middle lobe with small pleural effusion. Upper border of infarct delimited by transverse fissure.

B Three months later. Infarct cleared. Residual thickening of right transverse fissure (upper arrow) and vertical band of pleural thickening along lower right chest wall (lower arrow).

teriorly and the enlarged left ventricle occupies posterior sections Thus the bulk of the enlarged cardiac shadow is anterior if it involves the right ventricle posterior if it involves the left ventricle Body section radiography has also been used to delineate a large left atrium[209] (Fig 4 p 8)

The Electrocardiogram in Mitral Stenosis

The P waves in leads I and II are often widened notched and may be of increased voltage presumably due to enlargement and hypertrophy of the left atrium and asynchronous atrial activation [3, 83] (Fig 50 1 p 119) The P waves in leads III and V_1 may be diphasic When P is diphasic in V_1 and the negative phase of P is deep and broad left atrial enlargement is suggested There is usually right axis deviation (vertical electrical axis) and often evidence of right ventricular hypertrophy [3, 83] (p 113) (Fig 47 p 110)

Fig 12a Hemosiderosis of the lung in mitral stenosis Dense miliary nodular opacities throughout both lung fields

Distinctive signs suggesting right ventricular hypertrophy such as a large R wave with or without a small s wave followed by an inverted T wave in lead V_1 (p 115) occur as a rule in cases with more severe degrees of pulmonary hypertension and right ventricular hypertrophy [3] Right ventricular hypertrophy may be indicated more regularly if right precordial leads such as V_{3R} and V_{4R} are taken Occasionally there is evidence of right bundle branch block [203] Atrial fibrillation is frequent in advanced cases There may be occasional atrial premature beats If aortic valvular disease is associated there may be no axis deviation or deviation to the left

The Vectorcardiogram in Mitral Stenosis

The vectorcardiogram may disclose evidence of both left atrial (p 122) and right ventricular hypertrophy (p 116) It distinguishes the latter from mere rotation of the heart and especially from right bundle branch block [213] In severe mitral stenosis with right ventricular hypertrophy the mitral segment of the QRS loop in the horizontal plane is directed counterclockwise and the loop is deviated to the right In the frontal plane the loop is more vertical than usual

The Ballistocardiogram

A distinct deformity was described by Davis et al [6] This consisted of a presystolic headward wave followed by a more constant footward deflection which precedes the I and occurs 0 10 second after the electrocardiographic Q The footward wave is later than the G and deforms the H wave by lowering its amplitude or abolishing it The I wave is distorted and its inscription delayed That this abnormality is specific for mitral stenosis could not be confirmed by Izak and Braun [134]

Complications of Mitral Stenosis

These occur so frequently that they have been described as features of the disease For convenience they are recapitulated here

(1) Cardiac failure (2) atrial fibrillation (3) atrial thrombosis and arterial embolization (4) subacute bacterial endocarditis (5) bronchopulmonary infections (6) laryngeal nerve paralysis (7) dysphagia In later years mitral stenosis may be complicated by hypertension and coronary atherosclerosis

Rokitansky [60] first stressed that pulmonary tuberculosis is very uncommon in cases of mitral stenosis because of the protective action of pulmonary congestion but this classic belief has been repeatedly questioned [60]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF MITRAL STENOSIS AND MITRAL INSUFFICIENCY

The diagnosis of mitral stenosis depends on recognition of the characteristic diastolic presystolic murmur in association with roentgen ray evidence of a large left atrium or a mitralized heart If the murmur is typical the diagnosis is justified even if there is no demonstrable enlargement of the left atrium The diagnosis is supported by a history of rheu

matic fever or by fluoroscopic demonstration of calcium in the mitral valve cusps It should be reemphasized that the typical presystolic murmur may be absent if there is atrial fibrillation or a huge, dilated left atrium But the apical diastolic murmur usually persists Other diagnostic signs suggesting mitral stenosis are the sharp snappy first sound at the apex the "opening mitral snap" following the second sound at the apex and a diastolic thrill Electrocardiographic records showing right axis deviation large, notched P waves and atrial fibrillation also suggest mitral stenosis especially if there is a history of rheumatic fever

A major diagnostic problem has been encountered in determining whether a significant mitral insufficiency is associated with mitral stenosis or whether the insufficiency is the predominant lesion This is a problem because mitral regurgitation is not yet consistently amenable to surgical therapy and an unnecessary exploratory thoracotomy and cardiotomy may seriously impair the clinical course or result in a fatality When a satisfactory surgical procedure is available, diagnosis of associated or predominant mitral regurgitation will be less important Then, if mitral valvular disease is diagnosed and there is a clear indication for its surgical treatment, a thoracotomy may be performed and the procedure chosen can be adjusted to the type of mitral valvular disturbance

There is usually no problem in the large majority of cases of "pure" mitral stenosis in which the characteristic mid-diastolic and presystolic murmur, sharp first sound opening snap and electrocardiographic evidence of right ventricular hypertrophy are diagnostic The presence of an apical systolic murmur as well as a diastolic murmur is the usual basis for considering the possibility of a significant regurgitation as well as mitral stenosis But Janton et al[138] reported such a combination of systolic and diastolic murmurs in 30 per cent of 200 patients in whom "pure" mitral stenosis was found at operation The louder the systolic murmur, the more prolonged it is, especially if it replaces the first sound lasts throughout systole and encroaches on the second sound, the more likely it is to be due to mitral regurgitation A loud sharp first sound and the presence of an opening snap indicate that the systolic murmur is not due to significant mitral regurgitation

A number of other findings are commonly associated with mitral regurgitation but too many exceptions make them unreliable for application to the individual case[234] Among these usually corroborative findings are systolic expansion of the left atrium, as determined by fluoroscopy or electrokymography, very great enlargement of the left atrium, and an exaggerated systolic (regurgitant) V wave or plateau in pressure tracings obtained by a catheter wedged into a pulmonary "capillary", by a balloon in the esophagus at the level of the left atrium,[158] [11] or more directly by needle puncture of the left atrium through the chest wall,[30] [178] suprasternal notch[202] or bronchoscope[30] Bateman and January[21] found that the time of onset of the intrinsicoid deflection (peak of R wave) in V_5 or V_6 occurred later and the voltages of R in V_5 or V_6 and of S in V_1 were greater in mitral regurgitation than in cases of mitral stenosis Cardiac tomography and angiocardiography (p 663) may be useful in differentiating mitral stenosis from mitral insufficiency, but these procedures are not generally used Cardiac catheterization has been used to estimate the size of the ventricles in mitral valve disease[207] In practice, the most reliable finding indicative of mitral regurgitation is the presence of left ventricular hypertrophy as disclosed by the electrocardiogram especially the precordial leads (p 645 and p 111) when associated with a loud prolonged, apical systolic murmur But there must be no other disease such as severe hypertension or aortic valvular disease to account for the left ventricular hypertrophy

Recent studies with indicator dilution curves suggest that these may be used to distinguish between mitral stenosis and mitral regurgitation Conn et al[5 a] catheterized the left side of the heart by direct atrial puncture and made multiple radiopotassium (K^{42}) injections consecutively into the left atrium left ventricle and aorta of patients with mitral valvular disease Successive blood samples were drawn from the femoral artery and analyzed for radioactivity The findings in mitral stenosis differed from those in mitral regurgitation in that the atrial circulation time was longer than the ventricular, and the atrial total volume was increased while the ventricular volume was normal in mitral stenosis Following the injection of dye into the left atrium or ventricle of patients with

mitral insufficiency a disproportionate prolongation of the disappearance slope was observed in dilution curves recorded at the radial artery[1,4,134] After injection of the dye through a catheter in the left ventricle there was a rapid appearance of the dye in the right atrium in the presence of mitral regurgitation[134]

Sometimes there is diagnostic difficulty in differentiating mitral stenosis with a Graham Steell murmur of pulmonic insufficiency from aortic insufficiency with a presystolic murmur thought to be an Austin Flint murmur (p 689) Or else there is a problem whether an inoperable aortic insufficiency is associated with an otherwise operable mitral stenosis because of the presence of a diastolic murmur at the base of the heart or whether the latter represents a Graham Steell murmur An Austin Flint murmur rarely if ever occurs except in the presence of left heart failure with left ventricular dilatation A sole or associated aortic insufficiency should be distinguishable by the characteristic boot shaped cardiac configuration due to left ventricular enlargement prominent pulsating aorta frequent peripheral vascular phenomena (p 690) and especially evidence of left ventricular hypertrophy on the electrocardiogram Mitral stenosis when associated with a Graham Steell murmur is especially likely to be associated with electrocardiographic signs of right ventricular hypertrophy

Occasionally the systolic murmur of aortic stenosis is heard best or only near the apex of the heart It is usually more harsh and more likely to be associated with a thrill than the systolic murmur of mitral insufficiency Furthermore the murmur of aortic stenosis is more likely to start later in systole and to be accentuated in mid systole does not include the first sound and rarely extends to the second sound The second aortic sound is likely to be weak or absent and calcification may be demonstrable in the aortic valve (p 704)

In the presence of tricuspid regurgitation an apical systolic murmur due to that valvular disturbance may be misinterpreted as mitral insufficiency when there is actually a pure mitral stenosis Electrocardiographic evidence of right ventricular hypertrophy and maximal intensity of the murmur in the tricuspid area with increased intensity on inspiration are diagnostically helpful

An apical diastolic murmur may be heard in conditions other than mitral stenosis (p 659) The crescendo murmur and/or the sharp first sound of mitral stenosis may be simulated in asthenic individuals with tachycardias of various origins in persons with Graves disease or with cardiac neurosis The atrial sounds in cases of 2 1 heart block may simulate a diastolic rumble Splitting of the first sound or audibility of the atrial sound may be mistaken for the low pitched presystolic murmur of mitral stenosis but the duration is much less than that of a true murmur An apical mid-diastolic murmur in the absence of mitral stenosis may be heard in early rheumatic fever and disappear later[8] Duplication of the second sound in young recruits has been described as simulating the signs of mitral stenosis[49] The pulmonic second sound is accentuated in children and young adults

The physician may mistakenly interpret the various pulmonary symptoms and signs in mitral valvular disease as indicating pulmonary tuberculosis or he may make a diagnosis of bronchopneumonia without recognizing the underlying valvular disease or complicating pulmonary embolization Paralysis of the left recurrent nerve may suggest the diagnosis of syphilitic thoracic aneurysm or bronchogenic carcinoma The observation of large hilar shadows due to the dilated pulmonary vessels in mitral stenosis with pulmonary hypertension has led to x ray therapy for lymphosarcoma and to operative intervention for neoplasm

Occasionally mitral stenosis may be caused by tumor and thrombi[61] Since these like rheumatic mitral stenosis may be amenable to surgical relief preoperative diagnosis of the etiology of the mitral stenosis is not essential

PROGNOSIS OF MITRAL VALVE DISEASE

Since mitral disease is essentially a consequence of rheumatic fever its prognosis and treatment will be discussed with rheumatic heart disease (page 849) While some statistical studies indicate that the type of valvular disease is not significant for prognosis others suggest that the outlook in mitral disease especially mitral stenosis is less favorable than in aortic valvular lesions of rheumatic origin The average age at death varies between 40 and 45 years but about 20 to 25 per cent survive the age of 50[11] There is evidence that an increasing number of patients with mitral

stenosis survive the age of 50[127] and I have seen many patients beyond the age of 60. In one series 65 patients with mitral stenosis seen between 1913 and 1946, 26 had died at an average age of 49.4 years and of those still alive the average age was 58 years.[165] Many individuals live a virtually normal life span, and engage in normal activities. Most women with compensated mitral stenosis are able to bear one or more children without serious consequences. However, pregnancy in a person with mitral stenosis is occasionally complicated by the onset of cardiac failure or subacute bacterial endocarditis and rarely by acute pulmonary edema or a dangerous form of chorea.

Wilson and Greenwood[249] have been investigating the natural life history of mitral stenosis as a basis for comparing the operative mortality with the prognosis under conservative treatment. They noted three milestones. The first was characterized by the onset of attacks of pulmonary edema, orthopnea or severe dyspnea on mild exertion (walking one block or climbing one flight of stairs); the second by the onset of atrial fibrillation and the third by the development of right heart failure. Death in six months in 16 per cent of the cases followed the first and second. Death occurred in six months in 25 per cent of those who developed right heart failure.

Persistence of rheumatic activity warrants an unfavorable prognosis. The prognosis is generally worse the larger the size of the heart, since the heart size usually reflects the severity of myocardial damage and the degree of cardiac failure. Persistent atrial fibrillation is usually a late stage with death likely to follow in three to five years. But in a series of 65 cases studied by Love and Levine[168] the average duration of atrial fibrillation was 12.8 years and of congestive heart failure 10.6 years. Most of the patients were still alive. Such data should be considered in trying to compare the risk of surgical operation for mitral stenosis with the outlook on conservative treatment. Left-sided failure with pulmonary congestion may be present for many years but the outlook is not as good as for patients who are perfectly compensated. Right heart failure is a serious omen but death does not ensue as rapidly as with right heart failure in aortic valve disease. Many patients live for three to five years or more after its onset, if proper treatment is employed. Embolization is almost always an unfavorable omen, especially since it is frequently associated with heart failure and atrial fibrillation. There is a 50 per cent mortality with cerebral embolism and an even higher mortality with embolism to the mesenteric artery.[illegible] Once embolization occurs it is usually recurrent. Of 79 patients who had a single embolic episode, there was an immediate mortality of 30 per cent.[58] But patients may live for five years or more after an embolus in mitral stenosis. Associated valvular disease usually enhances the seriousness of the condition because the more valves involved, the more serious is the myocardial injury. Statistical observations are in disagreement on this point. Associated cardiac disease, such as coronary atherosclerosis, also diminishes life expectancy, but clinical coronary disease usually occurs in patients who have already survived a relatively long time.

The cause of death is cardiac in 70 to 90 per cent of cases. Stone and Feil[24] found that 81 per cent died of circulatory failure. Bronchopulmonary infections are frequent causes of death, either directly or by contributing to the development or persistence of cardiac failure. Pulmonary, cerebral or visceral emboli often play an accessory or primary role in causing death. Subacute and acute bacterial endocarditis occur less frequently than in aortic insufficiency.

Favorable factors in prognosis are: absence of rheumatic activity; survival beyond adolescence; absence of symptoms and signs of either left or right heart failure, little or no demonstrable cardiac enlargement, and favorable economic and social status which permits the avoidance of undue physical and mental stress or climatic hazards and an intelligent attention to the laws of good hygiene.

SURGICAL TREATMENT OF MITRAL STENOSIS

The surgical treatment of mitral stenosis by mitral commissurotomy (mitral valvuloplasty)[9, 11, 122, 35] has become fairly standardized.[10, 54] Some of the imperfections of the surgical procedure would be overcome if it could be performed under direct vision and if severe mitral regurgitation previously present or produced by commissurotomy could be properly repaired.

Indications for Mitral Commissurotomy (Valvuloplasty)

The objective of the operation is to enlarge the narrowed mitral orifice Therefore it is indicated whenever a patient suffers intolerable or progressive symptoms which are believed to be due to the mechanical impediment of severe mitral stenosis

In selecting patients for mitral commissurotomy the physician must assess (1) the probable outlook with non surgical treatment (2) the operative mortality and (3) the probability of improved function and longevity as a result of the operation

At the present time we have more accurate information about items 2 and 3 than about item 1 The over all operative mortality is about 10 per cent but it may be only 3 to 5 per cent in the better risk cases falling in Group II or III of the New York Heart Association (p 157) and 25 per cent in the poor risk cases (Group IV) It also appears that if patients are carefully selected on the basis that their symptoms are probably due to an extremely narrowed mitral orifice and if a thorough mitral commissurotomy is performed about 75 per cent of operated patients or [illegible] per cent of those who survive will be relieved of their symptoms and will experience a good or excellent functional improvement (p 676) The presence of a significantly tight mitral stenosis is indicated by the symptomatology especially attacks of pulmonary edema with exercise recumbency respiratory infection and so on by the classic signs of mitral stenosis and the electrocardiographic pattern of right ventricular hypertrophy Catheterization and other special studies need be undertaken only in doubtful cases But studies with transthoracic suprasternal or bronchial left heart catheterization may greatly enhance our diagnostic skill and our ability to appraise surgical indications and to evaluate surgical effectiveness A significant mechanical impediment at the mitral valve is improbable if the pulmonary arterial and capillary pressure and the left atrial pressure are not definitely elevated An elevated left atrioventricular gradient is a direct measure of mitral obstruction Adequacy of the mitral commissurotomy is indicated by ability to admit two fingers held side by side and especially by demonstration of almost complete reduction of the atrioventricular gradient (by simultaneous measurement of left atrial and ventricular pressures) as soon as the commissurotomy is completed

The outlook with conservative treatment is the most difficult to estimate because of the variable course of the disease In practice classifying patients according to the functional standards of the New York Heart Association (p 157) the outlook with conservative treatment is regarded as best in Group I and poorest in Group IV It is generally agreed that mitral commissurotomy is not indicated in patients without symptoms i e those in Group I Nevertheless Bailey has operated on about 40 patients in Group I among over 1000 commissurotomies and found that these patients had a tight mitral stenosis and were benefited by the operation Although asymptomatic many of these patients had no symptoms only because of imposed limitations in activity Many of the patients in Group II have too mild symptoms to be selected for commissurotomy Other patients in Group II have disturbing symptoms which occur only with unusual stresses In such borderline cases whether to operate or not will depend in part on the patient s subjective reaction to his symptoms and on his way of life The married woman who does not have to work for a livelihood who has domestic employees to free her of household activities and has the use of an elevator indoors and a car or taxi outdoors may not regard her symptoms or disability as severe enough to justify even minimal risk of an operation On the other hand symptoms may be frequently induced and become disabling in the woman who must perform her own house work raise a family or hold a job or the man who is employed at work which demands considerable physical exertion

Progression and intensification of symptoms not acutely but over a period of many months or years is a strong indication for mitral commissurotomy Harken s group II[1-4] consists of patients who are handicapped by their symptoms which in contrast with those of his group III are static or not particularly progressive This group II corresponds to the worst cases of Group II and the less severe cases in Group III of the New York Heart Association The patients are clearly limited in activity by exertional dyspnea or fatigability experience occasional episodes of paroxysmal dyspnea and cough and may have atrial fibrillation but there is no evidence of

frank congestive heart failure Relatively few are operated upon, namely those who find their symptoms intolerable because of their subjective reaction or the nature of their required or desired activities Those who are not subjected to operation must be carefully observed for progression of symptoms which would transfer them to Harken's group III This corresponds roughly to Group III of the New York Heart Association and includes patients suffering from pulmonary symptoms (dyspnea fatigability or cough on exertion, hemoptysis orthopnea, paroxysmal dyspnea and especially pulmonary edema) which are progressive in nature and which handicap the patient by significantly and increasingly limiting his ordinary activities A large number of them have atrial fibrillation and some have suffered peripheral emboli These form the bulk of patients who are suitable for mitral commissurotomy and in whom it is clearly indicated i e, the anticipated benefit justifies the relatively small operative risk in view of the present disability and relatively unfavorable outlook with conservative therapy With further reduction in operative mortality and possible improvement in the results obtained, more and more patients in group II may also be encouraged to undergo the operation

Group IV of the New York Heart Association includes patients with symptoms of heart failure at rest Group IV of Harken is roughly identical but is defined to include patients who are severely incapacitated or bedridden, suffer from "chronic congestive heart failure", i e right- and left-sided heart failure with atrial fibrillation in the majority and with a higher incidence of peripheral emboli than in Group III Mitral commissurotomy is indicated in most of these patients even though the operative mortality is substantially higher and the chances of substantial functional improvement are less than in Groups II and III The operative outlook is better when the manifestations of heart failure can be greatly ameliorated by vigorous medical therapy

Despite the presence of right-sided heart failure one cannot assume that there are irreversible pulmonary arteriolar changes or right ventricular damage If the stenosis is relieved, the increased arteriolar resistance may diminish and right ventricular function may be restored, although a contrary opinion has been expressed[118] Except in preterminal cases, mitral commissurotomy may be indicated, despite high operative risk, because of extreme disability and the probability of an early demise without operation However persistent gallop rhythm despite adequate medical therapy is regarded as a contraindication A fair percentage of even the most disabled patients may be salvaged, occasionally with dramatic improvement The calculated risk of surgery and the limited chance of improvement must be explained to the patient's family, and weighed against the complete present disability and the poor prognosis with conservative therapy

Contraindications

Mitral commissurotomy should not be undertaken if the predominant valvular lesion is *mitral insufficiency* or *aortic insufficiency* until operative correction of these lesions is perfected The basal diastolic murmur of pulmonary insufficiency secondary to severe mitral stenosis should not be mistaken for that of aortic insufficiency (p 660) In essence, mitral commissurotomy is contraindicated currently in the presence of left ventricular hypertrophy unless this is due to an associated aortic stenosis One must be careful not to misinterpret right ventricular enlargement as left ventricular enlargement on the basis of a posteroanterior x ray film of the chest Tricuspid insufficiency associated with right heart failure is not a contraindication to commissurotomy although its presence, like that of advanced right heart failure per se, tends to increase the surgical risk and diminish the incidence of clinical benefit Tricuspid stenosis is no contraindication and if severe, should be repaired by tricuspid commissurotomy

Rheumatic activity is generally regarded as a contraindication However *clinically significant* active rheumatic fever is so unusual in adult life that it should rarely pose a problem in those in whom mitral commissurotomy is indicated The operation is very rarely indicated below the age of 20 Symptoms of heart failure in patients below this age are much more likely to be due to active rheumatic carditis and consequent myocardial dysfunction than to mechanical impediment In the rare patient below the age of 20 in whom disability is regarded as due to the mitral stenosis itself there should be no evidence of rheumatic activity nor history of

rheumatic fever for at least three years The high incidence of Aschoff bodies in left atrial appendages resected at operation (p 817)[64, 179, 81] is not indicative of significant *clinical* rheumatic activity and the surgical results are at least as favorable in patients with as in those without Aschoff bodies in their atrial appendage

Bacterial endocarditis is a contraindication to mitral commissurotomy but the latter may be undertaken six months after the endocarditis has been cured

Other Factors in Relation to Mitral Commissurotomy

Age The usual and preferred age of patients undergoing commissurotomy is between 25 and 50 when cardiac disability usually develops In individuals younger than 25 severe disability usually denotes serious multiple valvular and myocardial disease and/or rheumatic activity but operation may be recommended if pure severe mitral stenosis is believed to be solely responsible for left sided heart failure In one series of 600 patients in whom mitral commissurotomy was performed there were 11 between the ages of 8 and 16[4] In no instance was there a reactivation of rheumatic fever Age beyond 50 and occasionally even beyond 60 is no absolute contraindication but there is increasing probability of myocardial disease as well as valvular stenosis accounting for disability Ellis and Harken[7] reported that 14 patients in Groups II and III between the ages of 50 and 60 and 3 patients in Group IV beyond the age of 60 were operated on without a single mortality but 15 (43%) of 35 patients between the ages of 50 and 60 and classified as Group IV succumbed Janton Glover and O Neill[187] reported successful mitral commissurotomies in 35 patients between the ages of 50 and 60 with only 8 5 per cent mortality

Atrial Fibrillation is not a contraindication and actually most patients undergoing mitral commissurotomy have atrial fibrillation according to some of the reported series of cases

Previous Embolization is not generally regarded as a contraindication although it may indicate increased risk of further embolization during the operation On the other hand repeated embolization which does not cause too serious deterioration of the patient s clinical status is actually regarded as an indication for commissurotomy because excision of the atrial appendage may remove one possible important source of embolization and because improvement in the circulation may diminish the tendency to thrombosis and embolism [6]

Valvular Calcification is no contraindication although it may be responsible for calcium embolization at operation Fracture of a calcified valve may often be accomplished more readily than that of a rubbery fibrotic valve

Pregnancy As a rule mitral commissurotomy should be deferred until after pregnancy *(p 1095) However there have been* occasional reports of successful mitral commissurotomy in patients who became decompensated during pregnancy and were enabled to complete their pregnancy because of the operation [103]

Cardiac Catheterization This procedure is not performed routinely preoperatively but may provide important information which facilitates a decision as to operation in doubtful cases It also provides useful data for evaluating hemodynamic improvement accomplished by the operation The pulmonary artery pressure the cardiac output and the response of both to exercise are objective measurements indicating the presence and severity of mitral stenosis Determination of the gradient across the mitral valve at rest and with exercise gives a more direct appraisal of mitral stenosis The absence of pulmonary hypertension as determined by cardiac catheterization was the basis for rejecting for commissurotomy 11 of 15 patients with mitral stenosis who were regarded as suitable for operation on clinical grounds [84] In some patients with mitral stenosis and unequivocal cardiac disability catheterization studies indicate that the symptoms are due to myocardial insufficiency and not to the mechanical effect of a mitral block [1,3] in these cases mitral commissurotomy was regarded as not likely to prove beneficial However the decision as to operation should not be made on the basis of the catheter findings alone

Preoperative Care

If congestive heart failure is present every effort is made to attain maximal improvement but bed rest should not be prolonged If digitalis was previously administered it is continued if not some surgeons digitalize the patient routinely Sodium intake is restricted activity minimized and

mercurial diuretics are administered as indicated These measures are not instituted if there is no overt evidence of heart failure, except that sodium is at least moderately restricted (1 to 1 5 gm of sodium daily) If the patient was receiving quinidine to control some arrhythmia it is continued but no effort is usually made preoperatively to convert chronic atrial fibrillation to sinus rhythm Sedatives should be administered if necessary to promote sleep at night Reassurance is very important Antibiotics may be started two days preoperatively Occasionally, transfusions are given if there is marked anemia Even if no blood is given preoperatively the patient's blood is grouped and cross matched with blood which is held in readiness if required during the operation Anticoagulants are usually discontinued if they had been administered to prevent thromboembolism, and prothrombin coagulation and bleeding times are checked to be sure that it is safe to operate On the other hand Storm and Hansen[225] found that mitral commissurotomy performed during anticoagulant prophylaxis with Dicumarol on 26 patients was associated with no increase in hemorrhagic phenomena and no case of thromboembolism, whereas these complications occurred as expected in 15 to 20 per cent of patients who did not receive anticoagulants

There is no uniformity about preanesthetic medication Usually a barbiturate is administered the night before operation, and morphine sulfate an hour before anesthesia In addition, Seconal may be given orally or by vein before the patient is taken from his room Bailey and associates[10] administer both Seconal grain 3/4 orally and atropine sulfate grain 1/200 to 1/100 subcutaneously one hour before the anesthetic, but others do not employ atropine procaine or neostigmine The orthopneic patient should be brought to the operating room with his head and shoulders elevated on pillows

Anesthesia

Skillful anesthesia and expert control of respiration with the chest open are of the utmost importance High oxygen intake and very light anesthesia are important features of good anesthesia in these cases Non-explosive anesthetics are used because of the frequent use of the electrocautery However, cyclopropane or ethylene is occasionally used for induction and endotracheal intubation, after which the anesthetist switches to light ether anesthesia Most commonly anesthesia is initiated with nitrous oxide and oxygen by endotracheal tube or by intravenous Pentothal with oxygen administered by endotracheal tube Endotracheal intubation is accomplished after adequate cocainization Because of the open chest, respiration is controlled by external positive pressure to avoid hyperventilation Great care should be taken to avoid anoxia, drug overdosage or excessive positive pressure

Role of the Cardiologist

The cardiologist is constantly in the operating room, observing and interpreting a continuous electrocardiographic tracing on the oscilloscope He must be alert to detect and correct cardiac arrhythmias There is no substantial agreement on the use of drugs to prevent or treat cardiac disturbances during the operation The treatment of cardiac arrest and ventricular fibrillation is discussed on pages 1109 and 377 respectively Atropine 0 5 to 1 0 mg is administered intravenously for severe bradycardia Neostigmine 0 25 mg may be given intravenously and repeated if necessary for paroxysmal (atrial) tachycardia Quinidine and procaine amide (Pronestyl) are not administered prophylactically to avoid myocardial irritability because they cause poor myocardial contractility They are used however, during the operation if necessary to control ventricular ectopic beats or ventricular tachycardia But in the presence of poor myocardial contractility calcium chloride (2 to 4 cc of a 10% solution) or epinephrine (0 2 to 0 5 cc of a 1 1000 solution) is administered

The cardiologist and the anesthetist must be on guard for changes due to hypoxia which may be controlled by an oximeter The cardiologist assists the surgeon in taking pressure measurements directly from the heart during the operation and in supervising the necessary apparatus He must keep the electric defibrillator on hand In addition, a member of the resident staff has the sole function of measuring blood loss and supervising apparatus and materials for infusions or transfusion The cardiologist should determine accurately and record the peripheral arterial pulses preoperatively and postoperatively especially in the presence of atrial fibrillation

The Operation

At the onset of the operation an isotonic

solution of 5 per cent dextrose in water is administered by very slow intravenous drip through a 15 gauge needle or a polyethylene catheter, preferably in two different extremities The use of two needles is recommended[4] to permit rapid transfusion of blood which may become necessary The blood may also be given under pressure For this purpose 2000 to 3000 cc of properly cross matched blood is kept available although only part of this may be used Blood loss is carefully estimated during the course of the operation by measurement of blood removed by suction and by weighing sponges Care must be taken both during the operation and postoperatively to avoid overloading the circulation and causing pulmonary edema

The patient is placed in a right lateral recumbent position[119] A curvilinear incision is made from the sternum anteriorly extending beneath the left breast and posteriorly below and behind the angle of the scapula Or a posterolateral incision is made The fourth intercostal space is opened widely the fourth costal cartilage being divided Sometimes the fifth rib is resected The tip of the pulmonary lingula may be resected for histologic study of the pulmonary vessels The common carotid and innominate arteries may be mobilized and tapes passed around them in order to occlude them temporarily and intermittently to prevent cerebral embolization during each intracardiac maneuver[11] ■ The effectiveness of this procedure has been questioned Despite all preventive measures cerebral emboli have occurred in 5 to 10 per cent of cases but recently preoperative and postoperative anticoagulant therapy was claimed to be effective in preventing thromboembolism[228]

The pericardium is incised posteriorly or anteriorly to the phrenic nerve and the edges held apart by traction sutures A purse-string suture is placed around the base of the atrial appendage and a non crushing Satinsky clamp applied distal to the suture An incision is then made into the apex of the appendage sufficient for the opening to accommodate the index finger snugly If palpation indicates the presence of thrombi the appendage is opened and the first gush of blood is allowed to carry out any free clots or clots are carefully extracted [1] all before the occluding clamp is applied The index finger then enters the left atrium by way of the incision in the appendage while one assistant manages the purse-string suture to prevent bleeding and another controls the tapes around the great vessels If the appendage is very small the commissurotomy may be effected by the small fifth finger If the appendage is too small for this or if it is completely obliterated by thrombus or calcification the finger may enter through an incision in the posterior wall cephalad to the left coronary vessels or through an incision in a left pulmonary vein or through a rubber diverticulum sewed to the myocardium ■

Neptune and Bailey[1] [9] have used a right thoracic (posterolateral or anterior) approach through the right fourth intercostal space when performing an operation for associated lesions such as tricuspid stenosis or interatrial septal defect in combination with mitral stenosis The mitral commissurotomy is carried out through the left atrial wall which is entered near the interatrial groove More recently this technique has been employed on a routine basis for the performance of mitral commissurotomy This is done partly to permit routine exploration of the tricuspid valve because Bailey and Bolton[9] encountered significant tricuspid stenosis in 15 and tricuspid insufficiency in 17 of 98 consecutive patients operated on for mitral stenosis In addition it is claimed that the right-sided approach permits a more effective mitral commissurotomy and avoids the danger of entering through a left atrial appendage which often contains a thrombus The left-sided approach is still recommended for the correction of mitral regurgitation

Simultaneous pressure measurements are taken from the left atrium and left ventricle before the actual commissurotomy and repeated after commissurotomy The difference in pressure in the left ventricle and left atrium in diastole the so-called left atrioventricular gradient is utilized as a criterion of the adequacy of the surgical procedure[138] The preoperative left atrial mean pressure usually between 20 and 40 mm Hg should fall to 10 to 15 mm or less (normal 5 mm) while the gradient of 15 to 35 mm Hg should be reduced to less than 5 mm Hg if possible

With the finger in the left atrium the mitral valve and the subvalvular region are explored The presence of a mitral regurgitant jet and its severity are determined by palpation A small regurgitant jet may be ignored and may in fact diminish if mobility of the cusps is restored Since the anterolateral commissure usually contributes most to the stenosis this is fractured first with the finger exerting gentle pressure toward the annulus sometimes reenforced by counter pressure exerted by the other hand on the outside of the heart A flat guillotine-type knife inserted between gloves on the volar surface of the index finger is often used to incise the commissure if inadequate separation is accomplished by finger fracture but blunt dissection may follow the incision to be certain the commissure is split clear through to the myocardium at the atrioventricular annulus Then the posteromedial commissure is likewise split but this is occasionally omitted if it is very difficult and sufficient enlargement has been attained by splitting the anterolateral commissure In some cases it is the posteromedial commissure which is most responsible for the stenosis and this commissure must then be completely opened by finger fracture or knife Creation of significant regurgitation must be avoided

In addition the finger must be advanced through the valve opening for subvalvular dissection if there is a subvalvular stenosis caused by fusion of chordae tendineae and papillary muscles to each other or to the myocardial wall[10] If the chordae are greatly shortened and finger dissection is ineffective multiple cuts of the commissures are made with a special guillotine knife[192] One may have to cut into the fused mass of papillary muscle

After the stenosis is corrected the finger is withdrawn gently and hemostasis effected by ligating the purse-string suture sometimes by a second ligature

after application of the Satinsky clamp Most of the appendage distal to the ligature is resected and studied histologically The atrial stump may be closed with a single row of closely placed interrupted silk sutures Care must be taken not to occlude the coronary arteries near the base of the appendix as cardiac arrest may result If tapes were placed around the cerebral vessels these are removed The pericardium is thoroughly irrigated with saline and closed loosely with a few stitches A tube is introduced through the seventh intercostal space for underwater closed drainage of the left pleural cavity The ribs are approximated and chest wall then closed in layer

Combined Valvular Lesions

For combined mitral and tricuspid stenosis Harken and Black[119] employ the usual left-sided thoracotomy to perform a mitral valvuloplasty They then explore the right atrium and tricuspid valve through another pericardial incision across the base of the pulmonary artery which exposes the tip of the right atrial appendage Neptune and Bailey[190] use a right thoracic approach and dissect the heart along the interatrial groove The left atrium is entered by incising the septum and a mitral commissurotomy is performed Then tricuspid commissurotomy is effected with the aid of a knife after the finger is introduced by way of the right atrial appendage In the presence of trivalvular stenosis the aortic obstruction is relieved first, then the mitral and finally the tricuspid Among 200 patients operated by Bailey for mitral stenosis from the right side a concomitant aortic commissurotomy was performed in 28 and trivalvular commissurotomy in 4 In 32 (16 per cent) a tricuspid stenosis was found in association with mitral stenosis but without aortic stenosis Of 41 patients operated on for combined mitral and aortic stenosis, 83 per cent were improved 9 per cent were unchanged and 7 per cent worse The over all mortality was 27 per cent but there were no fatalities in the group of 11 patients in whom mitral and aortic stenosis were uncomplicated by other valvular lesions[165]

Postoperative Care

The patient is kept in an oxygen tent for two or three days He is under constant supervision during this period A roentgenogram of the chest is made several hours postoperatively to exclude serious pneumothorax To encourage respiratory excursion of the chest and the elimination of retained secretions the patient is urged to take deep breaths and cough despite his reluctance Intermittent catheter suction, and rarely bronchoscopy, are employed to remove secretions Morphine and similar narcotics are avoided unless absolutely essential But analgesics must be given to relieve pain usually Demerol in small doses at four hour intervals and barbiturates, if essential, to alleviate anxiety and restlessness Fluids are given orally in moderation, but care should be taken to avoid abnormal fluid retention since water is retained, in excess of sodium, during the first three days following mitral surgery[245] Hyponatremia may occur during this period[44] A low sodium diet is maintained postoperatively Diuretics are given if necessary, but this is rare in the immediate postoperative period Digitalis is administered if it had been used preoperatively If antibiotics were not started preoperatively, they are administered postoperatively for about a week or according to the presence of fever or other evidence of possible infection If there is an indication for anticoagulants they may be administered beginning 48 hours after the operation The underwater drainage tube is removed on the day after operation if roentgen ray examination has demonstrated complete reexpansion of the left lung The patient is encouraged to be out of bed at intervals by the third postoperative day and to walk shortly thereafter Patients usually feel better by the fifth or sixth day and fairly well by the tenth Most patients are discharged 10 to 14 days after the operation

Postoperative Complications

The complications for which one must be on the alert include failure of expansion of the left lung acute pulmonary edema or congestive heart failure, pericardial effusion cardiac arrhythmias, pulmonary embolism arterial embolism, psychic depression or frank psychoses and much later the post commissurotomy syndrome[4] Saddle embolism of the aorta is an immediate complication of mitral commissurotomy which must be promptly recognized and corrected[183, 6, 207a]

Paroxysmal atrial fibrillation occurs commonly 24 to 72 hours postoperatively in those with previous sinus rhythm[133] Therefore some physicians administer quinidine prophylactically, 0 3 gm every six hours following the operation When atrial fibrillation occurs the patient should be digitalized speedily with intravenous Cedilanid if the ventricular rate is rapid or digitalis dosage should be increased in those already receiving the drug As a rule

the atrial fibrillation reverts spontaneously to sinus rhythm otherwise quinidine is administered in an effort to restore sinus rhythm if the arrhythmia persists more than a week Heinz and Hultgren[1, 3] found that 34 (45%) of 74 patients with sinus rhythm developed atrial fibrillation postoperatively Reversion to sinus rhythm occurred spontaneously in 30 per cent of these patients usually about the sixth postoperative day, in another 47 per cent conversion was accomplished by quinidine and in 23 per cent quinidine failed

Pulmonary edema should be prevented by avoiding overloading with fluids or sodium If it occurs it should be treated as described on page 292

Arterial embolism may occur in about 6 to 13 per cent of cases[177, 4, 238] Careful palpation of the femoral arteries should be carried out preoperatively and repeatedly postoperatively When indicated (p 582) prompt embolectomy should be carried out[65, 07]

Convalescence

When the patient returns home ordinary activities such as washing dressing and walking are gradually resumed as tolerated but no work or routine duties are undertaken for at least two months Complete improvement and resumption of an essentially normal life may require a year or more In some cases patients must be urged and continually encouraged to increase their activities if they have previously developed an abnormal anxiety regarding the risk of physical exercise On the other hand some patients develop such *euphoria postoperatively* that their enthusiasm must be tempered A low sodium diet is given varying from 200 to 1000 mg sodium daily according to the degree of previous heart failure After six months sodium intake may be gradually liberalized if there are no symptoms or signs of heart failure and if none appear as the sodium allowance is increased Similarly the need for digitalis may be reevaluated after six months to a year In those with persistent heart failure maintenance doses should be continued in those with chronic atrial fibrillation the dose should be sufficient to keep the ventricular rate between 60 and 80 per minute at rest

Post Commissurotomy Syndrome[77, 218, 1374]

After mitral commissurotomy 10 to 63 per cent of patients have been reported to develop a clinical picture which has been termed the post commissurotomy syndrome It is characterized by the sudden onset 10 days to two months after the operation of severe and often disabling pain in and around the area of the incision The pain is occasionally right sided as well as on the left often radiates to the left shoulder and is usually increased by deep inspiration Occasionally cough dyspnea hemoptysis and arthralgias are associated There is definite fever with daily spikes to 102 to 104° F and sweats but no chills Leukocytosis a rapid erythrocyte sedimentation rate and a positive serum C reactive protein are present but serum antistreptolysin is not increased A pleural pericardial rub and/or pleural effusion are common and similarly there may be a pericardial rub or *evidence of pericardial effusion* The attacks usually last one to two weeks occasionally longer and multiple attacks are common Recovery without sequelae is universal Bacteriologic cultures of pleural and pericardial fluid are negative

The etiology is unknown The site and nature of its manifestations suggest that the syndrome is caused in some manner by the local trauma and reaction to the operative procedure Likoff[166] reported a similar febrile illness in six adults following surgical correction of pulmonary stenosis with interatrial septal defect The interval between the operation and onset of symptoms suggests a hypersensitivity reaction to antigens in the operated area There is no consistent evidence of postoperative infection or pulmonary embolism to account for the syndrome The post commissurotomy syndrome has been attributed to a reactivation of rheumatic fever[218] but there is no direct evidence favoring this concept The usual finding that the effusions were blood stained led Papp and Zion[1374] to attribute the syndrome to postoperative oozing from the atrial wound with loculation of the effusion and left basal pulmonary consolidation as possible additional factors

Treatment is unsatisfactory but salicylates may afford relief occasionally and Demerol or opiates may be necessary for the most severe pain All in all prednisone cortisone hydrocortisone and pituitary corticotropin (ACTH) have proved to be most frequently beneficial

Results of Mitral Commissurotomy

The *evaluation of therapeutic results* following mitral commissurotomy is often difficult since it is based largely on subjective reports

of symptoms and capacity for physical work.[217] Patients are often anxious to be cooperative and exaggerate their increase in functional capacity. Many patients who claim to be entirely well are found to be unable to meet ordinary daily requirements of activity.[28] Psychologic factors often promoted by restrictions prescribed by physicians, have led in many patients to self imposed disabilities over a period of years. After the operation the *restrictions are removed and the patient* discovers capacities for activities which may have always been present but never tested. That the operation may be falsely credited with a beneficial result is exemplified by the instances in which striking improvement is reported even though the chest was opened but a mitral commissurotomy was not or could not be performed. But these cases should not be overemphasized because the improvement is temporary. Furthermore, it is highly probable that most instances of clinical improvement are due to relief of the obstruction at the mitral orifice. Conversely, there are occasional instances in which anxiety and other factors associated with the disability caused by the baneful effects of the mitral stenosis cannot be overcome, even though the operation relieves the stenosis. In such cases psychic resistance to increasing activity may *negate an anatomically and physiologically* satisfactory surgical result. Another difficulty in evaluation is raised by the possible role of better medical care and the rest period associated with the preoperative, postoperative and convalescent period, as contrasted with the role of the operation itself in effecting the improved clinical result.

In general, *satisfactory therapeutic results* have been reported in about 65 to 75 per cent of patients operated on for mitral stenosis.[[illegible], 4, 141, 113, 133, 211, 142, 98, 96, 104] About 10 per cent or somewhat less succumb to the operation and about 15 to 25 per cent do not experience substantial benefit. In evaluating reported data it should be remembered that the operation is designed essentially to alleviate a serious mechanical impediment imposed by the stenosed mitral valve. It does not usually restore normal valve function or directly modify persistent rheumatic carditis, myocardial damage or advanced pulmonary changes. A favorable result according to most reports is therefore based on the patient's functional ability to carry out normal activities without discomfort, and his freedom from distressing symptoms, especially attacks of pulmonary edema. It does not include any improvement in physical signs, in roentgen ray or electrocardiographic evidences of cardiac enlargement or hypertrophy or even substantial improvement in certain hemodynamic values.

In a report by L. B. Ellis and Harken[75] of *the clinical results in the first 500 patients* operated by mitral valvuloplasty, the over all mortality was 11.6 per cent, in the last 400 it was 9.3 per cent. However, whereas the mortality rate in Group IV has averaged about 25 per cent, that for patients in Groups II and III has ranged between [illegible] and 7 per cent and more recently is said to approximate 1 per cent.[75, 119] Similarly, F. H. Ellis, Kirklin, et al.[73] reported an operative mortality of 8.4 per cent in 131 patients, ranging from zero in Groups I and II (26 patients) to 4.5 per cent in Group III (67 patients) and 21 per cent of 38 patients in Group IV. Bailey and Bolton[9] reported an over all mortality of 7.7 per cent in 1000 cases of mitral commissurotomy. The mortality rate was 3 per cent for 32 patients in Class I, 3 per cent for 344 patients in Class II, 10 per cent for 562 patients in Class III and 18 per cent for 62 patients in Class IV. *Operative mortalities of 3 to 9 per cent have* been reported in various series by other surgeons.[15, 19, 133, 167, [illegible], 4, 104] In all the series, the mortality rate is much higher among patients classified as Group IV. Advancing age up to 60 had relatively little influence provided patients were in Group II or III. The operative mortality is somewhat higher in *patients with atrial fibrillation* than in those with sinus rhythm, and the incidence of peripheral embolization during operation was much higher in the former group.[177] The finding of significant mitral regurgitation, a discoid mitral valve with rubbery or leathery cusps or deforming plaques of calcium in the cusps, or inadequate surgical opening of the valve, led to poor or imperfect results.

Operative deaths are usually due to hemorrhage, shock, ventricular fibrillation or cardiac standstill, embolization, renal shutdown, tension pneumothorax and congestive heart failure, especially that due to induced severe mitral regurgitation. As technique has improved, embolism, due to migration of clots

from the left atrium or of calcium particles from the mitral valve [redacted] the chief source of morbidity and mortality

Follow up Results

From the viewpoint of relief of symptoms and greater capacity for work 70 to 90 per cent of those patients who survive the operation are reported to be greatly or significantly improved For example of 49 patients classified as Group III preoperatively by the standards of the New York Heart Association 20 were classified as Group II and 20 as Group I after the operation But even the results in the majority of patients in Group IV are very good relative to their previous state of invalidism

In addition to the preoperative clinical status of the patient the anatomic status of the mitral valve is a determining factor in the therapeutic result Immobile valves and rubbery cusps which do not yield readily to dissection by finger or knife are often responsible for failure In about half the cases failure is due to preoperative mitral regurgitation It has not been demonstrated that an unsatisfactory clinical result was due to irreversible preoperative pulmonary vascular narrowing

It is presumed but not proven that the favorable operative results are associated with greater longevity than [redacted] to be expected without operation There are claims that the incidence of peripheral embolization in patients with atrial fibrillation is diminished after the operation but such postoperative emboli have occurred [116]

Physical Signs and Hemodynamic Results There is usually no remarkable change in cardiac murmurs Occasionally the diastolic murmur is fainter or disappears and occasionally a systolic murmur appears [197] The intensity of the first sound is reduced in about half the cases and that of the loud second pulmonic sound is likewise reduced in about one third [197] Preoperative atrial fibrillation persists paroxysmal atrial fibrillation is common postoperatively in those with preoperative sinus rhythm and occasionally persists The cardiac size and configuration are not consistently altered except that the shadow of the left atrial appendage is decreased or absent The cardiac shadow may be temporarily enlarged by postoperative pericardial effusion In a serial study of preoperative and postoperative x ray films of the chest in 20 patients Soloff and Zatuchni [14] observed enlarged cardiac shadows in 11 Their belief that this is due to rheumatic reactivation is not supported by acceptable evidence It is possible that it is due in some cases to strain and enlargement of the left ventricle following relief of the mitral stenosis The electrocardiogram shows no consistent change but may show evidence of the postoperative appearance of left ventricular hypertrophy

Early follow up cardiac catheterization studies of cardiovascular hemodynamics indicated that marked functional improvement occurred without significant change in the pulmonary arterial and right ventricular pressures [183] This may be due to irreversibility of pulmonary vascular lesions or to a longer period necessary for return to normal In some instances however a fall in right ventricular and pulmonary arterial pressure has been noted The resting cardiac output and the increase with exercise have been augmented following operation The left atrial pressure is greatly diminished and the left atrioventricular gradient substantially diminished Judson et al [183] noted that physical improvement after mitral valvulotomy was generally paralleled by an increase [redacted] renal plasma flow glomerular filtration and salt and water excretion during and after exercise Furthermore there was usually a significant elevation of the stroke index a lowering of the pulmonary pressures and a reduction in total pulmonary resistance

It has been repeatedly reported that good or excellent clinical results have been obtained in patients in whom there was little or no improvement in the hemodynamic findings [183 4 241] In particular an elevated pulmonary artery pressure presumably due to irreversible narrowing of the pulmonary arterioles may persist virtually unchanged after [redacted] clinically successful operation However reversibility is possible but may require six months or longer On the other hand improvement in the hemodynamic abnormalities including a reduction in pulmonary artery pressure has been found to accompany a good clinical result in many cases [55 61 71] [redacted]

It is difficult to accept the implication that an operation designed to alleviate clinical symptoms by correcting the mechanical defect and consequent hemodynamic abnormalities which cause those symptoms can be successful clinically without altering the hemodynamic abnormalities When such a lack of

correlation is reported, one may infer that relief of the stenosis was inadequate and that the clinical functional improvement is due either to better medical care relief of anxiety regarding the danger of physical exertion or other psychic factors

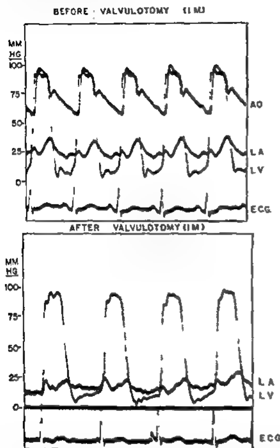

Fig 126 Simultaneous pressure pulses in left atrium left ventricle and aorta in mitral stenosis before and after mitral valvulotomy Note end diastolic pressure in left atrium is 24 in left ventricle is 6 i e there is a gradient of 18 mm Hg Following valvulotomy gradient is 3-5 mm Hg (Courtesy Dr A Gordon)

A successful mitral commissurotomy should permit the admission of two fingers into the mitral orifice, should reduce the left atrial and pulmonary capillary pressure to less than 15 and preferably less than 10 mm Hg should virtually eliminate the atrioventricular gradient[159, 40] or reduce it to less than 5 mm Hg (Fig 126), and significantly reduce the resting pulmonary arterial blood pressure as well as its rise on exercise One would anticipate also an increase in the diminished resting cardiac output with a greater rise in response to exercise but these improvements in blood flow have not been noted, as a rule[84] The improvement in hemodynamics actually obtained is indicated by the data of F H Ellis et al[73] The mean left atrial pressure, which was usually between 22 and 38 mm Hg preoperatively, was reduced to between 15 and 25 mm Hg the pulmonary artery wedge (pulmonary "capillary") pressure from between 20 and 35 to between 10 and 22 mm Hg, the resting mean pulmonary artery pressure from between 35 and 70 to between 15 and 35 mm Hg the pulmonary arteriolar resistance from a range of between 100 and 700+ to between 100 and 320 dynes/sec/cm^{-5} after operation The increase in cardiac output during exercise, which ranged from 0 to 1 liter per minute per square meter had increased several months after operation to between 0 5 and 2 5 liters Wade and associates[37] found the most marked improvement following mitral commissurotomy in the response of the cardiac output and ventilation during exercise

Restenosis of the Mitral Valve Isolated cases have been reported in which the authors have concluded that restenosis of an operated mitral valve has occurred[143, 67, 73, 151] It may be difficult to distinguish by clinical observation whether the valve has actually undergone restenosis or whether the symptoms and signs are due to inadequate commissurotomy of the preoperative mitral stenosis In a review of 42 late postoperative deaths among 600 patients operated on for mitral stenosis over a five-year period Glover et al[10] found no instance in which death could be attributed to the recurrence of mitral stenosis Autopsy studies in 31 cases failed to disclose any true endothelialization of the cut surfaces or evidence of any process which could cause restenosis of the valve

Late postoperative deaths may be due to progressive cardiac failure due to advanced irreversible heart disease, which could not be stemmed by relieving the mechanical hindrance to coexistent unrelieved dysfunction of other valves to aggravation of or induced mitral insufficiency or to failure to perform an adequate commissurotomy or to bacterial endocarditis or non cardiac diseases

Other Surgical Treatment

Other operative procedures previously recommended have been largely abandoned with the development of mitral commissurotomy This applies to the creation of an artificial

atrial septal defect[21] to provide an additional path of egress for the left atrial blood thus relieving pulmonary congestion Resection of the left atrial appendage for recurrent embolism[20] is now generally performed as part of the operation of mitral commissurotomy Resection of the left atrial appendage removes only about 50 per cent of the mural thrombi on the left side of the heart which may be responsible for systemic emboli[144] Inferior vena caval ligation has been performed in very advanced cases of mitral stenosis with right and left heart failure especially with recurrent pulmonary embolism and this procedure has also been used as a preliminary to mitral commissurotomy which is performed 6 to 24 months later[17]

Chapter 27

AORTIC INSUFFICIENCY (AORTIC REGURGITATION)

ETIOLOGY AND PATHOLOGY

Insufficiency of the aortic valve is due almost exclusively to rheumatic fever or syphilis. Occasionally aortic insufficiency may result from bacterial endocarditis or from trauma. It may be associated with pronounced hypertension[19] and aortic atherosclerosis, or dissecting aneurysm of the aorta (p. 556).[41] Congenital aortic insufficiency may be due to perforation or abnormal placement of the cusps and a congenitally bicuspid valve may result in aortic regurgitation. The relative incidence of rheumatic and syphilitic aortic insufficiency depends chiefly on the varying geographical incidence of rheumatic fever and syphilis. Aortic insufficiency in patients below the age of 35 is almost always rheumatic. Uncomplicated rheumatic aortic insufficiency may occur but it is often combined with mitral valvular disease. Aortic insufficiency occurs predominantly in males in contrast with the predominance of mitral stenosis in females.[3]

Rheumatic Aortic Insufficiency

Rheumatic fever invades the aortic valve by way of the aortic valve rings. The valve becomes thickened by edema, inflammatory cells and granulation tissue. Verrucae develop at the line of closure as a result of the extrusion of degenerated inflamed superficial valvular tissue and the secondary deposition of thrombotic material from the blood stream. The inflammatory exudate becomes organized and scar tissue is formed which subsequently contracts. The cusps become stiff, thickened and deformed. They are shortened and their free margins are thickened, rolled and often inverted toward the sinus pocket. These alterations become more advanced with recurrent attacks of rheumatic fever and secondary degenerative changes including atheroma and calcification.

The valve becomes insufficient because (1) the shortened cusps are too small to close the normal aortic orifice, (2) the deformity and rigidity of the cusps prevents their proper coaptation, (3) the annulus may become compromised by rheumatic changes with consequent loss of tensile strength and dilatation of the aortic ring. Subsequently aortic stenosis may be associated or may become the predominant lesion. Varying degrees of aortic stenosis may be associated with aortic insufficiency. But in the presence of free (wide open) aortic regurgitation severe aortic stenosis is rare.

Syphilitic Aortic Insufficiency

The cardiac and aortic lesion of syphilis will be described in detail (p. 89?). The *aortic valve* is affected by extension of the aortic syphilitic inflammatory tissue to the valve cusps. Unlike the rheumatic lesions, syphilis hardly ever attacks the valve cusps directly but confines its mischief to the aortic valve commissures (syphilitic commissural valvulitis). Aortic insufficiency in syphilis may be due to three factors: (1) widening of the commissures, (2) shortening of the cusps so they cannot reach each other to occlude the orifice, and (3) dilatation of the aortic orifice concomitant with dilatation of the ascending aorta. Since the cusps become separated, not adherent as in rheumatic fever, aortic stenosis does not develop. However, I have, in occasional instances, seen calcific aortic stenosis in hearts with syphilitic aortic insufficiency and similar cases have been reported.

Aortic Insufficiency in Bacterial Endocarditis

Aortic insufficiency in cases of subacute or acute bacterial endocarditis is usually the result of a previous rheumatic inflammation. Frequently, however, the bacterial vegetations erode the valve substance and either produce an aneurysm of the cusp or perforate it. Thus a previously normal valve may become insufficient or a previous insufficiency may be intensified. Furthermore, the valvular vegetations themselves, if large, may prevent perfect apposition of the cusps and closure of

the aortic orifice Non traumatic rupture of an aortic valve is usually due to bacterial endocarditis but may occur with syphilitic aortitis and rarely in rheumatic or atheromatous valves [11] In rupture of the aortic valve due to bacterial endocarditis there is often an abrupt onset or increase in heart failure there may be chest pain and usually there are signs of 'free' aortic regurgitation An aortic diastolic murmur first appears or undergoes a change in character [11, 5]

Traumatic Aortic Insufficiency

Aortic insufficiency results rarely from trauma In 1928 Howard[3] collected from the literature 113 cases of valvular disease due to trauma most of which were unproven The aortic valve is more often injured than any other valve The injury may result from the *strain* of an unusually strenuous muscular effort[11] or from *direct trauma* caused by a blow to the chest wall[40] or a fall from a height Rupture of the aortic valve by contrecoup as a result of a blow to the chest wall was demonstrated experimentally by Barié[3] on cadavers The injury is presumed to occur when the ventricles are in early diastole and the aortic valves under maximum tension Traumatic aortic insufficiency is encountered almost exclusively in males

Pathologic examination usually reveals a linear tear of a valve cusp More than one cusp may be affected Not infrequently the valve injury is part of an extensive tear involving the root of the aorta In instances of muscular strain the cusp is more apt to be torn at its attachment to the aorta, in instances of trauma it is usually torn through its free margin The ruptured valve or aorta is generally the seat of preceding disease especially syphilis or bacterial endocarditis Occasionally a normal valve may be ruptured [35]

Clinically traumatic rupture of the aortic valve may be characterized by chest pain and the rapid development of an aortic diastolic murmur, progressive intractable heart failure and the circulatory signs of free aortic regurgitation Surgical correction of a ruptured aortic valve has been accomplished by Leonard et al [40] by insertion of a plastic aortic valve in the first part of the descending aorta

Atherosclerosis and Hypertension (Functional Aortic Insufficiency)[25, 27]

I have occasionally observed clinical evidence of aortic insufficiency in patients with pronounced atherosclerotic dilatation of the aorta and hypertension, whose aortic valves were normal at postmortem examination Garvin[19] found 14 such cases among 200 consecutive cases of hypertensive heart disease studied at autopsy

Dissecting Aneurysm and Marfan s Syndrome

In occasional cases of dissecting aneurysm of the aorta the dissection may involve the attachment of the aortic cusps, or the aneurysm may interfere with their closure [29] Chronic dissecting aneurysm of the aorta may simulate chronic rheumatic heart disease due to the development of aortic insufficiency [41] In cases of Marfan's syndrome or arachnodactyly (p 728) aortic insufficiency is encountered more frequently than is generally recognized [28] The aortic valvular insufficiency is secondary to medianecrosis of the aorta and dissection

Rheumatoid Arthritis

Occasionally aortic insufficiency appears in adult life in patients with rheumatoid arthritis without a history of rheumatic fever

Congenital Interventricular Septal Defect with Aortic Insufficiency (p 747)

PATHOLOGIC PHYSIOLOGY

Volume and Effects of the Reflux

The dynamic effects of aortic insufficiency are due to a significant regurgitation of blood from the aorta into the left ventricle [53] Allan[1] observed in artificial circulation experiments that large refluxes were obtained with leaks equal to one half to one seventh of the area of the aortic orifice The normal valve area is 3 sq cm Gorlin et al [23] determined that a regurgitant orifice area of no greater than 0 5 sq cm was associated with refluxes of 2 to 5 liters per minute because of the large regurgitation pressure gradient (between aorta and left ventricle) in diastole Wiggers and Maltby[55] determined that the amount of the reflux depended essentially on the size of the leak the larger the leak the larger the reflux In addition to the size of the regurgitant orifice the size of the pressure gradient from the aorta to the left ventricle in diastole and the duration of diastole are important factors determining the amount of regurgitant flow The quantity of reflux may amount to more than 50 per cent of the systolic discharge [55, 43, 23] With large leaks most of the regurgitation occurs in the early part of diastole before the mitral valve is open so that there is little interference with the inflow

of blood from the *left atrium* In *small leaks* most of the regurgitation takes place late in diastole after the opening of the mitral valve But the magnitude of the reflux with small leaks is too slight to affect significantly the entrance of blood from the left atrium Thus neither with small nor large leaks is there a rise in intra atrial pressure

The effective cardiac output is usually normal at rest and as a rule rises with exercise in contrast with that in aortic stenosis[23] Also in contrast with aortic stenosis, left ventricular *pressure and work can be increased in response to exercise* The pulmonary capillary diastolic pressure in aortic regurgitation is normal at rest but rises with exercise Clinical symptoms may be correlated with the degree of this *increase in pressure* *Cardiac* catheterization of the left ventricle by way of the radial artery disclosed normal diastolic pressures in patients with compensated aortic regurgitation and elevated left ventricular diastolic pressures averaging 25 mm Hg in those with heart failure[58]

Cardiac Compensations for the Aortic Reflux

Despite the large reflux a relatively normal cardiac output is maintained by (1) a more forceful contraction of the left ventricle (2) a prolongation of the period of systolic ejection

1 The addition of the aortic reflux to the normal inflow from the left atrium increases the diastolic volume of the left ventricle and its initial intraventricular tension According to Starling s Law of the Heart this results in a more powerful contraction of the left ventricle and a greater ejection of blood in systole

2 In experimental and clinical aortic insufficiency the phase of isometric contraction is shortened while the period of systolic ejection is prolonged to the same degree Thus in addition to the higher pressure attained the left ventricle has a longer period of ejection in which to expel its increased diastolic volume The diminished *aortic diastolic pressure* against which the ventricle ejects its stream is an additional compensatory aid In animal experiments an increased cardiac rate also helps to maintain a normal cardiac output but this factor *does* not usually *operate* in human aortic insufficiency in the absence of heart failure

Effect of Aortic Insufficiency on Cardiac Size

The increased diastolic blood volume and intraventricular tension *in the left ventricle lead to enlargement of that chamber* Rosenbach[50] who first produced aortic insufficiency in rabbits noted an initial dilatation followed by hypertrophy of the left ventricle Other observers have also repeatedly demonstrated cardiac hypertrophy in animals following experimental aortic insufficiency[16, 4, 50]

In human aortic insufficiency dilatation and hypertrophy of the left ventricle are invariably found in cases with significant regurgitation The hearts in human aortic insufficiency are the largest encountered in cardiac pathology They are the so-called ox hearts or cor bovinum of classical literature The weight generally exceeds 500 gm often 750 gm and occasionally even 1000 gm The enlargement involves chiefly the outflow *tract (the anterior half of the left ventricle* and interventricular septum) which becomes greatly elongated and hypertrophied The endocardium in this region is often whitened and thickened and there may be crescentic thickenings or pockets (birds nests) resembling secondary valve structures below the aortic valve The e endocardial changes are mute evidence of the tension of the regurgitant stream

CLINICAL FEATURES

STAGE OF COMPENSATION

Whereas in mitral stenosis *perfect* compensation for a long span of years is the exception in aortic valvular disease it is the rule In mitral disease the *limited compensatory* power of the weak left atrium and the absence of an efficient valve between it and the pulmonary veins permit some degree of pulmonary congestion (and exertional dyspnea) *early in the disease* In *aortic valvular* disease the strong left ventricle and the efficient mitral valve may long prevent any stasis in the pulmonary circuit

In the absence of complications patients *with pure or predominant aortic insufficiency* often live many years or even a normal life span either without knowledge of their disease or without significant disturbance I have known a number of such individuals who engaged *actively in strenuous sports or in* occupations involving hard physical labor

Occasionally even with almost perfect compensation there are subjective disturbances due either to local cardiac compensations or to *the peripheral changes in vascular dynamics*

The enlarged heart with its forceful precordial heave may be very discomforting to the patient especially on lying down Lying on the left side must usually be avoided He may be greatly disturbed by the audible beat of his heart and cervical vessels as he rests against the pillow There is sometimes an uncomfortable ticking in the throat due to vascular pulsation of the uvula Sleep may be disturbed by these sensations or by terrifying dreams The latter usually occur when there is some degree of cardiac failure Generally the patient, if compensated becomes adjusted to the various pulsations and his sleep is little if at all disturbed *Dizziness,* particularly with sudden change of position, is not rare and is probably due to transient cerebral anemia caused by rapid severe changes in pressure in the cerebral vessels

Certain symptoms encountered in aortic insufficiency are not due to the valvular disease itself but to associated lesions When due to rheumatic heart disease aortic insufficiency is usually combined with mitral disease and not infrequently with aortic stenosis These may modify the clinical picture When aortic insufficiency is due to syphilis luetic narrowing of the coronary arteries is generally associated and aortic aneurysm may occur In patients beyond middle age with either rheumatic or syphilitic aortic insufficiency, there is frequently an associated atherosclerosis of the coronary arteries *Paroxysmal dyspnea* which Longcope[44] emphasized as a frequent manifestation of luetic aortic insufficiency is generally due to left ventricular failure and is not a symptom of the compensated stage *Cardiac pain,* also described as a typical feature of luetic aortic insufficiency is usually not due to the valvular lesion as such Its occurrence is of sufficient interest to merit special discussion

CARDIAC PAIN IN AORTIC INSUFFICIENCY

Angina pectoris has long been regarded as a symptom of aortic insufficiency, but it is rarely due to the uncomplicated valvular lesion itself In the cases of syphilitic origin *the cardiac pain is usually due to the frequently* associated stenosis of the coronary ostia and not infrequently to concomitant coronary atherosclerosis Angina pectoris is very uncommon in uncomplicated rheumatic aortic insufficiency but in older persons it may occur because of coronary atherosclerosis or because superimposed calcification of the aortic valve leads to stenosis It occurs rather frequently in patients with free aortic regurgitation and congestive heart failure

Schwartz,[51] and later Lewis,[42] reported a distinct form of angina pectoris in cases of rheumatic aortic insufficiency, occurring in severe paroxysms, usually at night The attacks were accompanied by a rise in blood pressure, increased pulse and respiratory rate palpitations and by vasomotor disturbances such as flushing and sweating The pain occurred at rest but sometimes was precipitated by excitement It was often relieved by nitroglycerin But I have seen one patient with this syndrome who had such severe and persistent pain that he took 25 or more tablets of nitroglycerin *(each 1/100 grain) daily to obtain* relief

Cardiac pain in uncomplicated (rheumatic) aortic insufficiency has been attributed to (1) diminished coronary flow because of a low diastolic pressure and (2) increased demand for blood because of the increased weight and work of the hypertrophied heart But this explanation does not completely explain all the facts Thus it is not clear why so many patients with rheumatic aortic insufficiency and an extremely low diastolic pressure fail to have angina pectoris Laplace[37] denied the significance of the low diastolic pressure in the production of cardiac pain in aortic insufficiency because this symptom was less frequent in a group of patients with extremely low diastolic pressure than in the group with moderately low diastolic pressure Finally it is uncertain whether the coronary blood flow is actually diminished in aortic insufficiency despite the low diastolic pressure Thus Green [7] found that the minute coronary flow was increased because the improved flow during systole more than compensated for the reduction during diastole By catheterizing the coronary sinus in patients with aortic insufficiency Bing et al [7] found the coronary blood flow and cardiac oxygen consumption increased

LEFT VENTRICULAR FAILURE IN AORTIC INSUFFICIENCY

Failure of the left ventricle in aortic insufficiency usually occurs after a relatively long period of perfect or nearly perfect compensation The left heart failure of aortic insufficiency differs in some respects from that of

mitral stenosis because in the former it is the left ventricle in the latter the left atrium that gives way Because of the greater strength of the left ventricle as compared with that of the left atrium a longer period elapses before left heart failure occurs in aortic insufficiency than in mitral stenosis

In rheumatic aortic insufficiency increasing fatigue of the greatly enlarged heart associated degenerative disease of the coronary arteries intercurrent infections and other factors may contribute to the development of heart failure In the syphilitic variety stenosis of the coronary ostia is an important contributory factor Left ventricular failure is associated with dilatation of that chamber and of the mitral orifice with consequent functional mitral insufficiency The dilatation of the left atrium which follows is inadequate to compensate effectively for the regurgitation due to the sudden failure of the left ventricle and mitral incompetence

Dyspnea on exertion is the earliest signal of left heart failure in aortic insufficiency as it is also of mitral stenosis This is slight at first but becomes rapidly and progressively worse Long periods of dyspnea on exertion without other symptoms of failure may occur occasionally but usually other severer symptoms are soon associated An outstanding and characteristic symptom of left heart failure in aortic insufficiency is a most distressing form of *paroxysmal dyspnea* It appears in sudden attacks lasting up to fifteen minutes sometimes after exertion but much more often while the patient is at rest especially while asleep Paroxysmal dyspnea is especially characteristic of luetic aortic disease as depicted in Longcope s vivid description [44] It also occurs with rheumatic aortic insufficiency but is much less common than with the syphilitic type The difference in incidence may be due on the one hand to the frequent narrowing of the coronary ostia in syphilitic disease and on the other to the modifying effect of associated mitral defects in rheumatic aortic insufficiency

Orthopnea sooner or later is added to the above-mentioned symptoms

In some patients with very severe aortic insufficiency with diastolic pressures below 50 mm Hg and with the hemodynamics of free aortic regurgitation gallop rhythm and left heart failure an atypical form of *angina pectoris* occurs commonly The pain is often worse in recumbency and during the night intensified in certain positions and only transiently or incompletely relieved by nitroglycerin Attacks of myocardial infarction are frequently suspected Recurrent and sometimes intractable epigastric or diffuse abdominal pain occurs commonly and various x ray studies are made repeatedly without disclosing an organic basis for the pain Deficient blood flow to the abdominal viscera analogous to the coronary insufficiency of aortic regurgitation and resembling that due to atherosclerotic narrowing in Ortner s syndrome is suspected Pounding of the heart distressing throbbing and tenderness of the carotid arteries excessive sweating and heat intolerance are additional manifestations Sudden death is frequent in this group of patients

In cases of aortic insufficiency due neither to rheumatic fever nor syphilis symptoms of left heart failure may be absent or overshadowed by other features of the causative disease In *subacute bacterial endocarditis* the valvular lesion may be indicated only by a change in character of the aortic murmur or by the fresh development of an aortic diastolic murmur In *atherosclerotic* aortic insufficiency there may be no clinical evidences of the lesion except the murmur In the uncommon cases of *traumatic aortic* insufficiency the lesion may be denoted by the murmur alone without associated symptoms but is characterized usually by anginal pain rapid development of progressive heart failure or by shock and a rapid demise

RIGHT SIDED HEART FAILURE IN AORTIC INSUFFICIENCY

The symptoms of left sided heart failure in aortic insufficiency are eventually combined with or overshadowed by those of failure of the right ventricle The agony of severe paroxysmal dyspnea is sometimes relieved when the right heart fails and diminishes the forward pressure and engorgement in the lungs The right ventricle dilates the tricuspid valve becomes insufficient and the right atrium is enlarged by reflux and stasis The venous pressure in the venae cavae and peripheral veins rises As a result the neck veins and those on the extremities appear engorged the liver becomes enlarged palpable and tender and peripheral edema is

observed Ascites may be somewhat less common than in mitral stenosis but hydrothorax is frequent

OBJECTIVE EVIDENCES OF AORTIC INSUFFICIENCY

Cardiac Signs

Inspection and Palpation The apical impulse is heaving and located to the left of and below its normal site Occasionally it is seen or felt far out in the left axilla or as low as the sixth or seventh interspace Sometimes there is a diffuse systolic *depression* of the anterior chest wall medial to the forceful apical thrust This depression is caused by the aspirating effect of the contracting ventricle on the chest wall as its large volume of blood is expelled into the arterial tree[14] A diastolic pulsation of the chest wall is due to the filling of the left ventricle

Percussion may disclose the enlargement of the left ventricle but this is best demonstrated by roentgenologic examination

Auscultation The characteristic sign is a soft, high pitched *diastolic murmur* likened to the sound made by the pouring of water In luetic aortic insufficiency it is often louder and lower pitched than in the rheumatic form of the disease In cases of traumatic etiology, the murmur is often extremely loud and musical in quality[8] or it may resemble the cooing of a dove[9] or the call of the sea gull (sea gull murmur)[10] In cases due to extreme physical exertion the murmur may be audible without applying the stethoscope or the ear to the chest

Interest in the sea gull murmur of aortic insufficiency has increased in recent years Most frequently it is heard in syphilitic aortic insufficiency but occasionally also in aortic insufficiency due to bacterial endocarditis to rheumatic fever or to rupture of the valve[20] This musical murmur has come to be regarded as a specific murmur usually due to eversion or retroversion of the right anterior aortic cusp[■ 82] The musical quality is related phonocardiographically to the regularity of its vibrations which are composed virtually of a pure sine wave in the oscilloscope[23] Musical or sea gull murmurs are not always aortic diastolic Loud musical murmurs in cases of ruptured mitral chordae calcification of the mitral valve or calcific aortic stenosis may be sea gull in character and systolic in time

The diastolic murmur starts immediately after the second sound Occasionally the second aortic sound is absent The murmur is best heard in the second right intercostal space or along the left border of the sternum in the third or fourth interspace Occasionally the murmur has been described as being loudest in the pulmonic area, and rarely near the apex or left axilla In my experience, the diastolic murmur of rheumatic aortic insufficiency is usually best heard along the left border of the sternum, while that due to luetic disease is best heard either in this location or in the second right interspace

The high pitch and soft quality of the diastolic murmur of aortic insufficiency make it one of the most difficult to hear, and one about whose presence in a given case there is most disagreement This applies particularly to the rheumatic form of aortic insufficiency, whereas the diastolic murmur of syphilitic aortic regurgitation is readily audible Thrills are rarely associated because of the high frequency of the murmur The murmur may often be more readily discovered with the naked ear or a straight, wooden monaural stethoscope I have heard the murmur most readily with the Bowles type of stethoscope Recognition is enhanced if the patient is examined while standing or sitting and bending slightly forward Elevating the arms and holding the breath in expiration also help

A *systolic* murmur over the base of the heart often accompanies the diastolic murmur of uncomplicated aortic insufficiency It may be high pitched and blowing or harsh and loud The combined systolic and diastolic aortic murmurs produce the characteristic "bellows murmur" In Corrigan's[12] original description of aortic insufficiency, the aortic systolic blowing murmur and its propagation into the carotid and subclavian arteries were described as characteristic of the disease In my experience, this systolic murmur usually occurs in the luetic cases, and is present in rheumatic aortic insufficiency when there is considerable stenosis The systolic murmur is probably due to concomitant dilatation and changes in the wall of the adjacent aorta it may therefore represent a functional (relative) aortic valvular stenosis

An *apical systolic murmur*, independent of that in the aortic region, may also be present when the left ventricle fails becomes dilated and produces a relative mitral insufficiency

The second pulmonic sound may then become accentuated due to increased pressure in the pulmonary circulation

The Austin Flint Murmur in Aortic Insufficiency

Occasionally there is a low rumbling late diastolic or presystolic apical murmur in aortic insufficiency which is indistinguishable from the characteristic murmur of mitral stenosis This murmur in a case of aortic insufficiency without organic mitral stenosis has been termed the Austin Flint murmur after the man who first described it [18] It may be associated with a diastolic thrill My experience conforms with the observation of Laubry and Pezzi[43] that the Austin Flint murmur is generally heard when there is left ventricular failure The frequency of the murmur has been variously estimated but in routine clinical practice it is encountered only occasionally

The explanation of the Austin Flint murmur is still disputed [18] The aortic regurgitant stream may force the anterior (aortic) mitral leaflet (which is nearest the aortic valve) upward thus producing a functional mitral stenosis impeding the inflow of blood from the left atrium This explanation is supported by the clinical and experimental observations of Herrmann[30] who found that the Austin Flint murmur occurred when the posterior aortic cusp was incompetent This is the leaflet nearest the anterior mitral cusp and the one whose insufficiency would most readily permit a regurgitant stream to strike the anterior mitral cusp Gouley [4] found evidence of a defect in the right aortic cusp The murmur occurs most frequently if left ventricular failure ensues With digitalization or relief of failure by other therapeutic methods the Austin Flint murmur may disappear This disappearance after relief of failure confirms the interpretation that the murmur was of the Austin Flint type According to the phonocardiographic observations of Luisada[45] the so-called Austin Flint murmur is usually either a gallop rhythm due to an audible atrial sound or an auditory misinterpretation of the heart sounds i e a first sound which is crescendo or split In rheumatic aortic insufficiency the diagnosis of an Austin Flint murmur is hazardous because of a frequently associated mitral stenosis which is more likely to produce a presystolic murmur The clicking third sound and palpable tap of organic mitral stenosis do not accompany the Austin Flint murmur and when present may help as distinguishing signs

Roentgenologic Examination of the Heart

1 With perfect compensation and slight or early lesions the cardiac outline may appear relatively normal since a small degree of left ventricular enlargement is indistinguishable With more advanced lesions the heart assumes a characteristic *aortic configuration*

Fig 127 Rheumatic aortic insufficiency Woman aged 38 Prominent ascending aorta Enlarged elongated left lower contour of hypertrophied left ventricle

(Figs 127 and 40 p 103) The lower left cardiac contour which in the anteroposterior view represents the left ventricle becomes elongated and enlarged downward and to the left The angle formed with the pulmonary artery salient is much sharper than normal The figure of the resulting heart shadow has been described as boot-shaped the rounded apex of the heart corresponding to the toe of the boot The aortic knob is usually prominent and the rest of the aortic shadow may be slightly dilated The pulsations of both the left ventricle and the aorta have an increased excursion as observed on fluoroscopic examination or on roentgenkymograms In the left oblique (second) position with the left shoulder rotated anteriorly toward the screen the large left ventricle is seen encroaching on or even extending behind the shadow of the spine (Fig 40*B* p 103)

2 *With left ventricular failure* there is a functional insufficiency of the mitral valve with secondary dilatation of the left atrium and of the pulmonary vessels The cardiac shadow now assumes some of the features of mitral disease which modify the aortic configuration ("mitralized aortic configuration") The modification is more striking if mitral stenosis is associated with aortic insufficiency

3 *When right heart failure develops* both the right ventricle and right atrium become dilated The total cardiac shadow appears huge with an extremely wide transverse diameter

The Electrocardiogram in Aortic Insufficiency

In well developed cases there is usually a pronounced left axis deviation The major deflections are of high voltage There may be a depression in ST_1 and an inversion of T_1 as well as corresponding changes in the precordial leads denoting left ventricular hypertrophy (p 111) (Fig 46 p 109) The R waves in the left precordial leads are of strikingly high voltage When aortic insufficiency is associated with mitral disease variable pictures are obtained Often there are tall broad or notched P waves as well as left ventricular preponderance

Peripheral Signs of Aortic Insufficiency

In many cases with small leaks there are slight or no significant alterations in blood pressure and pulse pressure and no striking peripheral vascular phenomena In cases with large leaks described as "free aortic regurgitation"[4] distinctive peripheral signs of aortic insufficiency listed below may be noted "Free aortic regurgitation" may occur in aortic regurgitation of any etiology but is observed most commonly with syphilitic aortic regurgitation and in that due to rupture of an aortic cusp

1 Low Diastolic and High Pulse Pressure A low diastolic pressure is characteristic of aortic insufficiency The pressure as indicated by the change in sound over the brachial artery to a muffled tone is usually 50 mm Hg or lower Often the sounds continue to be heard until the pressure in the blood pressure cuff is zero Since the systolic pressure is usually normal or somewhat elevated the difference between it and the low diastolic pressure gives a pulse pressure which is usually increased Instead of a normal of 30 to 50 mm Hg the pulse pressure usually exceeds 80 mm and often reaches 100 mm or more In a young man of 30 with syphilitic aortic insufficiency, I observed a blood pressure of 300/38 i e a pulse pressure of 262 mm Hg The diminished diastolic pressure is the result of aortic regurgitation with consequent relative diastolic emptiness and relaxation of the arterial tree

2 Corrigan (Radial) Pulse Aortic insufficiency is often associated with a characteristic pulse (*Corrigan pulse*[1]) which strikes the palpating finger with a rapid forceful jerk and quickly disappears (celer et alter) It is described as having a *waterhammer* quality because of its sudden impact, and a *collapsing* quality because it falls away so rapidly The waterhammer impression is the consequence of the sharp rise in aortic pressure and the rapid filling of the radial artery The collapse which begins toward the end of systole, is due to the sharp fall of pressure in both the central and peripheral arteries It has also been explained as the result of the very increased velocity head of the blood stream and the consequently rapid egress of blood from the arterial system[**] The waterhammer effect is accentuated if the pulse is examined by grasping the wrist with the examiner's whole hand with the patient's arm elevated because the radial artery is then in more direct line with the outflow stream from the aorta and because gravity increases the blood pressure changes at the wrist The waterhammer shock is also audible as a pistol shot sound if the examiner listens with his stethoscope over the radial artery[47] While the Corrigan pulse is characteristic of aortic insufficiency it may occur in cases of patent ductus arteriosus arteriovenous fistula Graves disease and in severe anemia, fever and conditions associated with peripheral vasodilatation

The *pulse wave* as seen on sphygmograms shows a sharp almost vertical tall upward limb and a steep downward stroke

The *pulse rate* is normal in well compensated cases In failure a moderate tachycardia (90 to 100 per minute) is frequent

3 Visible Arterial Pulsations. Sometimes a tentative diagnosis of aortic insufficiency can be ventured on observing marked pulsations in the neck vessels Such visible pulsations result from the sudden systolic filling of the large collapsed arteries Corrigan's[1] graphic description of aortic insufficiency contains a vivid picture of these visible pulsations in

both carotid arteries in the temporal arteries and in other large vessels The forcefulness of these pulsations may impart a to and fro motion to the entire head synchronous with the cardiac cycles (de Musset s sign) With the ophthalmoscope one may also observe pulsation of the retinal arteries as well as of the veins F Müller[48] described pulsations in the uvula Rosenbach[50] in the liver and Gerhardt[21] in an enlarged spleen

4 Capillary Pulsation Quincke[43] observed an alternate paling and flushing of the skin in aortic insufficiency which he ascribed to capillary pulsation (Quincke pulse) Clinically this phenomenon may be elicited in several ways (a) by observing the nail bed or skin at the root of the nail while pressure is made on the tip of the nail (b) by observing the edge of the blanched region when the mucous membrane of the lip is compressed by a glass slide, (c) by observing the earlobe or fingertip while it is being transilluminated by a flashlight Actually the phenomenon observed is due not to the pulsation of the capillaries but to that of the subpapillary arteriolar and venous plexuses which are essentially responsible for the redness of normal skin Lewis and Drury[13] attributed capillary *pulse to arteriolar dilatation but this explanation does not appear to apply to the ' capillary pulse of aortic insufficiency The capillary pulse is not pathognomonic of aortic insufficiency It may also be observed in a normal subject when the skin is warm in a number of unrelated conditions such as fever anemia Graves disease and whenever there is local dilatation of the terminal peripheral vessels*

5 *Disproportionate Femoral Systolic Hypertension (Hill s Sign)* Hill and Rowlands[21] observed that the slight physiologic excess of blood pressure in the femoral artery over that in the brachial was greatly exaggerated in aortic insufficiency Instead of the normal difference in systolic pressure amounting to 10 to 20 mm Hg in aortic insufficiency this difference may be 60 to 100 mm Hg or more Since the femoral artery is in a direct line with the aortic stream while the brachial issues from the aorta at a right angle the femoral artery receives not only the pressure head but also the velocity head of the aortic stream In normal persons the velocity head is slight and the femoral pressure exceeds the brachial by a correspondingly small amount But since in aortic insufficiency the velocity head is considerable there is a pronounced excess of pressure on the femoral as compared with the brachial artery Hill s sign is absent in cases of functional aortic insufficiency associated with hypertension

6 *Pistol shot Femorals Femoral Double Tone (Traube s Sign) Femoral Murmur (Duroziez s Sign)* Auscultation over the femoral artery reveals a booming sound synchronous with each pulse through the vessel This characteristic sound has been described as resembling a pistol shot and is probably due to vibrations of high frequency caused by the sudden elevation of pressure in the vessel [9, 34]

Sometimes a double sound (*Traube s double tone*[44]) is heard in aortic insufficiency instead of the single pistol shot ' Its mechanism is uncertain

A systolic murmur is heard over the femoral artery in normal individuals if the vessel is slightly compressed by the bell of the stethoscope This murmur is due to the vibrations set up by the rapid passage of blood past an obstruction In aortic insufficiency a diastolic as well as systolic murmur is audible over the compressed vessel because there is a rapid diastolic regurgitation toward the heart as well as systolic forward passage toward the periphery This characteristic double murmur is termed *Duroziez s sign*[15] Like capillary pulsation it is not a pathognomonic sign and is observed in other conditions with a rapid peripheral blood flow or vascular dilatation, such as Graves disease febrile states anemia and on warming the lower extremity

COMPLICATIONS

Cardiac failure is the most frequent complication of aortic insufficiency It is almost an integral part of the course of the disease because there are few or no significant symptoms before failure develops *Subacute bacterial endocarditis* frequently complicates aortic insufficiency usually while the lesion is still well compensated When the complication occurs the underlying aortic insufficiency is almost always rheumatic In luetic aortic insufficiency *narrowing of the coronary ostia* is generally associated This produces an *anginal syndrome* cardiac failure and often sudden death Bronchial and pulmonary infections and embolization may complicate aortic insufficiency but rarely in comparison with their occurrence in mitral stenosis Atrial

fibrillation and other arrhythmias are relatively uncommon

DIAGNOSIS

The diagnostic features of aortic insufficiency are (1) a *high pitched diastolic murmur* over the aortic area or along the left border of the sternum or occasionally in the cardiac apical region, (2) *enlargement of the left ventricle* especially as indicated by the characteristic boot shaped cardiac shadow seen roentgenologically, (3) *distinctive peripheral circulatory phenomena* such as the high pulse pressure and low diastolic pressure, the collapsing (Corrigan) pulse, visible arterial pulsations capillary pulse femoral pistol shot and Duroziez s sign

The characteristic diastolic murmur is in itself sufficient to justify the diagnosis, on the other hand a diagnosis of aortic insufficiency should rarely be made in the absence of the murmur even when the other clinical features are present Sometimes the roentgenologic findings of left ventricular enlargement and pronounced aortic pulsations, or the peripheral circulatory findings, first suggest the diagnosis, but the latter is proved by the subsequent discovery of the diastolic murmur

The diastolic murmur of aortic insufficiency may have to be distinguished from the Graham Steell murmur of pulmonic insufficiency The latter should be diagnosed only in the presence of mitral stenosis or pulmonary disease sufficient to produce significant right ventricular hypertrophy The peripheral phenomena of aortic insufficiency do not accompany the Graham Steell murmur, the cardiac shadow shows right not left ventricular enlargement and the aorta is not prominent and conspicuously pulsatile The electrocardiogram shows evidence of left ventricular hypertrophy when the diastolic murmur is due to aortic insufficiency of right ventricular hypertrophy when the murmur is due to pulmonary insufficiency

The *etiologic diagnosis* usually involves distinction between rheumatic and syphilitic aortic insufficiency The history of rheumatic fever or syphilis the knowledge of the duration of the murmur and serologic study may be helpful The association of mitral stenosis suggests that the aortic insufficiency is rheumatic The presence of a loud aortic systolic murmur and a diastolic murmur which is most audible in the second right interspace usually denote a syphilitic etiology for the aortic insufficiency A very soft high pitched diastolic murmur along the left border of the sternum is usually of rheumatic origin

Traumatic insufficiency is suggested by a history of unusual physical exertion or penetrating or nonpenetrating injury to the chest followed by a loud, musical murmur (sea gull murmur)

Aortic insufficiency may be attributed to a bacterial endocarditis if an aortic diastolic murmur first appears during the course of the disease Frequently this denotes a preexistent bicuspid aortic valve [8]

PROGNOSIS

The prognosis and treatment are discussed in detail in the chapters on rheumatic fever, syphilis bacterial endocarditis and congestive heart failure

In general the prognosis in cases of *syphilitic aortic insufficiency* is much less favorable than in the rheumatic cases Sudden death is common in the syphilitic cases due to associated coronary ostial involvement Sometimes specific antiluetic therapy relieves the chest pain, it probably prolongs life (p 902) Adequate early treatment of uncomplicated syphilis is more important, for it prevents the occurrence of the cardiovalvular complication

In the *rheumatic cases* the outlook is favorable once rheumatic fever becomes inactive Satisfactory treatment of bacterial endocarditis has greatly reduced the hazard from this complication

SURGICAL TREATMENT OF AORTIC INSUFFICIENCY

Various operative techniques have been employed for the correction of experimentally produced aortic insufficiency, but no method has been generally acceptable when applied to the human lesion Hufnagel and associates[33, 34] placed a rigid prosthetic plastic ball valve in the descending aorta thus preventing regurgitation of blood into the left ventricle The plastic valve is a one-piece barrel shaped tube composed of (1) an inlet (2) a chamber containing a polyethylene ball which opens and closes the valve and (3) an outlet The valve functions in any position and may be opened or closed by a differential pressure of 5 mm Hg The prosthesis is placed in the descending arch of the aorta just beyond the

left subclavian artery where it is capable of controlling about 75 per cent of the regurgitant flow The actual insertion of the valve requires 3 to 6 minutes whereas the aorta at this operative site may be safely occluded up to a maximum of 20 minutes The valve is not placed in the ascending aorta because of the danger of impairing the coronary blood flow and because it would be necessary to interrupt the venous flow to the heart To insure proper fit of the prosthesis in the aorta a small cuff of Orlon mesh is utilized and to prevent angulation a segment of the aorta is removed By these improvements in technique peripheral embolization has been eliminated

Hufnagel and associates[33, 34] operated on more than 100 patients with aortic insufficiency of varied etiology, but chiefly rheumatic In the first 80 cases 50 per cent of the patients had severe refractory heart failure and were virtually terminal patients All the patients had free wide-open aortic insufficiency with heart failure and most of them had angina pectoris There was an over all hospital mortality of 20 per cent Another 20 per cent died in the following two years Essentially all of the others were able to carry out a relatively normal routine after the operation Anemia and sudden death have occurred within the first postoperative week The functioning of the valve produces a noise to which the patient adjusts himself Other people do not hear the noise unless the patient stands with his mouth open and allows the sound to be conducted up the main stem bronchus

Following operation the pulse contours in the lower extremities became normal while those in the upper extremity (proximal to the plastic valve) remained Corrigan in type The absolute volume of regurgitation was diminished and the cardiac output increased[45] The cardiac murmurs diminished in intensity At first the sound of the opening and closing of the valve is audible with the stethoscope or even the unaided ear but it gradually diminishes after weeks or months as the valve becomes covered with fibrous tissue There was a marked increase in exercise tolerance and the need for mercurial diuretics was abolished or their frequency of administration diminished

If aortic stenosis is combined with insufficiency the aortic prosthesis may be inserted first and the aortic valvulotomy performed thereafter The possibility of performing a mitral commissurotomy and inserting an aortic valve may also be considered when mitral stenosis and aortic insufficiency are both significant lesions

Bailey[2] designed a prosthesis consisting of a ball of Nylon mesh suspended by two tails By a transaortic approach with partial exclusion of the aorta and the use of a pericardial pouch as a poncho the Nylon ball is properly placed in the aorta at the valve level and the proper position and mobility maintained by securely suturing its two tails brought through silicone discs The Nylon ball moves with the blood stream in systole and falls back to occlude the aortic orifice in diastole When aortic insufficiency is due to dilatation of the aortic annulus (ring) the defect is corrected by constricting the ring by a tapered Nylon sash sutured in position Among the last 18 patients operated on by these techniques Bailey and Likoff[2] reported three operative and two late deaths but most of the survivors showed marked benefit

ARTERIOVENOUS FISTULA

Arteriovenous fistula[66, 77, 88] denotes a direct communication between an artery and vein often with the formation of an aneurysmal sac This subject is included in this volume because the lesion imposes a strain on the heart and may induce heart failure Because its circulatory dynamics are somewhat similar to those of aortic insufficiency, they are discussed in this chapter There are also many similarities to patency of the ductus arteriosus which may be viewed as a form of congenital arteriovenous fistula

ETIOLOGY AND PATHOLOGY

Arteriovenous fistula may be acquired or congenital The commonest cause is *trauma* A stab gunshot or shrapnel wound often appearing small externally perforates an artery and vein which are in close proximity and often in the same sheath The femoral or

iliac vessels in the thigh and the carotid artery and internal jugular vein in the neck[46] are most often affected Rupture of a syphilitic aortic aneurysm into the superior vena cava, pulmonary artery, right atrium or ventricle produces many of the features of an arteriovenous fistula Surgical cure of traumatic arteriovenous aneurysm between the aortic arch and left innominate vein has been reported [76, 78]

The involved artery becomes dilated for a long distance proximal to the fistula and its wall becomes thinned Rarely it may become so atrophied that an aneurysm forms and may rupture The vein becomes dilated locally due to increased pressure Its wall may become as thick as that of an artery A local aneurysmal sac often forms and may pulsate Varicose veins may appear locally A collateral circulation gradually develops to supply the area distal to the fistula

PATHOLOGIC PHYSIOLOGY

The circulatory disturbances[64] are due to a shunt of 20 to 50 per cent of the cardiac output from a large artery to a large vein

The *cardiac output* is usually increased, owing both to an enhanced stroke output and accelerated heart rate [illegible], [79] The tachycardia has been attributed to a Bainbridge reflex due to an increased venous return or to an increased right atrial pressure But the right atrial pressure may be normal The increased rate is stimulated reflexly by the fall in blood pressure caused by the fistula (Marey s reflex) and is mediated by the vagus nerve

When heart failure develops, the cardiac output falls somewhat but still remains higher than normal Exercise is associated with an increase in cardiac output in compensated patients, with no increase or a reduction in output in patients with congestive heart failure [57]

The *blood volume* is usually augmented [68, 81] especially with the development of heart failure In experimental arteriovenous fistula only the plasma volume is expanded [63] The *circulation time* is diminished because of the short circuit of blood The combination of accelerated speed of circulation and enlarged blood volume is responsible for an increased venous return which is translated into an augmented cardiac output

The *systemic venous pressure* is normal in the absence of heart failure But Cohen and associates[67] observed a moderate increase in right atrial pressure as determined by intracardiac catheterization

Arterial blood pressure (see below)

Closure of the fistula diminishes the cardiac rate, the cardiac output and the blood volume and elevates the blood pressure by eliminating the region of diminished resistance [74] The mean right atrial pressure the diastolic pressure in the right ventricle and the mean pulmonary arterial pressure were found to decrease in some hearts but remained unchanged in others [64]

CLINICAL FEATURES

The diagnostic feature is a machinery like *continuous bruit* or murmur with slight systolic accentuation, heard over the site of the fistula [illegible] It is usually accompanied by a *thrill*

At the site of the fistula there may be a pulsating aneurysmal mass The superficial veins are often dilated and tortuous The affected vein proximal to the fistula has an elevated pressure and an abnormally high content of oxygen due to the arterial shunt [illegible] Chronic venous insufficiency due to venous hypertension may lead to varices, stasis pigmentation and ulceration

There may be ischemia of the part distal to the fistula and occasionally gangrene results Eventually the development of a collateral circulation and the elevated cardiac output provide more than the normal blood flow Consequently the affected extremity may have a higher skin temperature than the normal one and may grow longer if the fistula develops before growth is completed

The Blood Pressure A high pulse pressure is present due to a significant fall in the diastolic pressure with little or no change in the systolic The waterhammer pulse and other peripheral circulatory phenomena observed in cases of aortic insufficiency may also occur with arteriovenous fistula

The *pulse rate* is usually increased But especially characteristic is the slowing of this rate (bradycardiac reaction) on compression or excision of the fistula the so called Branham s sign [57] Following atropinization this slowing does not occur [79]

Cardiac enlargement is usual With small fistulae it may be demonstrable only by comparison of the size of the heart before and

after excision[73] The extent of cardiac enlargement varies with increasing size of the fistula with the size of the feeding artery with the duration of the fistula and perhaps to a slight degree with the proximity to the heart

Cardiac enlargement is dependent on the increased venous return and consequently on the increased stroke output of the heart With increasing venous return there is an increased diastolic volume and increased diastolic tension which result in dilatation and hypertrophy (Chapter 4) It is improbable[71] that a diminished coronary blood flow accounts for cardiac enlargement as Lewis and Drury[7] suggested The reversibility of cardiac enlargement following cure of the fistula has suggested that most of the enlargement is due to dilatation However it is probable that there is a significant degree of hypertrophy and that this is also reversible[III]

Cardiac failure eventually develops in long standing cases of large arteriovenous fistula In several such cases which I observed it appeared probable that coronary insufficiency due to atherosclerosis contributed to the failure of a heart enlarged by an arteriovenous fistula

Complications These include congestive heart failure ulceration or gangrene of an extremity and rarely bacterial endarteritis[69] or aneurysm or rupture of the proximal part of the artery supplying the fistula

Congenital Arteriovenous Fistula

This arises from embryonic communications between arteries and veins which fail to close[75] The extremities intracranial vessels and the face and neck may be affected In recent years congenital arteriovenous aneurysm of the lung has aroused special interest (p 792) Hemangiomata of the liver may provide multiple arteriovenous fistulae which produce right ventricular hypertrophy and right heart failure in infancy[88] The communications in congenital arteriovenous fistulas are more often multiple and more extensive than in the acquired cases Varicose veins ulceration increased growth of an extremity are also more frequent in the former Increased sweating and growth of hair near the fistula occur frequently Congenital hemangiomata are often associated On the other hand bruits are less common and the bradycardiac response less pronounced in the congenital cases

Congenital Pulmonary Arteriovenous Fistula (see p 792)

DIAGNOSIS

The diagnosis of arteriovenous fistula depends on the finding of the characteristic bruit over the fistula It is confirmed if the bruit disappears and the heart slows on compression of the artery proximal to the fistula Arteriovenous fistula should be sought whenever unilateral veins or signs of venous insufficiency are found following an injury or when one limb is warmer or longer than the other Arteriography may be helpful in diagnosis[III]

TREATMENT

Treatment of acquired arteriovenous fistula is essential to avoid cardiac strain and failure as well as the other complications listed Even when frank heart failure is present correction of the fistula usually causes a dramatic restoration of normal circulation as well as a reduction in cardiac enlargement It is important to permit sufficient time to elapse for the development of an adequate collateral circulation before operation and to preserve this collateral circulation at operation[44] Otherwise there is risk of gangrene or other evidence of acute or chronic ischemia Sympathectomy before or during operation diminishes this complication[80] Formerly quadruple ligation of the artery and vein and simultaneous excision of the aneurysm were usually performed[45] This obliterated a main artery It appears probable that more satisfactory results with less subsequent arterial insufficiency of an extremity can be obtained by a transvenous arteriorrhaphy in which the arterial leak is repaired while the vein is ligated[47] If the blood volume is very high it may be desirable to perform a venesection at the time of operation to avoid flooding of the heart when the fistula is closed

Treatment of congenital arteriovenous aneurysms is much more difficult because they are usually multiple and more extensive The treatment of arteriovenous aneurysm of the lung is discussed elsewhere (p 793) Congenital arteriovenous fistulas in the lower extremities may be treated conservatively by compression of the varices with pure rubber bandages

Chapter 28

AORTIC STENOSIS

ETIOLOGY AND PATHOLOGY

Aortic stenosis has long been considered an *uncommon* valvular lesion. In recent years, however, a number of clinical, roentgenologic and pathologic reports have emphasized the relative frequency of this lesion and led to its recognition during life as well as post mortem.[... 40, 1, 6] Clawson and his co-workers[16] reported 200 cases of calcified aortic valve out of 490 healed valvular deformities. More than 70 per cent of these 200 cases showed severe aortic stenosis. According to these figures this is the commonest lesion of the aortic valve. Aortic stenosis of varying degree is often combined with mitral stenosis and aortic insufficiency, lesions whose clinical and pathologic features frequently overshadow or obscure those of aortic stenosis. Thus in Cabot's[11] series of 148 cases of predominant aortic insufficiency, 93 also had aortic stenosis, and in the series of McGinn and White[49] of 159 cases of mitral stenosis 50 revealed a simultaneous aortic stenosis. Conversely, Bailey et al.[4] found that 44 per cent of their patients with aortic stenosis had significant mitral stenosis. Furthermore, tricuspid valvular disease was present in 17 per cent of the patients with rheumatic mitral and aortic valvular disease.

Non-calcific Aortic Stenosis

The *calcific* and *non-calcific* forms of aortic stenosis may be distinguished with respect to etiology and pathology. Non-calcific aortic stenosis is almost exclusively due to rheumatic fever and is usually associated with mitral stenosis and aortic insufficiency. It is encountered chiefly in patients below the age of 50; males predominate only slightly.

The rheumatic inflammatory exudate produces thickening and deformity of the aortic valve.[34] It leads to agglutination of adjacent cusps by filling the commissures between them. Adhesion usually begins at the less mobile portion of the cusps at their aortic insertion. With organization and scar formation the valve cusps become thickened, firm and more or less fixed in position. The fixity of these *rigid cusps* and their adhesion to each other leads to the formation of a solid ring of fused leaflets which greatly narrow the circumference of the aortic orifice. There may be only a minute triangular aperture in the center of the aortic ring. The degree of narrowing is variable, but significant dynamic effects and clinical symptoms are produced only when the normal circumference, which averages 7.5 cm., is reduced to 2 cm. or less or the *area* of the aortic orifice is reduced from the normal 3 sq. cm. to 0.5 sq. cm. or less. Gorlin et al.[?] estimated that the critical orifice area below which significant dynamic disturbances occur was 0.5 sq. cm. in cases of pure aortic stenosis and 1.5 sq. cm. in cases of aortic stenosis and insufficiency. As the cusps become completely fused and rigid, the aortic orifice is kept open in diastole and systole and there is some degree of insufficiency.

Occasionally there is a greater degree of fusion of the left and right (anterior) cusps than of the others, resulting in a virtual bicuspid valve resembling the congenital bicuspid valve. Thus there may be considerably more mobility in the posterior cusp than in the anterior cusps. Secondary calcification is more pronounced in the anterior cusps. The aortic aperture is displaced posteriorly.

Calcific Aortic Stenosis

Calcific aortic stenosis is distinguished from the non-calcific form by its remarkable clinical symptoms, its predominant occurrence in males (two to five times as often as females) and the relatively advanced age of death.[26, 33, 40, 6] It is agreed that *rheumatic fever* causes almost all of the cases of calcific aortic stenosis[15] but some are undoubtedly of non-rheumatic etiology.[15, 28, 43]

The *congenital origin* of some cases of calcific aortic stenosis has been claimed.[12] Boas and associates, on the basis of studies of

serum cholesterol level suggested that calcific aortic stenosis may be favored by or due exclusively to hypercholesterolemia.[9] Barr et al[5] reported a case of familial hypercholesterolemia in a boy who died at the age of 20 from the complications of extensive atherosclerosis and in whom there was extreme calcific aortic stenosis. There were lipophages deposits of cholesterol crystals and other evidence of atherosclerosis or xanthomatosis in the calcified valve but no stigmas of rheumatic fever in any part of the heart.

Monckeberg[31] separated a primary sclerocalcific form of aortic stenosis from that due to rheumatic fever on the basis of histologic differences (*Monckeberg's ascending sclerosis, sclerosis annularis valvularum*). These differences have been confirmed by the pathologic studies of Sohval and Gross.[35] The following are the essential pathologic distinctions: (1) In the rheumatic cases lipid and calcium secondarily infiltrate the preexisting rheumatic inflammatory lesions and scars. In the nonrheumatic cases sclerotic, lipoidal and calcific deposits are primary. (2) In the nonrheumatic valves calcification begins and is most extensive in the sinus pocket and base of the valve from where it progresses gradually to the free border. In rheumatic valves, the calcification begins and is most extensive in the distal third of the valve. (3) In the nonrheumatic valves the calcific process affects primarily the fibrous layer of the valve cusp on the aortic surface of the leaflet. Calcification in rheumatic aortic valves occurs predominantly in the spongiosa and ventricularis layers on the ventricular aspect of the aortic cusp. (4) Rheumatic calcific aortic stenosis is frequently associated with rheumatic disease of the other valves, especially mitral stenosis; the nonrheumatic form is much more apt to be an isolated valvular lesion. In advanced cases the valve cusps, ring and commissures are entirely converted into a nodular stony mass and an etiologic diagnosis may be difficult or impossible.

The calcific sclerosis may involve structures adjacent to the aortic cusps and sinus pocket. The calcific process may extend by way of the intervalvular fibrosa, like the extension of a luetic aortitis, to implicate the anterior mitral cusp or the bundle of His in the interventricular septum.[6] The coronary ostia and arteries are often remarkably free of atherosclerosis but I have observed cases with myocardial infarction or fibrosis due to recent or old atherosclerotic coronary occlusions. More frequently there are diffuse patchy areas of fibrosis or necrosis without coronary narrowing or occlusion and probably due to coronary insufficiency caused by the valvular lesion itself.[26] [illegible] Horan and Barnes[37] observed some degree of coronary atherosclerosis in all of their cases of calcareous aortic stenosis, but the amount of sclerosis was inversely proportional to the degree of valvular stenosis.

Congenital aortic stenosis and *subaortic stenosis* are being recognized with increased frequency.[47] (For discussion, see p. 787.) Congenital aortic valvular stenosis is often associated with a bicuspid aortic valve. Degenerative changes and calcification occur secondarily. In purely valvular stenosis the fused cusps present a dome-shaped or megaphone-shaped diaphragm with a small central aperture. Subaortic stenosis is somewhat analogous to pulmonic infundibular stenosis; in the former the left ventricular outflow tract is narrowed by musculo-fibrous tissue just below the aortic valve. Congenital aortic stenosis is usually associated with poststenotic dilatation of the ascending aorta.

An aortic stenosis has been produced by a mural thrombus of the left ventricle, secondary to myocardial infarction encroaching on the outflow tract.[14]

Acute bacterial endocarditis may produce a functional aortic stenosis by blocking the orifice with large vegetation. I have never seen healing of bacterial valvulitis result in stenosis. Syphilis per se does not produce an aortic stenosis. In 296 cases of aortic valvular disease studied by Campbell and Shackle[25] 50 were due to syphilis but all of these showed aortic insufficiency without stenosis. However, I have seen several cases in which a calcific aortic stenosis was apparently superimposed on or associated with a luetic aortic insufficiency and similar cases have been reported.[7] In these cases one may occasionally see the characteristic syphilitic widening of one of the aortic commissures while the others are obliterated by calcific masses which fuse adjacent leaflets.

The heart in aortic stenosis is usually considerably hypertrophied, and often weighs between 500 and 700 gm. The heart weight tends to increase in proportion to the degree of the stenosis.[6] The heart weight may be considerably less than 500 gm. when the stenosis is

slight or moderate and especially if death occurs from some intercurrent cause before the development of cardiac failure In some cases of asymptomatic aortic stenosis accidentally discovered post mortem I have seen normal heart weights

In the relatively smaller hearts the hypertrophy is entirely confined to the left ventricle In the larger hearts especially those weighing more than 500 gm there is a considerable degree of visible dilatation as well as hypertrophy *When failure is present* the dilatation and hypertrophy involve the right as well as the left ventricle and often also the atria

PATHOLOGIC PHYSIOLOGY

Degree of Obstruction and Circulatory Disturbance

With slight aortic stenosis there may be no disturbances in circulatory dynamics even when the lesion produces a loud systolic murmur In experimental models and animals the aortic orifice must be reduced to approximately one quarter of its normal size to diminish significantly the cardiac output or alter pressure relationships[3] Such extreme lesions are common in human aortic stenosis especially those associated with calcification The effect of a severe experimental lesion is to increase the resistance to the outflow of blood from the left ventricle and cause incomplete emptying of that chamber[44] and this occurs also in human aortic stenosis But *as a rule this disturbance is compensated for* many years Some degree of aortic insufficiency is often associated with aortic stenosis but when the stenosis is very severe the valvular opening is too minute to permit *a significant degree of regurgitation*

During the stage of compensation measurements at operation have shown that the left ventricular systolic pressure is elevated whereas the diastolic pressure is normal (10 *mm* Hg or less) *With left ventricular failure* the diastolic pressure is also elevated More indicative of the degree of aortic stenosis is the gradient between left ventricular and aortic pressures Thus a normal aortic pressure of 120/76 may be *associated* with a left ventricular pressure of 220/30 indicating a gradient in systole of 100 mm Hg Normally the gradient is only a few mm Hg with moderate aortic stenosis 20 to 50 mm Hg and *severe stenosis* 50 to 100 *mm* Hg *or* more[31, 14a, 41a]

Direct measurement of the left ventricular pressure by way of the bronchoscope and a needle in the left atrium[7] similarly shows a left ventricular systolic pressure significantly higher than the pressure in the right brachial artery By means of transthoracic left heart catheterization not only can the degree of aortic stenosis be appraised by measuring the left ventricular aortic systolic gradient but also an associated aortic insufficiency can be detected and the relative severity of each determined[40]

The pulmonary capillary pressure is usually normal but rises with exercise[3] The pulmonary arterial pressure is normal but may be elevated owing to left ventricular failure coexisting *mitral stenosis* or pulmonary vascular changes[30]

The resting cardiac output is usually within normal limits and may rise with exercise but frequently less than normally[31] In cases of severe stenosis the cardiac output is diminished and more significantly it cannot be increased with exercise[32] The limited cardiac output is due to the severity of the stenosis but may be due also to coexisting mitral disease or left heart failure

Compensations in Aortic Stenosis

The residual blood in the left ventricle due to its incomplete emptying is augmented by the normal inflow from the left atrium The diastolic volume and pressure in the left ventricle rise Compensation is effected in two ways

1 The increased diastolic volume and intraventricular pressure cause a more forceful systolic contraction with restoration of normal stroke output (Starling s Law of the *Heart)*

2 There is a slight increase in the period of isometric contraction and a considerable prolongation of the ejection phase and of total systole Thus the diminished output due to *the obstruction is restored to normal in part* by a more forceful systolic ejection and in part by prolongation of the period during which ejection occurs

In humans these temporary mechanisms are eventually *supported by the development* of left ventricular hypertrophy Because clinical aortic stenosis is a lesion which develops very gradually and over a period of many years there is adequate opportunity for the *production of considerable hypertrophy* while the amount of dilatation remains rela

tively insignificant When the stenosis is superimposed on a pronounced insufficiency or when cardiac failure supervenes, there may may be extensive dilatation as well as hyper trophy

CLINICAL FEATURES

Compensated Aortic Stenosis

Compensated aortic stenosis is often asymptomatic being discovered as an accidental postmortem finding Only 6 of the 42 patients in the series studied by Margolis and his co workers[46] complained of symptoms referable to the circulation However in many cases especially late in the course of the disease and when the valvular obstruction is extreme a number of characteristic symptoms may develop even when compensation appears adequate[80] These symptoms, including dizziness, syncope or cardiac pain, may occur prior or subsequent to the development of cardiac failure

In a series of patients with severe aortic stenosis who were subjected to aortic commissurotomy fatigue was the earliest and most frequent symptom dyspnea on exertion was the second and angina pectoris the third most common[44] Vertigo occurred in 48 per cent and syncope in 42 per cent of patients with pure aortic stenosis and less frequently in those with aortic stenosis and insufficiency Atrial fibrillation did not occur in any patient with pure aortic stenosis in this series Peripheral edema hemoptysis and pulmonary edema were relatively infrequent[4]

Angina Pectoris in Aortic Stenosis

Cardiac pain has been noted in 10 to 20 per cent of proven cases of aortic stenosis Angina pectoris occurs more frequently in aortic stenosis than in other valvular lesions Its occurrence in luetic aortic insufficiency is generally due not to the valvular lesion as such but to the syphilitic narrowing of the coronary ostia (p 894)

The cardiac pain is usually a typical angina pectoris of effort, located over the sternum or precordium and radiating to the left arm Boas[5] reported several cases in which the cardiac pain resembled the excruciating persistent variety seen in coronary thrombosis I have personally observed 3 cases in which death occurred with the clinical and electrocardiographic picture of acute myocardial infarction

The pathogenesis of the cardiac pain is still uncertain, a number of possible explanations having been offered (1) Because of the frequent presence of a diastolic murmur in calcific aortic stenosis the cardiac pain has been ascribed to an associated aortic insufficiency This explanation is unlikely because despite the diastolic murmur there is rarely a dynamically significant insufficiency Nor is angina pectoris frequent in uncomplicated aortic insufficiency Furthermore, I have observed angina pectoris in cases of aortic stenosis in which there was no diastolic murmur nor any other clinical evidence of a possible aortic insufficiency (2) Boas[5] believed that the pain was caused by myocardial ischemia due to the obstruction at the aortic orifice But there is no clear explanation as to the mechanism of this ischemia since a normal aortic pressure is often maintained despite the stenosis (3) Contratto and Levine[1] ascribed the angina pectoris to a relative myocardial ischemia caused by the increased velocity of blood flowing past the coronary orifices This was said to result in a tendency to withdraw blood from the coronary vessels by suction This is hypothetical

My own studies support the concept of myocardial anoxia as the basis of cardiac pain in aortic stenosis The pathogenesis of this anoxia varies in different cases (1) Despite the fact that the coronary arteries in aortic stenosis are usually surprisingly smooth not infrequently there is severe *coronary atherosclerosis with narrowing of the lumina* and occasionally there is an atherosclerotic coronary occlusion Bergeron and associates[3] reported that severe coronary atherosclerosis with or without occlusion was found at necropsy in 13 or 17 cases of aortic stenosis in which a clinical diagnosis of angina pectoris had been made Thus angina pectoris in some cases of aortic stenosis is due to the same cause as in cases without valvular disease namely *coronary narrowing with consequent myocardial anoxia* This may be exacerbated by occasional narrowing of the coronary ostia by calcific deposits in the sinus pockets (2) Acute *coronary thrombosis* which may occur as a result of coronary artery disease accounts for most of the cases in which there is an attack of prolonged, excruciating cardiac pain (3) Myocardial ischemia may result from *functional coronary insufficiency* with or with

out associated coronary artery narrowing[26] This merits special discussion

Coronary Insufficiency and Myocardial Necrosis in Aortic Stenosis

The existence of coronary insufficiency in aortic stenosis is supported by clinical pathologic physiologic and electrocardiographic observations The occurrence of angina pectoris in cases with relatively normal coronary vessels has been noted it suggests that there is a physiologic inadequacy in coronary flow despite the absence of mechanical obstruction We have found pathologic support for this concept in a number of cases of aortic stenosis carefully studied at autopsy In several of these cases in which the most detailed search failed to reveal an acute coronary occlusion I have encountered acute myocardial damage varying in extent from focal areas of necrosis to extensive myomalacia[58, 2] In the more severe cases the clinical picture and electrocardiographic changes were those of acute myocardial infarction These are examples of intense functional coronary insufficiency But it is reasonable to assume that similar less intensive myocardial ischemia may account for the cases of angina pectoris without anatomic change either in the myocardium or the coronary vessels

Physiologic support for coronary insufficiency in aortic stenosis is found in the experiments of Green[31] He demonstrated that there was a significant reduction in the minute flow through the coronary arteries and that this flow could not easily be increased when the myocardial demand for blood was increased Even with extreme aortic stenosis an essentially normal aortic pressure is often maintained by an increased left ventricular contraction associated with a tremendous elevation of intraventricular pressure But the latter diminishes the systolic flow (and minute flow) of blood through the coronary arteries by producing an increased peripheral coronary resistance during systole Thus there may be an inadequate coronary flow even at rest This deficiency is greatly increased by exertion since the left ventricle finds it difficult or impossible to augment further the force of its contraction and the aortic pressure

Conduction Disturbances in Aortic Stenosis

Complete heart block bundle branch block intraventricular conduction defects and delayed atrioventricular conduction occur with sufficient frequency in calcific aortic stenosis to be considered features of the disease

The cause of the conduction defects especially of complete heart block has been found in organic disease of the bundle of His owing to an extension of the calcific process from the aortic valve to the fibrous septum[60] While I as well as others have observed such calcific obstruction of the bundle I have also seen various grades of heart block in cases in which such organic changes could not be demonstrated There are additional reasons for believing that the conduction disturbances are not invariably or even usually due to organic interference with conduction by calcium deposits The type and grade of conduction disturbance in a given case vary from time to time Thus in one case of calcific aortic stenosis which I observed the electrocardiogram first revealed only a left axis deviation and a negative T wave in lead I A week later the P R interval was prolonged to 0 28 second shortly afterward there was a transient complete heart block and eventually an intraventricular conduction disturbance In one case in Boas[8] series heart block was likewise transient and occurred only on exertion Angina pectoris developed simultaneously It is difficult to correlate these observations with a fixed organic lesion (lime) in the bundle or its main branches On the other hand they are compatible with the belief that the disturbances in conduction like the cardiac pain are due to myocardial ischemia caused by functional coronary insufficiency In a variable number of cases conduction disturbances are due to associated coronary atherosclerosis The calcification in the septum may be an underlying or predisposing factor

Dizziness and Syncope in Aortic Stenosis

On careful questioning one can often elicit a history of dizziness or faintness especially with exertion or change of position Not infrequently there are more severe attacks associated with syncope which may last for fifteen to thirty minutes McGinn and White[48] noted this symptom in 31 out of 98 clinical cases and Hammarsten[35] in 16 of 63 patients with aortic stenosis Gallavardin[28] and his students have stressed the frequency of syncope of effort in aortic stenosis It is often related to the occurrence of angina pectoris Occasionally there are petit mal seizures or hemiparesis[40]

Several explanations have been offered for the occurrence of dizziness and syncope in this disease (1) Marvin and Sullivan[48] suggested that syncope is due to a hyperactive carotid sinus reflex Contratto and Levine[17] were able to confirm the presence of a hypersensitive carotid sinus in some cases of aortic stenosis with syncope but not in others (2) Gallavardin[28] believed the syncope to be due to a sudden transient cerebral anemia caused by an insufficient aortic output This theory was based on an electrocardiographic observation, made during syncope of effort, that the heart did not stop contracting while the pulse beat disappeared an observation confirmed by Hammarsten[35] But no explanation is presented as to why the aortic output suddenly became inadequate (3) A third explanation, which we have suggested [illegible] attempts to clarify not only the cause of the syncope, but also its occurrence during effort and in individuals who suffer from angina pectoris Both syncope and angina pectoris occur in those individuals in whom the degree of aortic narrowing and consequently the compensatory left ventricular hypertrophy are extreme With usual activity, a normal aortic and consequently a normal cerebral arterial circulation is maintained in these individuals by a tremendously elevated left intraventricular pressure But so little reserve is left for further elevation of this pressure that it cannot be augmented adequately or with sufficient speed when exertion increases the body's requirements for blood Thus with effort, dizziness and syncope result from the cerebral anemia due to cerebral arterial insufficiency As we have seen above (p 701), similar events in these individuals lead to coronary insufficiency and angina pectoris, especially with effort But syncopal attacks may occur in such patients without anginal symptoms

The above explanation does not preclude the occurrence of syncope as a result of a hyperactive carotid sinus reflex in some cases In still others, syncope may be one of the manifestations of an Adams-Stokes syndrome due to the complete heart block occasionally present in aortic stenosis

Sudden Death in Aortic Stenosis

The frequency of sudden death in calcific aortic stenosis has been repeatedly noted but its pathogenesis remains obscure Of 76 patients followed by Willius,[61] 8 had died suddenly Reports of sudden death are also found in 5 to 15 per cent of the cases of McGinn and White,[49] Contratto and Levine,[17] Margolis and his co-workers[46] and of Bergeron et al[4] Marvin and Sullivan[48] gave a detailed account of 9 cases of sudden death in calcific aortic stenosis Sudden death often occurs in individuals who have previously suffered from dizziness, syncope or angina pectoris, and its occurrence may be an extreme expression of the same factors which produce the latter symptoms Sudden death may occur in patients with aortic stenosis with or without cardiac failure

There are probably multiple causes of sudden death in aortic stenosis

(1) The commonest cause of sudden death in general is coronary artery occlusion As we have mentioned, although the coronary arteries are usually fairly normal in aortic stenosis, occasionally there is a typical acute coronary artery thrombus with myocardial infarction

(2) In other cases of aortic stenosis with open coronary vessels, myocardial infarction is occasionally seen as a result of extreme coronary insufficiency This may also account for sudden death In still other cases, similar severe myocardial ischemia may cause death so rapidly that there is insufficient time for the development of an infarct

(3) Severe myocardial ischemia may produce a high degree of heart block which may be associated with cerebral anemia cardiac standstill or ventricular fibrillation These are all theoretical causes of sudden death

(4) Cerebral anemia which in some patients produces dizziness or syncope, may, if extreme result in sudden death

(5) A hypersensitive carotid sinus may produce cardiac standstill and sudden death In some patients this outcome may be the result of a combination of factors Thus reflexes from a hypersensitive carotid sinus may more readily cause sudden death if there is already some degree of myocardial ischemia and conduction disturbance

(6) Two cases have been reported in which sudden death may have resulted from the formation of an occluding thrombus over the stenotic valvular orifice[48] In one case it was suggested death was due to occlusion of the aortic orifice when one cusp became locked under a shelf formed by the other two[19]

Left Sided Heart Failure in Aortic Stenosis

Symptoms of left ventricular failure are

often the first subjective manifestations of the disease *Dyspnea on exertion* may be the earliest and most frequent symptom but usually fatigability is as ociated This may be present for a year or two but often for many years before other symptoms develop The dyspnea often becomes much more intense a few weeks or months before the end Attacks of *nocturnal paroxysmal dyspnea* (cardiac asthma) are infrequent except in the presence of associated mitral stenosis While they usually develop much later in the course of the disease than exertional dyspnea I have seen two patients in whom uch nocturnal at tacks were present for months before there was any respiratory disturbance during the day In both of the e patients there was an as sociated free' aortic insufficiency *Insomnia and nightmares* with or without associated cardiac asthma occasionally occur when there is early heart failure Cough and expectora tion are not infrequent and rarely there is hemoptysis *Orthopnea* is a late and frequent manifestation occurring when the exertional dyspnea is quite severe

Right Sided Heart Failure in Aortic Stenosis

As in aortic insufficiency severe failure of the left ventricle leads to pulmonary con gestion, elevated pulmonary arterial pressure and strain on the right ventricle Failure of that chamber follows shortly but occa ionally only after years of left-sided heart failure In the patients I have observed the symptoms of left sided heart failure did not sub ide when evidences of systemic venous engorgement de veloped as a result of right sided heart failure Peripheral edema appears when dyspnea and orthopnea are severe The course of the dis ease thereafter is rapidly progressive The liver becomes huge reaching to the level of the umbilicus The cervical veins are distended and may pulsate The venous pressure is ele vated Cyanosis appears toward the very end of the disease Effusions in the serous cavities are not uncommon particularly hydrothorax Frequently weakness lo s of weight and emaciation are prominent near the termina tion

OBJECTIVE FINDINGS IN AORTIC STENOSIS

The Heart

Inspection and *percussion* are usually of little assistance especially in elderly persons in whom a rigid barrel shaped chest obscures the pulsations of the heart In younger per sons, one may occasionally note a slow lifting pulsation of the hypertrophied heart

Palpation is important as it may supply a leading clue to the diagnosis There is frequently a *systolic thrill* at the base of the heart to the right of the sternum or along the right cervical vessels Its frequency in verified ca es has undoubtedly been understated because this sign is not always specifically sought when the diagnosis of aortic stenosis is unsuspected Occasionally it can only be elicited if the patient sits or stands and bends forward

Auscultation reveals a long-drawn loud and usually rough rasping squeaking or musical high pitched systolic murmur over the aortic area and the cervical vessels The murmur may radiate not only to the neck, but down ward along the sternum toward the apex and occasionally to the back Occasionally the systolic murmur is most prominent at the apex of the heart An apical systolic murmur may represent a radiation from the aortic area or a complicating relative mitral insuf ficiency when left ventricular failure occurs

The *phonocardiograph* shows the vibrations of a high pitched murmur which may be ex clusively systolic [38] (see also congenital aortic stenosis p 787) Occasionally the phonocardiogram shows the murmur to have a characteristic diamond shaped configuration Leatham[42] and others[43] stress the observation that the systolic murmur of aortic stenosis at the apex as well as the aortic area reaches its peak in mid-systole and is completed before the second sound This contrasts with the systolic murmur of mitral regurgitation which is evenly distributed throughout systole or is late systolic in time and differs from the systolic murmur of pulmonic stenosis which usually extends up to the second sound

The *second sound* over the aortic area is characteristically faint or absent Its absence indicates extreme fixation of the aortic cusp and is associated with the most severe cases of aortic stenosis In milder forms of aortic stenosis there may be no alteration in the second aortic sound Occasionally a normal second sound in the second right intercostal space actually represents a normal second pulmonic sound Auscultation over the first right intercostal space may disclose whether the second aortic sound is actually ab ent, diminished or normal [1]

A *diastolic murmur* over the base of the heart is heard in almost half the ca es of

"pure" monovalvular aortic stenosis It is sometimes accompanied by the peripheral circulatory signs of aortic insufficiency

Pulse and Blood Pressure

The pulse in severe aortic stenosis is often characteristic It is of small amplitude, rises slowly and falls away slowly (pulsus parvus et tardus) Its slow, prolonged elevation (systolic ejection being prolonged in aortic stenosis) gives it the form of a plateau There is an actual delay in the arrival of the pulse at the radial artery as compared with that of the normal pulse In aortic stenosis, the interval between the apex beat and the radial pulse is 0 2 second instead of the normal interval of 0 07 to 0 1 second

Pulse tracings from the radial artery often show a slight anacrotic notch on the ascending limb Hence the pulse of aortic stenosis has sometimes been described as an *anacrotic pulse* The greater the stenosis the lower is the position of this notch When rarely, the notch is quite sharp a double peak is formed and the wave is described as pulsus bisferiens Vibrations at the height of the carotid pulse have been termed carotid shudder [21] Feil and Katz have shown that the anacrotic notch in aortic stenosis is not present in the central arteries e g, in the subclavian Its appearance in the radial artery is merely the peripheral wave manifestation of the sudden change in pressure (recoil) in the aorta when the narrowed aortic orifice offers marked resistance to flow after the first rapid ventricular ejection of blood [0] However Wright[61a] described a similarity in contour of the simultaneously recorded central and radial artery pulses

The *blood pressure* in uncomplicated cases is normal Sometimes, however, the systolic pressure is slightly diminished, and the diastolic is normal or slightly elevated, with a resultant small pulse pressure There is often a prominent auscultatory gap In various series, both the average systolic pressure and the average pulse pressure are elevated because of an associated free aortic insufficiency or essential hypertension in many of the cases Contratto and Levine[17] found 17 cases of hypertension in their series of 180 The average blood pressure was 145/84 the range being between 260/156 and 80/10 In one case of calcific aortic stenosis combined with syphilitic aortic insufficiency, I observed a blood pressure of 300/40

Roentgenologic Examination of the Heart in Aortic Stenosis

In uncomplicated, well compensated aortic stenosis, the cardiac silhouette may appear normal even when there is slight hypertrophy There is usually hypertrophy of the outflow tract of the left ventricle with relatively little dilatation In anteroposterior views, this is indicated by a blunt rounding of the lower left cardiac contour (Fig 39A p 102) By fluoroscopy or roentgenkymography, one may observe a slow ventricular thrust or a gradual prolonged systolic contraction When left heart failure develops, the heart may become "mitralized" as in aortic insufficiency (p 690) When right-sided heart failure also develops, the cardiac shadow shows universal enlargement to the left and right

The aortic shadow in "pure" aortic stenosis, in contrast with that of aortic insufficiency is either normal or diminished in size and pulsation

Roentgenologic examination of the heart has assumed special importance in the diagnosis of the calcific type of aortic stenosis Fleischner [4] first diagnosed calcification in the annulus fibrosus during life, and subsequently Sosman and Wosika,[47] and other have reported series of verified cases in which antemortem diagnoses of calcified mitral and aortic valves were made by roentgenologic examination The calcification can be demonstrated fluoroscopically and on overpenetrated films In fluoroscopy, it is important to be extremely well accommodated, and to use a beam of high penetration coming through a very small aperture in the screen The calcified deposits should be localized by rotating the patient so as to determine the best views Recent studies indicate that tomography (planigraphy) is superior to all other methods for the roentgenologic demonstration of valvular and other cardiac calcification [15, 44]

Fluoroscopically, the calcified valves appear as dense nodular pulsating shadows which are described as dancing in a jerky fashion Their excursion is greater than that of the cardiac borders (1 to 2 cm) and is best observed in the oblique views and by roentgenkymography They are not apparently affected by deep respiration The calcified valves are seen slightly to the left of the midline (in a slight right oblique position which removes them from the dense spine shadow) and in the lowest

third of the cardiac shadow near the junction with the middle third. The mitral valve is in the posterior third of the cardiac shadow and the aortic valve slightly anterior and caudad to it. The motion of these shadows is rotatory or elliptical, their direction being downward and toward the apex in systole and upward and toward the midline in diastole. Both valves may be calcified. Calcification of the annulus fibrosus[24] may be distinguished from calcification of the cusps by a tendency to ring-like forms and less pulsation (Fig. 118). The discovery of calcification of the aortic valve on roentgenologic examination does not necessarily indicate aortic stenosis. But such discovery is a strong diagnostic confirmation when aortic stenosis is suspected clinically. Calcification of the valves may be distinguished from calcified pericardium, calcified tumors, thrombi or aneurysms of the heart by the characteristic shape, position and pulsation of the calcified valves. They can be distinguished from calcified lymph nodes and other extracardiac calcifications by the fact that calcified valvular shadows cannot be projected outside the cardiac outlines on rotating the patient.

The Electrocardiogram in Aortic Stenosis

The electrocardiogram may be normal or show only a left axis deviation if there is no associated mitral stenosis. In severe cases there is evidence of left ventricular hypertrophy. Not infrequently there are (1) permanent or transient severe conduction disturbances and (2) abnormalities of the T waves and RS-T transitions similar to those seen in coronary artery disease.

The conduction disturbances in order of frequency appear to be left bundle branch block, intraventricular conduction defects, partial and complete heart block.[■] I have seen cases in which the electrocardiograms showed first one, then another and even a third of these disturbances at different times.

Atrial fibrillation is uncommon in well compensated pure monovalvular aortic stenosis except when it is due to associated mitral stenosis.[■] However, it has been noted in as many as 30 per cent of one series of cases,[8] probably due to associated lesions.

The Ballistocardiogram

Distinctive angulation or bowing of the J-K segment of the low frequency ballistocardiogram has been described in cases of aortic stenosis with or without insufficiency.[■] The K wave may be small and M prominent. Likoff et al[■] stressed a shallow K wave as the most constant finding.

COMPLICATIONS OF AORTIC STENOSIS

Heart failure occurs most often and is the commonest cause of death. Sudden death is not infrequent. Bacterial endocarditis is uncommon except in cases with predominant aortic insufficiency. Myocardial infarction with or without coronary thrombosis is occasionally observed. The Adams-Stokes syndrome may be a fatal complication. Bronchopneumonia, pulmonary infarction and acute pulmonary edema are occasional complications which may result fatally.

DIAGNOSIS

The diagnosis is simple if the classic cardinal criteria are satisfied, namely: (1) a loud, rough aortic systolic murmur, (2) an aortic systolic thrill, (3) absent or faint second aortic sound and (4) a characteristic small delayed pulse. The most common oversight is failure to palpate the chest wall for a thrill. The importance of a high-pitched squeaking systolic murmur in the diagnosis of aortic stenosis and calcification of the aortic valve has been stressed by Braun and Comeau.[19] When an associated mitral stenosis dominates the clinical features, an aortic stenosis may be easily overlooked unless two or more of these signs are present. Usually the murmur and thrill suffice to justify the diagnosis. The finding of calcification of the aortic valves on roentgenologic examination and the characteristic pulse tracings are confirmatory. The presence of an aortic murmur for many years in a middle-aged or elderly male should suggest the possibility of calcific aortic stenosis, especially if such a murmur is associated with a history of angina pectoris, dizziness or syncope. In the absence of syphilis or a positive Wassermann reaction and in the absence of the peripheral signs of aortic insufficiency, a combined systolic and diastolic murmur over the aortic area should suggest calcific aortic stenosis. In cases of mild aortic stenosis a diagnosis of calcific aortic stenosis may have to be ventured merely on the basis of a rough aortic systolic murmur and the fluoroscopic demonstration of a calcified aortic valve. To confirm the diagnosis of aortic stenosis and to determine its severity in patients in whom an aortic commissurotomy is being considered

left and right heart catheterization and measurement of the left ventricular aortic gradient may be undertaken (pp 77 and 699)

PROGNOSIS

Individuals with pure aortic stenosis, especially the calcific form of the disease have a good prognosis and are usually long lived The outlook remains favorable only so long as compensation is maintained and there are no symptoms Clawson Bell and Hartzell[15] found the average age at death of 29 cases with predominant aortic stenosis to be 55 8 years as compared with an average age of 41 7 years for mitral stenosis Clawson Noble and Lufkin[16] found that the majority of their 200 cases survived until the seventh decade or later

The occurrence of angina pectoris or syncopal attacks is unfavorable Once heart failure develops the prognosis is extremely poor and the course of the disease is rapidly progressive Contratto and Levine[17] noted the occurrence of death in aortic stenosis on an average of 23 months after the onset of dyspnea, 9 3 months after the onset of peripheral edema 9 months after the onset of syncope 6 months after the appearance of râles in the lungs and 4 months after the development of the first attack of pulmonary edema

TREATMENT

MEDICAL MANAGEMENT

The medical treatment of aortic stenosis is essentially symptomatic Restriction of physical activities may be necessary when there are attacks of angina pectoris or syncope or when congestive heart failure develops The treatment of these complications has been considered in previous chapters

SURGICAL TREATMENT

Following experimental studies various procedures have been devised to correct the aortic stenosis by surgical means [41 43 45 4 52 44] As with mitral stenosis it would appear that the strain imposed on the heart could be alleviated by enlarging the stenotic opening in the aortic valve

Indications and Choice of Patient for Aortic Valvulotomy

In general aortic valvulotomy (commissurotomy) appears indicated when aortic stenosis is very severe when there is a high gradient between the left ventricle and aorta (over 50 mm Hg), and there are clinical manifestations which are due directly or indirectly to the stenosis Actually it is difficult to determine accurately the severity of the stenosis before operation Attempts are being made to determine the pressures within the left ventricle and the aorta by means of catheters passed through a needle inserted into the left atrium by way of the bronchus or thoracic wall, and thereby measuring the pressures in the left ventricle and aorta thus calculating the gradient The gradient between the left ventricle and aorta can be determined at the time of operation for a concomitant mitral stenosis

In practice the selection of patients for aortic valvulotomy is determined by a consideration of the symptoms and the clinical stage of the disease Patients who are well compensated and are asymptomatic are not regarded as candidates for the operation A second group of patients with well defined manifestations of aortic stenosis complain only of general heart consciousness or vague precordial distress palpitation fatigability or mild dyspnea on more than ordinary exertion This is a very favorable group for aortic valvulotomy if one can carefully exclude other causes for these symptoms and if one is reasonably certain that they are due to the aortic stenosis Similarly aortic valvulotomy is regarded as indicated in patients with angina pectoris or syncope when these manifestations are due to the stenosis But it should be reemphasized that coronary atherosclerosis with narrowing or occlusion is not uncommon in patients with aortic stenosis, particularly in those patients past middle age who have the calcific aortic stenosis Similarly other causes for syncope should be excluded before attributing this symptom to the stenosis and before regarding it as a clear indication for surgical therapy

The outlook is so poor after patients with aortic stenosis have developed definite left sided heart failure, and especially after right sided heart failure has appeared that aortic valvulotomy may appear to offer the only hope for improvement Harken[38] found that of 34 patients with aortic stenosis to whom aortic surgery was recommended because they had developed left ventricular failure syncope or angina pectoris but who refused operation 30 were dead in less than six months

Therefore the indication for surgery in these groups of cases is partly a negative one in that there is very little to lose and perhaps much to gain Unfortunately the mortality rises progressively with left and right sided heart failure respectively and the results become proportionately less favorable since myocardial damage as well as the mechanical effect of the stenosis accounts for the patient s symptoms Furthermore in about 20 per cent of patients with severe clinical manifestations of aortic stenosis the aortic valve is so calcified and fixed that the aortic orifice cannot be materially dilated[44]

Aortic valvulotomy for aortic stenosis offers less of a problem when the aortic stenosis is combined with mitral stenosis and a mitral commissurotomy appears indicated The aortic valvulotomy may be performed even when there is some degree of mitral insufficiency provided that the mitral stenosis is the dominant lesion Relief of the aortic stenosis may actually diminish the degree of mitral regurgitation since the left ventricular pressure is diminished

Aortic valvulotomy may be performed for an aortic stenosis even when there is a diastolic murmur denoting concomitant aortic insufficiency provided that the aortic stenosis is definitely the predominant lesion and there are no hemodynamic evidences of a free aortic regurgitation Aortic valvulotomy is indicated whether the stenosis is rheumatic or congenital and the association of a coarctation of the aorta is not a contraindication

Contraindications

At the present time aortic valvulotomy should not be performed if there is a marked aortic insufficiency associated with the stenosis if there is complete heart block if there is evidence of infection or intercurrent diseases which would make the patient a poor risk or if there is advanced right heart failure which does not respond to therapy Patients beyond the age of 50 are not regarded as desirable candidates for aortic valvulotomy

Technique of Operation

The patients with left or right sided heart failure should be treated by bed rest digitalis low sodium intake and diuretics until maximum benefit has been obtained but without undue delay of the operation Frequently heart failure in aortic stenosis is not readily responsive to medical treatment

The patient is maintained by endotracheal anesthesia with oxygen and ether after induction with Pentothal sodium or cyclopropane The chest may be entered through an anterolateral incision in the fifth intercostal space the incision extending from the left border of the sternum to the posterior axillary line Or the chest may be entered through a transverse sternal splitting incision which exposes the ascending aorta and heart anteriorly Bailey[3] employs a right thoracic approach in cases of combined mitral and aortic stenosis (p 674)

There is no universal agreement as to whether the valve should be dilated by an instrument inserted through the left ventricle or through the aorta just above the aortic valve Bailey and associates[4] have operated on 170 patients with aortic stenosis by the ventricular route using a dilator with parallel blades Muller[45] made a small stab wound in an avascular area of the left ventricle near the apex and inserted a special aortic valvulotome with dilating components When the surgeon believes that he has dilated the aortic valve satisfactorily the valvulotome is withdrawn the pressures in the aorta and left ventricle are measured and if the gradient has been sufficiently reduced the stab wound in the ventricle is closed with interrupted sutures The gradient should be reduced at least below 50 mm Hg but preferably as close to zero as possible If the gradient is still too high the valvulotome should be introduced again and further dilatation of the valve effected

Bailey[4, 5] now prefers a retrograde approach by the transaortic route and has operated on 47 patients with aortic stenosis by this technique The aortic wall is pinched off with the aid of a curved Potts toothed clamp or a special type of Satinsky clamp and a pouch of pericardium is sewed to an opening made in this excluded portion of the aortic wall A purse string suture is placed around the periphery of the opening to maintain homeostasis A finger is then inserted through the pouch and the aortic opening into the aorta and aortic valve As with mitral commissurotomy the finger fractures the commissures or separates the cusps in the majority of cases If necessary a mitral guillotine knife or similar knife carried along the finger may be used to separate unyielding commissures A somewhat similar transaortic technique has been employed by Fell[11] to

dilate stenotic aortic valves in 8 patients varying in age from three months to 50 years He utilized a dilator calibrated to 24 mm

In patients operated on for mitral stenosis, the coexistence of severe aortic stenosis may be determined or verified at operation by palpation of a systolic thrill near the stenotic valve and by measurement of pressures in the left ventricle and aorta Either the mitral or aortic stenosis may be corrected first On theoretical grounds it might appear that relief of the aortic stenosis may improve coronary artery perfusion, diminish any mitral regurgitation by diminishing left ventricular pressure and reduce the danger of overloading the left ventricle when the mitral valve is dilated However, Bailey usually dilates the mitral valve first, and Muller[52] recommends dilating first the valve which is most severely affected

Another method used to correct experimental aortic stenosis consists in a permanent by pass of the aortic valve A lucite tube, placed in the apex of the left ventricle conducts blood through a modified Hufnagel valve and into the thoracic aorta[54]

Surgical Mortality and Results

In the largest series, that of Bailey et al,[4] the operative mortality was 25 per cent (in 173 cases) by the ventricular route and 14 per cent (in 47 cases) by the transaortic route[3, 4a] However, the mortality was significantly lower in patients with combined aortic and mitral stenosis In such cases of combined valvular disease, the mortality was 18 4 per cent among 87 patients operated on by the transventricular route and only 1 death among 14 *patients operated on by the transaortic* route Muller[52] operated on 26 patients with pure aortic stenosis (with or without mild *aortic insufficiency), 10 patients with aortic* and mitral stenosis and 1 with aortic stenosis and coarctation of the aorta There were 7 operative deaths (27%) among those with aortic stenosis alone, and 3 deaths (30%) among those with aortic and mitral stenosis Glover[30] reported that the mortality was only 8 per cent in patients with early symptoms with a favorable result in about 75 per cent The mortality rose to 44 per cent when there was a history of episodes of pulmonary congestion and to 85 per cent in the presence of frank congestive heart failure

The surgical complications and causes of mortality are chiefly ventricular fibrillation, cardiac arrest, hemorrhage from the incised ventricle and the production of frank aortic insufficiency Cerebral and pulmonary embolism and temporary or persistent complete heart block or bundle branch block have also occurred In a number of cases bacterial endocarditis has developed within a few months after aortic commissurotomy[4a]

It is still too early to evaluate the clinical results of aortic valvulotomy Excellent results have been claimed in about 75 per cent of cases Evaluation depends chiefly on reports of subjective alleviation of symptoms such as palpitation, dyspnea, orthopnea, fatigability, poor exercise tolerance, syncope and angina pectoris[4a] Objective improvement was denoted by pressure changes and reduction in left ventricular aortic gradient at operation and by reduction in cardiac size postoperatively The aortic systolic murmur does not disappear but a diastolic murmur may appear or become louder

Chapter 29

TRICUSPID AND PULMONIC VALVULAR DISEASE

TRICUSPID VALVULAR DISEASE

ETIOLOGY

Tricuspid insufficiency is usually a functional disturbance but may be due to organic disease of the valve[11]

Organic tricuspid insufficiency is almost always caused by rheumatic fever, but it may occasionally result from trauma which tears a cusp or ruptures its chordae or papillary muscle Rarely bacterial endocarditis causes or increases a tricuspid insufficiency Malignant carcinoid of the small intestine may be associated with scarring of the tricuspid valve and tricuspid insufficiency (p 1042) Congenital tricuspid insufficiency is rare, and may be due to incomplete differentiation of the cusps or to a downward displacement of the right ventricle (Ebstein type) (p 788)

Frequent involvement of the tricuspid valve in rheumatic heart disease was noted by Sansom[31] There is almost always concomitant rheumatic mitral disease and often also aortic valvular involvement Gross and Friedberg[16] found microscopic evidence of rheumatic inflammation in the tricuspid valve almost as often as in the mitral but significant insufficiency or stenosis is uncommon

Functional tricuspid insufficiency occurs in a great variety of conditions associated with failure and dilatation of the right ventricle When the right ventricle fails the tricuspid valve becomes insufficient for two reasons (1) Weakness of the right ventricular contraction removes the important muscular factor normally necessary to close the tricuspid orifice completely[20] For even normally there is a slight physiologic tricuspid insufficiency because the tricuspid leaflets are not quite large enough to close the tricuspid orifice Effective muscular contraction which narrows the tricuspid ring is important for complete closure of the tricuspid valve Atrial fibrillation usually present in functional tricuspid insufficiency, may intensify the insufficiency, since atrial contraction is required for normal closure of the atrioventricular valves[26] (2) Failure of the right ventricle is associated with enlargement of its chamber and consequent retraction of the papillary muscles and their attached chordae tendineae from the tricuspid valve Thus the tricuspid leaflets are held taut within the ventricular chamber and are unable to move sufficiently to close the orifice At the same time dilatation of the right ventricle stretches the tricuspid ring and enlarges the orifice

Tricuspid stenosis is less common than tricuspid insufficiency but not so rare as was formerly believed[9, 2, 28, 14, 5] As a rule insufficiency is associated with tricuspid stenosis Tricuspid stenosis is almost always associated with a more severe mitral stenosis the latter being present in all 30 cases of tricuspid stenosis reported by Dressler and Fischer,[9] and in 181 of the 195 cases reported by Futcher[18] Aortic insufficiency or stenosis is also associated in one half to two thirds of the cases Occasionally tricuspid stenosis may occur as an isolated lesion[14, 11, 19] g, in 14 of the 187 cases collected by Herrick[18] Tricuspid stenosis may be associated with disease of the other three valves[17]

Tricuspid stenosis may be congenital or acquired The congenital lesion is very rare and is due to adhesion of the free borders of the valve More often there is an atresia of the tricuspid valve with ventricular malformation

Acquired tricuspid stenosis is almost invariably due to rheumatic fever but occasionally a functional tricuspid stenosis results from bacterial vegetations thrombi

or tumors projecting into the tricuspid orifice The obstructing vegetations which are polypoid and massive occur in bacterial endocarditis Obstructing atrial thrombi occur rarely in cases of heart failure with atrial fibrillation[47] or in cases of myocardial infarction with a mural thrombus occluding the tricuspid valve from below The tumors are usually primary myxoma or sarcoma or secondary metastases of hypernephroma sarcoma of the testis carcinoma of the thyroid or other neoplasms

Tricuspid stenosis has been found by Smith and Levine[42] in 10 per cent of 340 and by Cooke and White[8] in 15 per cent of 217 autopsied cases of rheumatic heart disease These and other observers have noted additional cases of rheumatic involvement of the tricuspid valve without significant deformity In still other cases of rheumatic tricuspid valvular disease no differentiation is made between stenosis and insufficiency Among 147 autopsied cases of rheumatic heart disease reported by Aceves and Carral[2] 50 per cent had some tricuspid involvement and 33 per cent (49 cases) had a valvular deformity classified as tricuspid insufficiency Of the latter 49 cases 11 disclosed predominant stenosis and another 11 equally marked stenosis and insufficiency Tricuspid valvular disease was found in 17 per cent of a large series of patients operated on for mitral and aortic valvular disease In 11 per cent predominant tricuspid stenosis was recognized by direct digital examination[2] Several cases of isolated tricuspid stenosis have been reported[19, 14]

Age and Sex

These are the same as in patients with other rheumatic valvular lesions The usual age is between 25 and 40 for the organic rheumatic cases of tricuspid valvular disease but occasional cases are encountered in persons beyond the age of 50 There is a distinct predominance of females especially among those with pronounced tricuspid stenosis

PATHOLOGY

The pathologic findings in the valves are described in the chapters on the causative disease (i e rheumatic fever congenital heart disease etc) In the rheumatic cases the cusps undergo inflammatory swelling and thickening which interfere with their proper coaptation Closure of the tricuspid orifice is further impaired by shortening and retraction of the cusps and their chordae Tricuspid insufficiency is enhanced when dilatation of the right ventricle is associated with concomitant dilatation of the tricuspid ring Tricuspid stenosis is the predominating disturbance when rheumatic inflammation and scarring causes adhesion of the cusps to each other This leads to a single fused cylindrical or conical curtain or to a buttonhole type of stenosis with a rigid slot like aperture Some degree of tricuspid insufficiency is associated The associated mitral stenosis is almost always more pronounced than the tricuspid stenosis Instead of the normal circumference of 11 to 13 cm the tricuspid ostium measures usually 15 to 17 cm or more in tricuspid insufficiency or 8 cm or less in tricuspid stenosis With severe stenosis the tricuspid valve area may be less than 1 sq cm

Bacterial endocarditis may enhance a rheumatic tricuspid stenosis by forming a large obstructing vegetation or increase an insufficiency by destruction of a cusp or chordae However the tricuspid valve is uncommonly involved in bacterial endocarditis Following intravenous injection of heroin in addicts there may occur an isolated staphylococcus or other bacterial or yeast endocarditis of the tricuspid valve

The Heart

The size of the heart and of the individual chambers is determined in part by associated lesions The right atrium is dilated and hypertrophied with both tricuspid insufficiency and stenosis In tricuspid stenosis the right atrium may be so enormous that it appears as a supplemental heart and in Taussig's[44] case it was the only hypertrophied chamber Sometimes the dilated right atrium appears as a huge fibrous sac in which the muscle has undergone atrophy

The right ventricle is dilated and hypertrophied both in organic and functional tricuspid insufficiency In the presence of pronounced tricuspid stenosis the right ventricle may be normal in size or only slightly hypertrophied The associated mitral stenosis often causes right ventricular hypertrophy of some degree but this is less pronounced when the tricuspid stenosis is marked than when it is slight In a recent observed case of pure tricuspid stenosis the right atrium was the predominant cardiac chamber whereas the right ventricle appeared atrophic

The left atrium is usually dilated and hypertrophied in organic tricuspid stenosis or insufficiency because of the concomitant mitral stenosis. In cases of functional tricuspid insufficiency the left atrium may be dilated and hypertrophied if left-sided heart failure preceded failure of the right heart, but not if the latter is due to cor pulmonale.

The size of the left ventricle is determined by the presence, order of development and predominance of mitral stenosis or of an aortic valvular lesion.

The *venae cavae* are prominently dilated and may form a continuous sac with the dilated right atrium. As a result of venous stasis, the internal viscera, particularly the liver, spleen and kidneys, show severe chronic passive congestion. Cardiac cirrhosis of the liver is more frequent than in other forms of valvular disease and heart failure.

PATHOLOGIC PHYSIOLOGY

Both with tricuspid stenosis and insufficiency there is an increased diastolic volume of blood in the right atrium. In the former it is due to incomplete emptying through the narrowed valvular orifice, in the latter to regurgitation of blood into the atrium during right ventricular contraction. The increased stretch results in a more forceful atrial contraction with at least a temporary restoration of normal output. During this process of compensation the right atrium becomes dilated and eventually hypertrophied.

Because of the limited compensatory capacity of the thin right atrial wall, systemic venous distention occurs early. This serves to diminish the outflow from the right side of the heart and reduces or prevents pulmonary engorgement. When tricuspid stenosis is the predominant lesion, its effect is somewhat similar to that of constrictive pericarditis in that it obstructs the inflow of blood into the right ventricle.

The dynamics of tricuspid lesions may be modified and are often overshadowed by those of associated mitral or aortic valvular disease. In the instances of functional tricuspid insufficiency the prevailing circulatory dynamics are determined by the conditions which produce ventricular dilatation and failure.

Intracardiac catheterization has disclosed characteristic pressure tracings in cases of tricuspid insufficiency.[3, 11, 21] In cases of right-sided heart failure with competent tricuspid valve there is a pronounced fall in atrial pressure early in ventricular systole due to descent of the tricuspid valve. But when the tricuspid valve is insufficient, blood spurts back into the atrium during systole and the atrial pressure is unchanged or rises instead of falling. This positive pressure wave, persisting throughout systole, produces a peak-dome or peak-plateau contour. The mean atrial pressure is markedly elevated and increases further with exercise. The calculated pulmonary resistance was much higher in a group of patients with mitral disease and tricuspid insufficiency than in those without tricuspid insufficiency.[48] In pure tricuspid stenosis the striking feature of the atrial pressure tracing is the presence of giant "a" waves.

The right atrial pressure is elevated, often to a mean pressure between 10 and 25 mm Hg instead of the normal of 3 mm Hg.[21] The atrial pressure rises further with the onset of ventricular contraction in tricuspid insufficiency but not in pure tricuspid stenosis.[11] Not only the right ventricular systolic but also the right ventricular diastolic pressure is elevated, denoting right ventricular failure.

Normally, with opening of the tricuspid valve, right atrial and ventricular pressures are essentially equal in diastole, i.e., there is virtually no gradient. In tricuspid stenosis there is an abnormal pressure gradient between right atrial mean pressure (or Z-point pressure) and the diastolic pressure in the right ventricle.[11, 6, 34] The gradient is increased by exercise. Such a diastolic gradient is not present in tricuspid insufficiency and distinguishes "pure" stenosis from "pure" insufficiency of the tricuspid valve.

CLINICAL FEATURES

The clinical picture of tricuspid valvular disease resembles that of advanced right-sided heart failure with systemic venous engorgement. In cases of organic tricuspid disease there is usually a preceding period of known mitral stenosis or of mitral and aortic valvular disease, with or without left-sided heart failure. When organic tricuspid disease is added, the clinical picture may be indistinguishable from that of mitral and aortic valvular disease

with heart failure or it may be dominated by the effects of the tricuspid lesion

The clinical features of pure tricuspid insufficiency may be gleaned from rare cases of traumatic origin Todd[15] reported the case of a man of 21 who following a stab wound in the right chest suffered a rupture of the chordae tendineae of the anterior cusp of the tricuspid valve Two and a half years later he was in advanced right heart failure with hepatic enlargement widespread anasarca and ascites

In cases of functional tricuspid insufficiency the clinical picture is characterized by the combination of left and right-sided heart failure or of primary pulmonary disease with secondary right heart failure

In cases of *pure or predominant tricuspid stenosis* there may be virtually no subjective symptoms except pain in the right upper quadrant of the abdomen due to an enlarged tender liver Physical signs include pulsating cervical veins with prominent giant a waves a pulsating liver a rumbling diastolic murmur at the left border of the sternum and apex sometimes with an opening snap P_2 is not accentuated Roentgenologic examination shows a greatly enlarged right atrium producing a horizontal shelf in the left anterior oblique view Atrial fibrillation edema and ascites are late developments

Symptoms of Tricuspid Valvular Disease

Dyspnea on exertion is the commonest subjective symptom probably due to pulmonary congestion caused by a concomitant mitral stenosis or other lesion producing left sided failure However the remarkable feature of tricuspid disease is the relative freedom from orthopnea and paroxysmal dyspnea Careful questioning and observation does disclose orthopnea in most patients but the degree is surprisingly mild for many of these patients with edema and ascites are seen to be lying flat in bed without apparent discomfort Sometimes the development of tricuspid stenosis or insufficiency is documented by partial or complete relief of preceding dyspnea and orthopnea due to left sided heart failure This relief in pulmonary congestion is regarded as the consequence of diminished right ventricular output into the lungs because of the tricuspid lesion

Persistence of dyspnea in the presence of tricuspid valvular disease may be due to hydrothorax or the pressure of abdominal ascites as well as to pulmonary congestion secondary to mitral valvular disease When functional tricuspid insufficiency follows cor pulmonale and right heart failure dyspnea persists because of the primary pulmonary disease

Other subjective symptoms include anorexia nausea eructations vomiting and abdominal pain due to chronic passive congestion of the gastrointestinal tract to enlargement of the liver or to ascites Rarely hematemesis or melena occurs from secondary ulceration of the congested inflamed mucosa of the gastrointestinal tract

In cases of isolated pure tricuspid stenosis there may be no subjective symptoms or only fatigability without dyspnea cyanosis edema or ascites

Objective Signs

Hepatic enlargement is a constant finding The liver may be huge There is usually a systolic liver pulsation in cases of tricuspid insufficiency or a presystolic pulsation in cases of tricuspid stenosis (infra) In my experience most physicians overlook hepatic pulsation even when it is readily ascertainable Pulsating liver can be distinguished from a transmitted pulsation by simultaneous palpation of the liver and carotid artery[37] In tricuspid insufficiency hepatic pulsation is felt late in systole after the carotid pulsation

Venous engorgement especially of the cervical veins is a striking feature of tricuspid disease There is a pronounced systolic pulsation with tricuspid insufficiency and a characteristic double pulsation with giant a waves in tricuspid stenosis provided the rhythm is regular Similar venous distention and pulsation may be visible in the more peripheral veins such as the basilic veins and those in the dorsum of the hands[16] The *venous pressure* is greatly elevated and increases with pressure over the right upper quadrant of the abdomen (hepatojugular reflux) The *circulation time* is increased

Ascites is a predominant manifestation Its relatively long duration and its recurrence despite repeated abdominal tappings are characteristic features However ascites has been absent in the cases of isolated tricuspid stenosis without associated valvular lesions

Edema is present in most cases of severe tricuspid stenosis or insufficiency In cases of tricuspid stenosis and often in cases of tricuspid insufficiency peripheral edema may be absent

or relatively slight in contrast with the usual findings in right-sided heart failure In the series of 21 cases studied by Muller and Shillingford [31] peripheral edema was severe in 6, moderate in 8, slight in 3 and absent in 4 of the patients

Effusions in the pleural cavities are common in all types of tricuspid valvular disease

The explanation for the relatively early and disproportionate ascites in tricuspid stenosis is unknown Extreme rapid and prolonged congestion of the liver may account for the predominant ascites reminiscent of hepatic cirrhosis Eventually edema of variable degree develops in most cases of tricuspid disease *Hypoproteinemia* due to hepatic dysfunction is an important contributory factor The edema may also involve the face, since patients with tricuspid stenosis do not usually suffer from orthopnea and lie flat in bed

Cyanosis is a frequent finding in advanced cases but Sepulveda and Lukas[41] noted it in only 15 per cent of their patients with tricuspid insufficiency Cyanosis is due essentially to longstanding pulmonary congestion secondary to mitral stenosis or to preceding pulmonary disease Pulmonary infarction may be a contributing or primary causative factor Pronounced slowing of the blood stream with peripheral stasis may also contribute to cyanosis by increasing the tissue extraction of oxygen from the capillaries

Cyanosis is usually more pronounced and dyspnea less pronounced in cases of tricuspid and mitral stenosis than in mitral stenosis alone This may denote that the relief of pulmonary engorgement afforded by the tricuspid lesion diminishes the rigidity of the lung and thereby alleviates dyspnea On the other hand in the presence of tricuspid disease, the associated mitral stenosis is almost always very severe and the fibrosis and thickening of the pulmonary alveolar septa are pronounced The latter changes impair aeration of the blood Thus arterial anoxemia and cyanosis result from poor aeration of the pulmonary capillary blood, even though pulmonary compliance improves as the vascular congestion diminishes Secondary *polycythemia* may develop as a compensation to the anoxemia

Icterus or a subicteric tint is often combined with the cyanosis in the cases of organic tricuspid disease The resulting yellowish blue or olive coloration often suggests the diagnosis [9, 51] The jaundice is probably due to hepatic dysfunction caused by longstanding congestion and fibrosis of the liver Frequent *pulmonary infarcts* seen in organic tricuspid disease have also been held responsible as a contributing causative factor (p 206)

Systolic or Positive Venous Pulse in Tricuspid Insufficiency The right atrium is never completely emptied and there is an elevated pressure In addition blood is regurgitated into this chamber during ventricular systole As a result of the persistent atrial stasis and the impulse of the regurgitant stream the cervical veins remain filled and expand during systole The negative wave or depression "x" which is present in the normal jugular venous pulse (p 72) disappears This results in the so-called *positive venous pulse* or *ventricular venous pulse* of tricuspid insufficiency The absence of the x depression produces a characteristic plateau in systole [9] The pulse is often visible, without the aid of tracings, as a broad systolic wave ascending the neck along the course of the internal jugular vein up to the very ear lobe The external jugular vein may be too distended to disclose pulsation In less severe cases of tricuspid insufficiency the jugular phlebogram may show a positive systolic wave after an abbreviated x depression and before the v wave [27, 31]

The right atrial pulse similarly shows a diminution in the x depression or replacement by a plateau or positive wave [9, 11, 23] Moderate rises of venous pressure are associated with an impairment of systolic (x) depression whereas with greater increases in venous pressure a positive systolic wave replaces the x descent

When tricuspid regurgitation is associated with tricuspid stenosis the appearance of the positive wave after the "c" wave is delayed the rise of the wave is slower the peak occurs later and the diastolic collapse is slower [10]

A positive venous pulse may be insignificant in tricuspid insufficiency if the right atrium is greatly dilated and the regurgitant stream has little effect on its large content On the other hand a positive venous pulse may be observed in the absence of tricuspid insufficiency when there is atrial fibrillation with right sided heart failure and advanced venous stasis [22] But the systolic pulsation is rarely as well defined as in tricuspid insufficiency

Atrial Venous Pulsation in Tricuspid Stenosis In tricuspid stenosis the cervical venous pulse

often shows an accentuated 'a' wave due to the increased force of contraction of the hypertrophied right atrium. In addition the obstruction at the tricuspid orifice may cause a regurgitation of blood from the right atrium into the cervical veins. These factors cause a rise in venous pressure and a consequent venous pulsation during atrial systole. This is known as the *atrial venous pulse* and is a characteristic feature of tricuspid stenosis. But it may occur if there is pronounced left atrial hypertrophy with a large interatrial septal defect. It may be absent if the atria are fibrillating.

Sometimes there is a distinctly visible *double* pulsation of the cervical veins, one synchronous with ventricular systole and one presystolic in time. The latter denotes tricuspid stenosis and the former concomitant insufficiency or pronounced right atrial stasis behind the tricuspid obstruction. I have also observed distinct double jugular venous pulsations in a case of rupture of a congenital aneurysm of the sinus of Valsalva into the right atrium and in two cases of coronary heart disease with left- and right-sided heart failure and tricuspid insufficiency, with regular sinus rhythm.

Systolic (Ventricular) and Atrial Liver Pulse. In cases of tricuspid insufficiency there is usually a palpable pulsation of the liver during ventricular systole. It is explained by regurgitation of blood from the right ventricle into the atrium. This leads to a transmitted pulse into the inferior vena cava, hepatic veins and their tributaries, corresponding to the systolic jugular pulse.

Clinically the systolic liver pulse is best noted as an expansile sensation when the liver is examined bimanually, one palm being held over the posterolateral surface of the lower right axilla and the other anteriorly over the right upper quadrant of the abdomen, i.e., over the liver. The patient should hold his breath. This pulsation must be differentiated from the pulsations of a large right ventricle transmitted through the diaphragm or from similar transmitted pulsations from a dynamic or aneurysmal abdominal aorta. But these pulsations are rarely expansile and strike only one of the two examining hands. A systolic liver pulse may be absent in tricuspid insufficiency if the regurgitant flow is too slight, if there is a hugely dilated right atrium or if longstanding passive congestion has produced a pseudocirrhotic liver which cannot pulsate.

A systolic pulsation of the spleen has been described in tricuspid insufficiency.[43]

In *tricuspid stenosis* there may be a *presystolic or atrial liver pulse* corresponding to the *atrial venous pulse* and due to a similar mechanism.[15, 34] This is best demonstrated by graphic registration but may be recognized by bimanual palpation. A double liver pulse may be encountered when there is a combination of tricuspid stenosis and insufficiency, one pulsation being due to atrial contraction and the other to ventricular systole, which causes a regurgitant impulse in the right atrium and inferior vena caval tributaries. Grishman and associates[15] have recently emphasized that the presystolic liver pulse is not specific for tricuspid stenosis but occurs also in a variety of other conditions. They described its occurrence in congenital heart disease, especially interatrial septal defect, in certain cases of myocarditis with congestive heart failure, in cor pulmonale and in chronic atrial flutter without organic heart disease. I have observed it in a case of rupture of a congenital aneurysm of the sinus of Valsalva into the right atrium, which was included in the series of Grishman et al. As in tricuspid stenosis, the presystolic liver pulse in these conditions is due to a pulse transmitted to the vena cava and liver by a rapid rise in pressure in the right atrium as a result of valvular obstruction or high resistance (pressure) in the right ventricle. Presystolic venous pulse is often but not invariably associated with presystolic liver pulse. Right ventricular enlargement and right ventricular failure are often but not always present in cases of pure tricuspid stenosis. Although the early diastolic 'v' wave is also exaggerated, it is not as prominent as the 'a' wave. Occasionally double pulsations corresponding to the 'a' and 'v' waves are palpable. But the late systolic pulsation of tricuspid insufficiency is not observed except when the presystolic liver pulse is due to tricuspid stenosis and insufficiency.

The Heart in Tricuspid Valvular Disease

The physical signs over the heart are often determined by the associated mitral stenosis or other valvular disease.

In cases of *tricuspid insufficiency* there may be a characteristic see-saw movement of the

chest wall [8] This is due to a propulsion of the lower right side of the sternal region by the pulsating liver while simultaneously ventricular systole causes a pronounced depression of the precordium The latter is due to the aspiratory effect on the chest wall of ventricular ejection of blood out of the thorax while the influx of blood into the heart is prevented by the regurgitant stream

Percussion reveals enlargement of the heart, especially to the right In cases of pronounced *tricuspid stenosis* the dilated and hypertrophied right atrium may occasionally cause the right border to reach the right midclavicular line

Auscultatory Findings These are determined by the tricuspid valvular disturbance and the usually associated valvular lesions *Tricuspid insufficiency* is accompanied by a systolic murmur which is best heard at the lower end of the sternum or left fourth interspace When there is marked right ventricular hypertrophy with clockwise rotation of the heart in tricuspid insufficiency and mitral stenosis the tricuspid murmur may extend toward the apex and be mistaken for the systolic murmur of mitral insufficiency This distinction is important when mitral stenosis must be differentiated from mitral insufficiency in patients being considered for mitral commissurotomy The systolic murmur of tricuspid insufficiency is often increased in intensity with deep inspiration whereas most systolic murmurs are diminished with deep inspiration [11, 31] The murmur may vary in intensity and often disappears with clinical improvement

A short, low pitched diastolic murmur immediately after the second sound, may be present in some instances of tricuspid insufficiency [30, 31] presumably due to associated tricuspid stenosis Rarely, if the murmur is loud it may be accompanied by a thrill In two patients with clinical evidence of tricuspid as well as rheumatic and aortic valvular disease a short loud high pitched, early diastolic snapping sound was heard at or below and to the right of the xiphoid process This abnormal sound was interpreted as the opening snap of the stenotic tricuspid valve [23, 33]

In the rare cases of *pure tricuspid stenosis* there is a low pitched rumbling diastolic murmur at the left border of the sternum It may also be audible at the apex and be mistaken for the murmur of mitral stenosis But unlike the loud second pulmonic sound in mitral stenosis, the second pulmonic sound is not accentuated in isolated tricuspid stenosis A rumbling diastolic murmur, loudest parasternally in the fourth and fifth left intercostal spaces and increased in intensity by inspiration, is usually heard also in the cases of tricuspid stenosis associated with mitral stenosis

Occasionally an accentuated second pulmonic sound present in cases of mitral stenosis or pulmonary hypertension due to pulmonary disease, becomes soft with the development of tricuspid insufficiency

Chronic atrial fibrillation of long standing is the rule in patients with advanced tricuspid valvular stenosis or insufficiency

A *reversal of the paradoxical pulse* may be observed in cases of tricuspid insufficiency Instead of the slight reduction in pulse volume with deep inspiration felt normally or the pronounced reduction associated with constrictive pericarditis (pulsus paradoxus), there is an increased pulse amplitude with deep inspiration and a diminution with expiration For the pulmonary vascular capacity increases little during inspiration, while the venous return and therefore the cardiac output are significantly augmented

Roentgen Ray Examination of the Heart

Right atrial enlargement is the most consistent distinctive finding [41] The enlarged right atrium produces a widening of the transverse diameter of the heart The right lower cardiac contour is displaced to the right In the right oblique position the enlarged right atrium encroaches on the most caudad portion of the right retrocardiac space Even though mitral stenosis is present, the enlarged right atrium may displace the barium-containing esophagus to the left The combination of left atrial enlargement due to mitral stenosis and of right atrial enlargement due to tricuspid stenosis may produce double atrial concentric contours on the right side of the cardiac silhouette In isolated tricuspid stenosis the huge right atrium forms a horizontal shelf like projection from the upper anterior cardiac contour in the left anterior oblique view There is no enlargement of the pulmonary artery or right ventricle and no pulmonary congestion

In cases of pronounced tricuspid insufficiency, with or without stenosis the right

ventricle as well as the right atrium is enlarged and the heart has a globular triangular or transverse configuration The size and shape of the left contours are determined by associated mitral and aortic disease

The vascular shadow of the superior vena cava is widened and pulsates in systole or presystole The right innominate vein may also appear prominent and may pulsate Occasionally also there is widening and pulsation of the left innominate vein below the medial end of the left clavicle The diaphragm may be elevated in systole by the pulsating liver when normally it is depressed

Angiocardiography

Angiocardiography may be helpful in demonstrating right atrial enlargement and in distinguishing it from enlargement of the left atrium A jet sign i e a filling defect in the opacified right atrium produced by the regurgitant stream has been noted in some cases[7] In tricuspid stenosis angiocardiography discloses a persistent sharp opacification of the right atrium in contrast with delayed and poor opacification of the right ventricle

The Electrocardiogram

The electrocardiogram is usually characterized by right axis deviation by inversion of the T_3 and often also of T_2 and frequently by the pattern of right ventricular hypertrophy in precordial leads (p 115) Particularly in tricuspid stenosis there may be wide notched and high voltage P waves when there is sinus rhythm A diphasic P wave in right precordial leads has been described by Ellis and Brown[10] as distinctive of tricuspid disease but it may occur with mitral stenosis alone (p 120) A delayed onset of the intrinsicoid deflection in V_1 and V_2 of more than 0 04 second has been observed in the majority of cases of tricuspid disease and frequently there is an rsR con figuration in V_1 denoting incomplete right bundle branch block A QRS complex in V_1 of small amplitude (less than 7 mm) with a delayed onset of the intrinsicoid deflection was the most consistent electrocardiographic feature distinguishing cases of mitral disease and tricuspid insufficiency from those without tricuspid insufficiency in the series of Sepulveda and Lukas[11] In cases of pure tricuspid stenosis without significant mitral stenosis a tall right atrial P wave is present without the above-mentioned changes of right ventricular hypertrophy[11] Atrial fibrillation occurs in most cases Tricuspid stenosis with nodal tachycardia and atrioventricular dissociation has been reported[3]

DIAGNOSIS

Tricuspid insufficiency should be suggested by the presence of a large pulsating liver and pulsating cervical veins The diagnosis is simpler if in addition atrial fibrillation edema ascites cyanosis and evidence of valvular heart disease or cor pulmonale are present A characteristic bluish yellow facies due to combined cyanosis and mild icterus in a patient with mitral stenosis should suggest the association of tricuspid disease Evidence of pronounced right heart failure with relatively little orthopnea should also suggest this diagnosis Prolonged venous congestion with hepatomegaly and recurrent ascites out of proportion to edema in a patient with mitral stenosis who has had seemingly adequate treatment usually denotes organic tricuspid disease

Confirmation of the diagnosis may be provided by the following (1) Right atrial pressure curves showing a sustained peak plateau or dome throughout systole in cases of tricuspid insufficiency (p 712) (2) graphic demonstration of a systolic liver pulse and a positive jugular venous pulse in cases of tricuspid insufficiency or of an atrial or double liver pulse and giant atrial jugular venous pulse in tricuspid stenosis (3) prominent enlargement of the right atrium in addition to changes due to associated cardiovalvular disease

Differentiation of organic from functional tricuspid insufficiency is difficult[8] but the latter may occasionally disappear with active treatment of the congestive heart failure

A definite diagnosis of tricuspid stenosis may assume practical importance because of the *possible need for its surgical correction* Tricuspid stenosis is indicated by pulsating cervical veins with giant a waves a large pulsating liver a low pitched rumbling diastolic murmur over the tricuspid and mitral regions a normal second pulmonic sound in cases of pure tricuspid stenosis without mitral stenosis and roentgenologic and electrocardiographic evidence of right atrial enlargement A definite diagnosis requires cardiac catheterization with recording of pressure curves from the right atria and ventricle The characteristic finding is a large gradient between the atrium and ventricle throughout ventricular diastole

COURSE AND PROGNOSIS

Patients with organic tricuspid valvular disease are often ambulant and experience relatively long periods of comfort even after venous engorgement hepatic enlargement and ascites appear

The comfort which is due to the absence of orthopnea and paroxysmal dyspnea, is only relative because activity is greatly limited and the patient must lead a life of semi invalidism or invalidism The manifestations of heart failure persist substantially longer in cases of tricuspid disease than in those of isolated mitral stenosis or of mitral and aortic disease On the other hand, the general outlook for organic tricuspid disease is less favorable than for other valvular disease in that heart failure and death occur at a much earlier age Organic tricuspid stenosis and insufficiency are almost always combined with mitral and aortic valvular disease and indicate as a rule, more severe and more extensive rheumatic inflammation than in cases of mitral and aortic disease alone This may account for the poorer prognosis in the former Death in tricuspid valvular disease eventually results from progressive right heart failure pulmonary embolism and infarction or bronchopulmonary infection

The outlook in cases of functional tricuspid insufficiency depends on the underlying disease responsible for the right heart failure Most often functional tricuspid insufficiency denotes the end stage of chronic valvular or pulmonary disease and is therefore of ominous significance But temporary improvement and disappearance of the valvular insufficiency occur frequently with adequate therapy

TREATMENT

The treatment is that of the underlying disease and of advanced right-sided heart failure (Chapter 11) Bed rest, extreme restriction of sodium intake digitalization and the administration of mercurial diuretics are the cardinal therapeutic measures With adequate diuresis, abdominal paracenteses to remove ascitic fluid may not be required Sometimes, however, this procedure must be repeated many times over a period of years in order to afford symptomatic relief Thoracentesis affords relief when a large hydrothorax is responsible for dyspnea

Surgical Treatment

Surgical treatment must be considered in cases of organic tricuspid stenosis[8, 19, 21] Since mitral stenosis is present in almost all cases, the problem of surgical correction arises in connection with the performance of a mitral commissurotomy, provided there is no

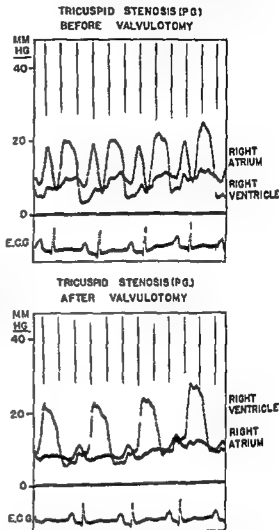

Fig 128 Simultaneous pressure pulses in right atrium and right ventricle obtained at operation in a case of isolated tricuspid stenosis before and after tricuspid valvulotomy Note tall atrial waves with pressure of 18 mm Hg during atrial systole After valvulotomy right atrial pressure markedly reduced and atrioventricular diastolic gradient almost eliminated (Private case operated on by Dr H A Nabatoff To be published by Gordon A J et al Am J Med)

other significant valvular deformity besides that of the mitral and tricuspid Tricuspid stenosis, without significant aortic or pulmonic valvular disease was found in 6 per cent of 66 cases of mitral stenosis[6] There is a possibility that an unsatisfactory result

from mitral commissurotomy may be due to failure to recognize and correct a concomitant tricuspid stenosis O Neill et al[5] performed a tricuspid commissurotomy four years after a mitral commissurotomy because of persistent signs of right sided heart failure and the clinical and hemodynamic features of pure tricuspid stenosis Following enlargement of the narrowed tricuspid valve edema and ascites disappeared As a rule correction of both the mitral and tricuspid stenosis is performed in a one-stage procedure both atria being exposed by an anterior thoracotomy and interatrial dissection Mitral commissurotomy is performed first to avoid excessive pulmonary congestion which might occur from increased right ventricular output if the tricuspid stenosis were relieved first In a recent case of isolated tricuspid stenosis operated on at Mount Sinai Hospital the right atrium appeared to form most of the cardiac mass Following tricuspid commissurotomy the right atrium promptly contracted in size the giant cervical venous pulsations disappeared and the right atrioventricular gradient was abolished (Fig 128) (See also p 674)

PULMONARY INSUFFICIENCY

ETIOLOGY AND PATHOLOGY

Organic insufficiency of the pulmonary valve is very rare[60] A relative or functional insufficiency is common but statistics as to its occurrence are extremely varied and unreliable[4] It is being observed with increasing frequency in patients with severe mitral stenosis and occasionally in cases of cor pulmonale Pulmonary insufficiency may be classified as *acquired* and *congenital* and the acquired lesions may be further subdivided into the *organic* and *functional* varieties The following causes of pulmonic insufficiency have been noted

I Acquired pulmonary insufficiency
- A Organic
  - 1 Bacterial endocarditis
  - 2 Rheumatic fever
  - 3 Pulmonary arteritis and valvulitis secondary to aortic aneurysm
  - 4 Syphilis of the pulmonary artery
- B Functional (pulmonary hypertension)
  - 1 Mitral stenosis
  - 2 Bronchopulmonary disease
  - 3 Primary pulmonary vascular occlusion (primary pulmonary hypertension)

II Congenital pulmonary insufficiency
- A Deficient or supernumerary pulmonic cusps
- B Congenital dilatation of the pulmonary artery

Acquired Organic Pulmonary Insufficiency

The commonest cause is a bacterial endocarditis involving the pulmonic valve Of 119 cases of pulmonic insufficiency taken from the literature and the autopsy records of Guy s Hospital Pitt[24] found that 60 were due to a bacterial endocarditis Insufficiency results from improper closure of the valves because of the attached vegetations or because of destruction or perforation of a cusp Multiple bacterial pulmonary emboli may arise from the vegetations Thayer[47] had noted the relative frequency with which the gonococcus attacks this valve and a similar tendency has been noted for the pneumococcus Bacterial endocarditis of the pulmonic valve is usually an isolated valvular lesion Of 26 cases Langeron and Gardère[4] found that the bacterial vegetations were confined to the pulmonic valve in 21 and associated with bacterial endocarditis of other valves in 5 I have not observed such localization in recent years

McGuire and McNamara[29] recently reported 3 cases of rheumatic pulmonary insufficiency one of them with slight pulmonic stenosis In all three cases the other valves were simultaneously affected I have occasionally seen gross rheumatic vegetations on the pulmonic cusps as well as mild microscopic inflammatory lesions of the valve and valve ring But except for slight thickening of these cusps I have never seen rheumatic valvular deformity of sufficient degree to interfere with their function

Occasionally a pulmonic insufficiency arises from pressure of an aortic aneurysm on the pulmonary artery at or just above the level of the pulmonary cusps especially the left cusp Inflammation of the pulmonary artery and cusp results from the pressure of contact or from perforation of the aneurysm The cusp subsequently becomes adherent to the arterial wall so that it can no longer aid in closing the pulmonic orifice

Syphilis of the pulmonary artery has been recorded in 66 cases, but according to Brenner[5] the diagnosis is established in only 15. This may produce pulmonic insufficiency by dilatation or aneurysm of the main vessel with concomitant dilatation of the pulmonic ring or by a widening of the commissure similar to that in luetic aortic insufficiency.

Many of the cases of pulmonic stenosis are accompanied by auscultatory or anatomic evidences of insufficiency.

Functional Pulmonic Insufficiency

The pulmonic valve becomes relatively insufficient when the pulmonic ring becomes dilated. Functional or relative pulmonic insufficiency has been known also as the insufficiency of high pressure in the pulmonary artery. The pulmonary hypertension is caused presumably by resistance to blood flow due to mitral valvular obstruction (p. 649), long standing disease of the lungs, or narrowing of the small pulmonary arteries and arterioles.

Congenital Pulmonary Insufficiency

Pulmonary insufficiency may be caused by two types of congenital defect, namely, *dilatation of the pulmonary artery* and *abnormality in the number of pulmonic cusps*. In 1000 cases of congenital heart disease studied by Abbott,[1] there were 8 primary cases of pulmonary insufficiency, 2 of which were due to valvular abnormalities and 6 to congenital dilatation of the pulmonary artery. There were 13 additional cases in which the pulmonic insufficiency was associated with other congenital defects of the heart. Kissin[1] noted that there were reports of 151 hearts with four pulmonic cusps but in only 3 of these cases was there sufficient functional disturbance to produce clinical signs. Insufficiency occurs despite the supernumerary cusp because the pulmonary artery and ring are greatly dilated.

Pulmonic insufficiency has been associated with isolated tricuspid pulmonary valve. Catheterization revealed a characteristic pulmonary artery pressure curve like the arterial curve in aortic insufficiency.[11] A decrescendo pulmonic diastolic murmur, prominent pulmonary arteries and hilar dance on fluoroscopy, and electrocardiographic evidence of right ventricular hypertrophy and prominent P waves were noted.

Dilatation of the pulmonary artery may occur as a primary solitary defect or in association with other major defects. Oppenheimer[33] reported 8 cases of idiopathic dilatation of the pulmonary artery and its branches, in 4 of which there was evidence of pulmonary insufficiency.

The Heart in Pulmonary Insufficiency

Two of the features common to all the varieties of pulmonic insufficiency are (1) hypertrophy of the right ventricle and (2) regurgitation of blood from the pulmonary artery into the right ventricle, with the consequent production of a diastolic murmur. In many cases there is also (3) a considerable dilatation of the pulmonary artery, the normal circumference of 6 to 8.5 cm. being exceeded in varying degree. Dilatation and hypertrophy of the right ventricle may develop as a consequence of the regurgitation of blood and may represent a compensatory phenomenon similar to that of the enlarged left ventricle in aortic insufficiency. Right ventricular hypertrophy with relatively little dilatation may, however, have preceded the onset of pulmonary insufficiency due to the increased resistance of pulmonary hypertension in chronic pulmonary disease.

CLINICAL FEATURES

Symptomatology

The symptomatology[4] is usually overshadowed by the primary disease of which the pulmonic insufficiency is a mere incident. Thus dyspnea on exertion, cough, mild or intense cyanosis, hemoptysis, somnolence, peripheral edema and ascites may also be attributed to the underlying pulmonary, valvular or congenital heart disease independent of the pulmonary insufficiency.

The cases with congenital dilatation of the pulmonary artery may be asymptomatic and discovered only on routine fluoroscopy. Dyspnea is a frequent symptom. Cyanosis is usually present and may be intense. Polycythemia of moderate degree is observed in the cyanotic patients. Cough also is relatively frequent but not severe.

Examination of the Heart

Physical examination of the heart reveals the abnormalities due to the associated cardiac disease as well as those of pulmonary insufficiency. The dilated pulmonary artery causes dullness in the second and third left interspace and occasionally a pulsation in this area. The diagnostic sign is a soft or loud blowing, or harsh diastolic murmur in the second or third left interspace. In cases of mi

tral stenosis this has been termed the Graham Steell[14] murmur (p 660) There is often an associated systolic murmur attributed to eddies in the dilated pulmonary artery The second pulmonic sound may be accentuated, owing to the increased pressure in the pulmonary artery and closer approximation of the dilated artery to the chest wall

Roentgen ray examination discloses evidence of right ventricular hypertrophy (p 105) and of the dilatation of the pulmonary artery [23] The hilar shadows may be prominent and even so large as to be mistaken for mediastinal tumors e g in the cases of congenital or idiopathic dilatation of the pulmonary artery [11] Often there is a distinct pulsation of the pulmonary artery

The electrocardiogram is that observed with right ventricular hypertrophy (p 115)

DIAGNOSIS

The diagnosis depends on the discovery of a pulmonic diastolic murmur and right ventricular hypertrophy and on the absence of left ventricular enlargement or the peripheral circulatory phenomena of aortic insufficiency The diagnosis may be suggested on roentgenologic examination by the finding of a large right ventricle and large pulsating pulmonary arteries

PROGNOSIS AND TREATMENT

These are determined by the underlying or associated disease

PULMONIC STENOSIS

Pulmonic stenosis is almost exclusively a congenital lesion and is discussed in the chapter on congenital heart disease (p 749) Acquired pulmonic stenosis is extremely rare especially as a clinically significant lesion There may be a true stenosis due to inflammation and adhesion of the valves or a functional stenosis incidental to other diseases

Acquired organic stenosis of the pulmonary valve has been attributed to rheumatic valvulitis bacterial endocarditis and to trauma All are very rare Rheumatic inflammation may be engrafted on a congenital bicuspid pulmonic valve [40] In the case of McGuire and McNamara,[29] rheumatic pulmonic stenosis and insufficiency were associated with stenosis of the other three valves The stenotic adherent cusps form a single protruding diaphragm or dome pierced at its center by a small opening There have been a number of reports of right sided valvular lesions including pulmonic stenosis and tricuspid insufficiency in cases of malignant carcinoid of the small intestine with hepatic metastases presumably due to abnormal tryptophan metabolism and excessive serotonin production (p 1042)

Functional pulmonic stenosis results from obstruction of the pulmonary orifice by massive bacterial valvular vegetations and by large emboli extending from the right ventricle into the pulmonary artery I have seen both of these conditions characterized by the sudden development of a loud harsh systolic murmur and a systolic thrill over the pulmonic area Litten [5] has reported pulmonic steno is due to the plugging of the pulmonary artery by echinococcus cysts Pulmonic stenosis may also be caused by the pressure of tumors mediastinal glands or of an aortic aneurysm on the pulmonary artery at or near the level of the valves

There is hypertrophy and dilatation of the right ventricle when the right ventricle fails the right atrium may also become dilated and hypertrophied The left chambers are normal unless there is associated disease of the mitral and aortic valve

A prominent feature is the frequency of pulmonary tuberculosis The pulmonary artery is usually dilated beyond the stenotic site possibly because of atrophy of its wall

CLINICAL FEATURES

The clinical features of congenital pulmonic stenosis are discussed in the chapter on congenital heart disease (p 750) The clinical features of the rare instances of acquired pulmonic stenosis are usually determined by the underlying bacterial endocarditis neoplasm embolism or other causative or associated disease

The *diagnostic signs* due to the pulmonic stenosis per se are the loud rough systolic murmur in the second or third left interspace the palpable thrill in the same area the weak or absent second pulmonic sound the roentgenologic and electrocardiographic evidence of an enlarged right ventricle (coeur en sabot) and prominent pulmonary artery salient

COMBINED VALVULAR DISEASE

For didactic reasons the individual valvular lesions have been described separately. As a rule multiple valves are the site of significant lesions due to rheumatic fever. Mitral stenosis and aortic insufficiency or stenosis occur most commonly. Occasionally organic tricuspid stenosis and insufficiency coexist while significant disease of all four valves is rare. Functional tricuspid insufficiency is not uncommon in the late stages of combined mitral and aortic disease.

The clinical picture including the physical and roentgenologic signs is usually determined by the relative severity of the individual lesions and by their order of development. *As a rule each lesion produces its own* characteristic effects on individual cardiac chambers and its own physical and roentgenologic signs which permit recognition of the multiple lesions. Therefore it is unnecessary to devote separate discussions to the various combinations of valvular lesions.

In some instances one valvular lesion may relieve the strain, or partially neutralize the effects of another. Accordingly, various modifications in prognosis have been attributed to the different combinations of valvular disease. However, such attempted correlations are untenable because other factors, such as rheumatic activity, severity and extent of myocardial damage and the development and severity of complicating coronary atherosclerosis, are extremely important in *determining the course and prognosis* of rheumatic cardiovalvular disease. For *surgical correction* see page 674

PART VI

ETIOLOGIC FORMS OF HEART DISEASE

Chapter 30

CONGENITAL HEART DISEASE

Despite the epochal contributions of Peacock[311] Rokitansky[335] and Vierordt[405] the subject of congenital heart disease long remained an academic study This was due both to the rarity with which an accurate diagnosis of the lesion could be made and to the inability to remedy the lesion In recent years the scholarly clinical pathologic contributions of Maude Abbott[1] and of Laubry and Pezzi[347] have lent a fruitful stimulus which has resulted in the development of great accuracy in the diagnosis of the exact congenital cardiac lesions or at least of the major defect present in a given case The utilization of contrast media to portray roentgenographically the individual portions of the heart and great vessels (p 11) has enhanced our diagnostic accuracy in this field The employment of intracardiac catheterization (p 74) to determine the oxygen content and pressure within various cardiac chambers and to determine cardiac output and pulmonary blood flow has provided additional diagnostic data The subject of congenital heart disease is now squarely within the domain of the clinical cardiologist great surprises at the pathologist s table should become uncommon At the same time amazing progress has been achieved in the surgical treatment of certain congenital cardiovascular anomalies and these advances enhance the importance of diagnostic accuracy

INCIDENCE

The incidence of congenital cardiac abnormalities is still uncertain and varies in the different age groups According to most reports major congenital cardiac anomalies are found in 0 3 per cent of total births[266] Among adults it is improbable that congenital heart disease forms more than a fraction of 1 per cent of the cases of clinical heart disease On the other hand among school children with cardiac ailments the incidence of congenital heart disease was reported to be 11 per cent and among children above the age of two 14 per cent[44] Below the age of five the vast majority of cases of heart disease are of congenital origin since rheumatic fever is very uncommon in children before this age For this reason the diagnostic importance of determining whether a cardiac lesion was present in infancy or early childhood is obvious

ETIOLOGY

Basic Cause

Congenital anomalies of the heart and great vessels are due to *arrested or defective prenatal development* But it is uncertain whether intrinsic factors in the germ plasm or extrinsic factors in the embryo s environment are of major importance[14] Disease of the fetal envelopes amniotic adhesions or other mechanical disturbances in the environment of the embryo may interfere with that perfection and symmetry of growth which is essential for the normal development of the heart and great vessels That this is the chief causative factor is indicated by the frequent association of other congenital anomalies elsewhere in the body of subjects with cardiac defects and by the occurrence of cardiac anomalies in siblings[6] In some cases the origin of defective development of the heart may be situated in the germ plasm rather than in the environment of the embryo This is indicated by evidence of hereditary factors but *in the great* majority of cases the role of heredity is insignificant

Much of the evidence that disturbances of development (whether due to fetal environment or defective germ plasm) account for congenital cardiac disease is based on a correlation of the lesions observed in human hearts with a phylogenetic study of the structures in the hearts of lower forms including the reptiles amphibians and fishes Notable contri

butions have been made by Rokitansky[335] with respect to septal lesions by Keith[23] on the abnormal development of the bulbus cordis and by Spitzer[375] on the transposition of the great vessels These will be discussed under general embryology and embryology of the individual lesions

Associated Anomalies

The likelihood that congenital cardiac anomalies *are due to disturbances in the* embryo s environment is supported by the frequency of anomalies in other parts of the body in the same subjects, for it is to be anticipated that defects in the localized milieu surrounding the embryo would disturb not only the development of the heart but also that of other structures Vierordt[408] observed *associated anomalies in 80 of 700 cases* (11 per cent) of congenital heart disease Abbott[1] in 188 of 1000 cases (18 8 per cent) Keith[3] found cardiac anomalies in 14 of 23 malformed fetuses

While some of the associated anomalies are of a hereditary nature (see below) others are not and therefore point to the presence of abnormalities *in the fetal environment* Although, on the one hand the occurrence of congenital cardiac disease in identical twins has been used to support a hereditary etiology, in other instances the occurrence of such congenital cardiac malformations in only one of identical twins has refuted the concept of hereditary etiology [18] Mongolian idiocy occurs rather frequently Morse[90] found 6 Mongolian idiots in 100 cases of congenital heart disease and Irvine Jones[18] 7 in her 100 cases Conversely, congenital heart disease was found in 28 (44 per cent) of a series of 63 autopsy cases of Mongolian idiots dying in the first five years of life [149] The cardiac defect most often associated with Mongolian idiocy is either a complete absence of the interatrial septum, a persistent common atrioventricular canal or a persistent ostium primum (p 735 defect in the lower portion of the atrial septum) But in the series studied by Evans,[149] ventricular and atrial septal defects occurred with equal frequency and patent ductus arteriosus and pulmonic stenosis were also associated with mongolism There are often accessory spleens or the spleen is absent

Gargoylism This is associated with some degree of cardiac abnormality in 85 per cent of cases Cardiac enlargement, especially of the right chambers, deformity of the valves subintimal fibrosis *and narrowing of the coronary* arteries, myocardial fibrosis and congestive heart failure have been reported[143] (p 629)

Arachnodactyly or Marfan s Syndrome[79, 230] This hereditary disorder is characterized by congenital subluxation of the lenses, pectus excavatum and pigeon breast dolichocephaly *and highly arched palate long* ' pidery fingers and hyperextensible joints, and a variety of congenital cardiovascular lesions notably (1) medionecrosis of the ascending aorta which may be complicated by *dissecting aneurysm, aneurysm of the sinuses of Valsalva and ascending aorta* and *aortic insufficiency* due to aortic dissection or dilatation, *(2) interatrial septal defect* (patent foramen ovale) and occasionally coarctation of the aorta, subaortic stenosis, pulmonary arterial disturbances, fibromyxomatous endocardial lesions, and others Cardiac murmurs may be due to chest deformities rather than to organic heart disease

Heredity

The possibility that *defects* of the germ plasm account for at least some cases of congenital heart disease is indicated by the following evidences of the role of heredity (1) There are associated anomalies which are generally recognized as being of a hereditary nature These include polydactylism, clubbed foot fetal lobulation of the kidneys and congenital dislocation of the hip (2) There is occasionally an ancestral history of congenital heart disease (3) Cardiac defects have been reported in identical twins (4) There are records of families with multiple instances of similar or identical congenital cardiac anomalies in more than one generation

Virus and Other Infections

The occurrence of rubella (German measles) in the first two or three months of pregnancy has been associated with a significant incidence of congenital cataracts and cardiac anomalies in the offspring [189] This may be related to the fact that the entire development of the heart and great vessels is completed in the first two months of embryonic life At the present time it is recommended that pregnancy be interrupted with the occurrence of rubella in the first trimester of pregnancy

The above observations suggest the possibility that other maternal and fetal infections

may be responsible for congenital heart disease Fetal endomyocarditis and syphilitic myocarditis have been reported as the cause in occasional cases Endometrial bleeding during the first trimester may be a factor in some cases

Nutrition Vitamin Deficiencies Altitude

Animal experiments suggest that dietary deficiencies in the mother may result in congenital malformations [11] But there is no significant evidence of such a relationship between vitamin or other nutritional deficiencies and the occurrence of congenital heart disease in man The determination of certain cardiovascular anomalies has been related to gestation or childbirth at high altitudes [7]

Sex

If all forms of congenital cardiac lesions are considered the incidence of congenital heart disease is almost equally divided between the sexes However certain individual lesions occur with predilection for one sex or the other Thus coarctation of the aorta (3 1) anomalies of the semilunar cusps (5 1) defects of the aortic septum and transposition of the great vessels (2 1 or 3 1) are more frequent among males while patency of the ductus arteriosus (Botalli) occurs more commonly in females (2 or 3 1)

GENERAL EMBRYOLOGY AND PATHOLOGY

In its prenatal development the human heart passes through a series of stages whereby a simple cardiac tube is transformed into four distinct chambers separated by septa and valves and leading into the aorta and pulmonary artery An important effect of this development is the separation of the systemic circulation from that in the lungs The original simple tube is fixed at two points the arterial or cephalic end and the venous or caudal end As the heart grows this tube elongates and since its ends are fixed it bulges and twists in a spiral fashion so as to assume an S shape This so-called torsion is normally clockwise at the arterial and counterclockwise at the venous end By the fourth week (3 mm embryo) the heart is differentiated into a successive series of four chambers which from the venous to the arterial end are (1) the sinus venosus which receives the vitello-umbilical veins (later to become the inferior vena cava) and the ducts of Cuvier (later the superior vena cava and coronary sinus) (2) the atrium (3) the ventricle and (4) the bulbus cordis from which the primitive truncus arteriosus (later the aorta and pulmonary artery) arises

Most of the congenital cardiac disturbances arise between the fifth and eighth weeks of embryonic life During this time the atrium and ventricle are each divided by a septum into two chambers the atrioventricular canal is divided by a septum into left and right segments the atria are separated from the ventricles by valves and the primitive truncus arteriosus is divided into the aorta and pulmonary artery which lead respectively from the left and right ventricles Details concerning the embryologic basis of the various congenital cardiac lesions will be presented in the discussion of the individual anomalies

In most cases of congenital heart disease the lesions are not isolated two or more lesions being present in the same subject The frequency of combined lesions is due in many instances to simultaneous maldevelopment of two different structures in the heart which are in close anatomic juxtaposition Thus proper closure of the upper part of the ventricular septum requires normal development of the aorta and pulmonary artery and the septum between them Hence ventricular septal defects are frequently associated with dextraposition of the aorta and pulmonary stenosis or atresia In other cases a primary lesion produces changes in pressure in the chambers of the heart or great vessels so that fetal openings do not close as they normally should A patent foramen ovale or ductus arteriosus may result secondarily from atresia or stenosis of a valvular orifice or transposition of the great vessels and this patency may be a compensatory lesion to maintain a continuous circulation In other cases a combination of lesions represents simultaneous disturbance in multiple unrelated portions of the heart

GENERAL SYMPTOMATOLOGY

Certain congenital anomalies are of no clinical importance since they produce neither subjective symptoms physical signs nor other objective abnormalities These include bifid apex of the heart persistent left superior vena cava and most instances of patent foramen ovale and of anomalous septa and chordae Other anomalies produce neither symptoms nor signs but are the site of serious

complications e.g., a bicuspid aortic valve is often complicated by bacterial endocarditis In cases of pure dextrocardia with situs inversus there are no symptoms but physical signs and the roentgenoscopic and electrocardiographic examinations reveal a characteristic picture

In another group of lesions there are usually *cardiac murmurs* which may be typical in location and character and associated with palpable *thrills* There are often also *changes in the size and shape of the cardiac silhouette* There may also be *abnormalities in blood pressure* as in cases of coarctation of the aorta or patent ductus arteriosus The latter may be associated with altered circulatory dynamics similar to those in cases of free aortic insufficiency

Symptoms may appear early, as indicated by poor feeding subnormal gain in weight constipation difficulty in swallowing and stridor, syncopal attacks and recurrent respiratory infections Cyanosis may appear with crying and dyspnea with exercise or feeding

Dyspnea on exertion is a common symptom and often appears early in the course of the disease A striking form of dyspnea is that which appears in paroxysms and is usually associated with an intensification of cyanosis In many cases exertional dyspnea is secondary to pulmonary congestion associated with left sided heart failure Dyspnea with signs of pulmonary congestion due to heart failure in infancy is often misinterpreted as pneumonia Often however the dyspnea appears to be due to excessive arterial oxygen unsaturation especially following exercise with consequent anoxia of the carotid sinus and respiratory center *Squatting* especially after exercise is common in certain forms of congenital heart disease with cyanosis and characteristically with the tetralogy of Fallot

Cough complicates dyspnea when the latter is due to pulmonary congestion but both dyspnea and cough may be due to tracheal compression by a double aortic arch or aberrant vessel Congestion of the abdominal viscera with digestive disturbances, hepatic enlargement and ascites and peripheral edema, results from failure of the right side of the heart Excessive fatigability and weakness are relatively common

Cerebral symptoms including faintness dizziness headache are observed occasionally, and more rarely syncope, convulsions, delirium paralyses and coma, especially in patients with cyanosis [3] These symptoms are due partly to cerebral hypoxia (arterial hypoxemia) especially during exertion[213] and partly to the polycythemia with consequent circulatory stasis or complicating cerebral thromboses or hemorrhage Cerebral symptoms may be due to inadequate cerebral blood flow in cases of aortic or subaortic stenosis, to cerebral embolization in complicating bacterial endocarditis or endarteritis, to ruptured congenital aneurysms of the circle of Willis in coarctation of the aorta or to cerebral abscess in cases of septal defects and paradoxical embolism Adams-Stokes attacks may occur in cases of congenital heart block [96]

Cardiac pain was noted in 4 8 per cent of 180 cases of congenital heart disease notably aortic or subaortic stenosis and severe pulmonary stenosis [383] It was related to inadequate coronary perfusion during exercise

Vascular disturbances in the extremities including coldness, numbness and tingling or pain may appear in patients with or without cyanosis and polycythemia These symptoms as well as intermittent claudication are not uncommon in cases with the adult type of coarctation of the aorta Malnutrition and underdevelopment may result from deficient peripheral blood supply

Special symptoms may be identified with individual lesions Thus the pressure of a dilated pulmonary artery a persistent right aortic arch or of an anomalous vessel on the esophagus trachea or recurrent laryngeal nerve may cause dysphagia dyspnea or hoarseness respectively

Sudden death is most likely to occur in cases of idiopathic hypertrophy of the heart subaortic stenosis or Ebstein's disease Otherwise, death in congenital heart disease is due to congestive heart failure anoxia, cerebral complications, vascular thromboses, bacterial endocarditis or some intercurrent illness

The detailed cardiac signs and other features associated with congenital heart disease are best discussed below with the important individual cardiac anomalies

The symptoms often attributed to congenital heart disease are *cyanosis* and *clubbed fingers* But it is erroneous to believe that

these are characteristic of the majority of cases The diagnosis will usually be overlooked if it depends on the discovery of these manifestations since in most cases cyanosis is absent or occurs only as a late or terminal event Cyanosis of varying intensity was encountered in 351 of Abbott s[1] 1000 cases and in 124 others it appeared terminally Since cyanosis is almost always associated with the severe multiple cardiac anomalies which lead to death in infancy or very early childhood this symptom is much less common than indicated by the above figures if only cases above the age of three are considered

The cyanosis is most marked in the lips tips of fingers or toes nose ears conjunctivae and mucous membranes especially of the lips and tongue but it may be generalized In cases of interruption of the aortic isthmus cyanosis is limited to the lower extremities if atresia of the aortic isthmus is combined with transposition of the great vessels there is more intense cyanosis of the head and upper extremities than in the lower In patent ductus arteriosus with reversal of flow (i e flow is from pulmonary artery to aorta) cyanosis is more marked in the lower than in the upper extremities in the left than in the right hand and is especially visible on exercise A distinct cyanosis may be observed in the retina (cyanosis retinae) The optic disc is usually congested The veins are congested purplish red and tortuous Retinal hemorrhages suffusion of the conjunctiva and rarely exophthalmos may be associated Clubbing of the fingers and toes was noted in 132 of Abbott s[1] 1000 cases It usually appears later than cyanosis in any given case time being an important factor in its development

A secondary *polycythemia* occurs frequently in the cases with cyanosis This appears to compensate for the oxygen unsaturation of the blood The red blood count in such cases usually varies between 6 and 7 million per cubic millimeter More marked polycythemia is observed in association with intense persistent cyanosis Occasionally there are 10 to 12 million red blood cells per cubic millimeter The hemoglobin is correspondingly elevated to 110 to 130 per cent in the patient with moderate cyanosis and occasionally reaches 150 to 200 per cent with extreme polycythemia An *increase in blood volume* and *blood viscosity* is associated with polycythemia The *hematocrit* usually exceeds 55 per cent

PATHOGENESIS OF CYANOSIS IN CONGENITAL HEART DISEASE

Cyanosis appears in cases of congenital heart disease when there is more than 5 gm of reduced hemoglobin per 100 cc of blood For pathogenesis see page 204

In the absence of cardiac failure many cases of congenital heart disease never present cyanosis for there is no venous-arterial shunt This group includes the cases of adult coarctation of the aorta pure mitral aortic or subaortic stenosis uncomplicated dextrocardia uncomplicated bicuspid or quadricuspid semilunar valves persistent right aortic arch and many anomalies of the coronary or pulmonary arteries and of the pericardium

In cases with an abnormal communication between the left and right sides of the heart or great vessels cyanosis is absent if the flow is from the left to the right or from the aorta to the pulmonary artery Thus patients with a patent ductus arteriosus (Botalli) a patent foramen ovale or an uncomplicated atrial ventricular or aortic septal defect are usually free from cyanosis because the pressure in the arterial circuit (aorta and left side of the heart) is normally higher than that in the venous circuit and therefore the venous blood does not contaminate the arterial However cyanosis may appear sporadically or terminally (cyanose tardive) in these cases if the pressure on the venous side is elevated sufficiently to reverse the flow through the abnormal communication and thus produce a venous arterial shunt This may result from exercise and in infants from crying or sucking due to an increased venous return to and an elevation of pressure in the right side of the heart Certain pathologic conditions especially pneumonia and other bronchopulmonary disease stenosing or obliterating pulmonary vascular lesions and cardiac failure may also cause cyanosis by elevating the pressure in the right chambers of the heart thus causing a reversal of flow through the arteriovenous shunt

In a third group of cases cyanosis usually is present throughout most of the course of the disease In these cases the flow of blood through the abnormal shunt is constantly from the venous to the arterial side because some associated lesion has caused the pressure on the right or venous side to exceed that on the left side of the heart and aorta In some congenital cardiac lesions such as complete

transposition of the great vessels, extreme dextroposition of the aorta or drainage of the pulmonary veins into the right atrium, there is no actual shunt and there is an adequate pulmonary blood flow, but venous blood is being pumped into the systemic circulation and it is difficult or impossible to direct oxygenated blood to the tissues. Even when the shunt is from the venous to the arterial side, cyanosis develops only if a considerable amount of venous blood is so shunted. This requires either an abnormal communication of large size or a considerably higher pressure on the venous than on the arterial side of the communication.

According to the calculations of Lundsgaard and Van Slyke[265] cyanosis appears in patients with normal hemoglobin if the venous-arterial shunt exceeds 38 per cent of the cardiac output of the heart. Shunts of 40 to 75 per cent of the blood flow in which venous blood bypasses the lungs or mixes freely with arterial blood are common in the tetralogy of Fallot and other congenital lesions, such as tricuspid stenosis, bilocular and trilocular hearts, persistent truncus arteriosus, transposition of the great vessels and combined lesions.

The volume of the shunt can be calculated as the difference between the systemic blood flow and the pulmonary blood flow. Normally, the cardiac output, the systemic blood flow and the pulmonary blood flow are the same and can be calculated as follows:

$$\text{cardiac output (liters per min.)} = \frac{O_2 \text{ consumption (cc./min.)}}{\text{arterial } O_2 \text{ (cc./liter)} - O_2 \text{ of mixed venous blood (cc./liter)}}$$

When there is a right-to-left shunt, the shunt equals systemic blood flow minus pulmonary blood flow.

$$\text{systemic flow} = \frac{O_2 \text{ consumption}}{\text{arterial } O_2 \text{ content} - \text{rt. atrial } O_2 \text{ content}}$$

$$\text{pulmonary flow} = \frac{O_2 \text{ consumption}}{O_2 \text{ content pulmonary vein} - O_2 \text{ content pulm. artery}}$$

O content pulmonary vein is assumed to be 95 per cent of O_2 capacity of systemic arterial blood.

Polycythemia is not usually a factor in the original development of the cyanosis because the latter appears before the former. However, the subsequent development of polycythemia may intensify the degree of cyanosis both because of the increase in the total amount of hemoglobin (and therefore of the concentration of reduced hemoglobin) and because polycythemia leads to engorgement of the subpapillary venous plexus (p. 205) and to peripheral circulatory stasis with increased deoxygenation in the capillaries (p. 205).

The cases of congenital heart disease in which cyanosis appears at birth or shortly thereafter have given rise to the terms "blue baby" and morbus caeruleus. Obviously not all cases of congenital heart disease are blue babies or examples of morbus caeruleus. Furthermore, cyanosis at birth may be due to pulmonary atelectasis or intracranial hemorrhage. In some cases of congenital heart disease cyanosis is absent at birth but appears after weeks or months because a compensating open ductus arteriosus becomes obliterated.

PATHOGENESIS OF CLUBBING IN CONGENITAL HEART DISEASE

Clubbing of the fingers and toes usually occurs only in those cases of congenital heart disease with persistent and longstanding cyanosis. The soft parts of the fingers and toes, especially of the nailbed and sometimes of the nose, increase in size until they present a drumstick or bulbous appearance. The pathogenesis of clubbing whether in cases of congenital heart disease or other conditions is still unclear. In cases of congenital heart disease, clubbing has been attributed to the oxygen unsaturation of the blood with consequent capillary stasis and accumulation of noxious products in the most peripheral parts of the body. On the other hand, clubbing has been viewed as a growth phenomenon which suggests an increased blood flow to the parts affected.[283, 284] The evidence of growth is seen not only in the increased size of the soft part of the fingers and toes but also in the convex forward curvature of the nails, this shape resulting from excessive growth within a confined space.

Direct microscopic study of the capillaries of the nailbed by Redisch and Roesler[illegible] has revealed a sharp increase in their number, marked dilatation of the venous and of the

capillary curve the presence of many fine newly formed capillaries and great dilatation of the subpapillary venous plexus It is likely that these changes in the peripheral venules and capillaries associated with slowing of the circulation as well as the increase in hemoglobin and erythrocyte content of the blood serve to compensate for its oxygen unsaturation But at the same time an excessive supply of other nutriments may be provided which incidentally promotes the proliferation of the soft tissues and thus produces clubbing

COMPLICATIONS

Many of the clinical phenomena in cases of congenital heart disease are not due to the lesions themselves but to the complications to which these lesions predispose These complications are important especially in those subjects who pass adolescence or reach adult life and are apparently asymptomatic or well compensated The chief complications are (1) congestive heart failure (2) subacute (and acute) bacterial endocarditis (3) pulmonary tuberculosis (4) paradoxical embolism (5) cerebral abscess and (6) rupture of the aorta or of a cerebral vessel

Cardiac failure requires no special discussion here

Bacterial endocarditis (p 864)

Pulmonary tuberculosis is more than an occasional complication in cases of congenital heart disease particularly with pulmonary stenosis According to Abbott[1] the incidence of tuberculosis is particularly high in the latter disease (9 of 25 cases or 36 per cent) when the ventricular septum is closed The frequent association of pulmonary tuberculosis with pulmonic stenosis ■ related supposedly to the deficient blood supply to the lungs and ■ contrasted with the relative rarity of tuberculosis in the chronically congested lungs of patients with mitral stenosis (p 665) The association of tuberculosis with pulmonic stenosis has of course become uncommon in areas where the incidence of tuberculosis itself has diminished

Paradoxical embolism (crossed embolism) refers to the passage of ■ portion of thrombus from systemic veins usually in the lower extremities or right side of the heart to the systemic (arterial) circulation In the normal circulation such an embolus would tend to lodge in the pulmonary artery or its branches since it could not traverse the pulmonary capillaries which form the only route to the systemic circulation However in the presence of a cardiac anomaly permitting direct communication between the venous and arterial circulations and notably in the presence of an open foramen ovale a venous thrombus by passing from the right to the left atrium occasionally embolizes a systemic arterial vessel That this is the mechanism of paradoxical embolism is occasionally demonstrable at necropsy in certain cases in which the thrombus is found straddling both sides of an open foramen ovale[102]

In the majority of cases a cerebral artery usually the middle cerebral or one of its branches is the site of embolization But frequently multiple emboli appear the kidney as well as the brain being commonly affected Since the origin of paradoxical emboli is usually in the systemic veins there are often simultaneous uncrossed emboli to the lungs In all six cases of paradoxical emboli reported by Ingham[217] there were also pulmonary emboli Usually the pulmonary embolism precedes the paradoxical embolism In fact the rise of pressure in the right cardiac chambers consequent to pulmonary embolism ■ believed to facilitate the venous to arterial shunt of thrombotic material through a patent foramen ovale or through some other atrial or ventricular septal defect A diagnosis of paradoxical embolism is suggested by occlusion of a systemic artery after pulmonary embolism provided there is no other obvious cause of the systemic embolization such as bacterial endocarditis mitral stenosis with atrial thrombi or myocardial infarction with mural ventricular thrombi

The occurrence of *brain abscess* in cases of congenital heart disease not due to the direct extension of suppuration from neighboring structures was pointed out long ago by Ballet[15] This association has been reviewed by several groups of observers[4, 7, 273, 97] We are not concerned in this discussion with cerebral suppuration secondary to bacterial endocarditis with bacterial embolization of the cerebral arteries As a rule the abscess develops from ■ paradoxical embolism in cases with a patent interventricular septum especially with tetralogy of Fallot and less often with a defect of the interatrial septum Bacterial endocarditis is absent in these cases The abscess is solitary in 90 per cent of the cases Headache and vomiting with or with

out fever, occur early Focal neurologic signs, including hemiplegia and papilledema, are also early manifestations Progression is rapid with early perforation of the ventricular system Meningitis may dominate the clinical picture Early diagnosis, vigorous use of antibiotics aspiration, and drainage or resection of the abscess are important I have twice seen patients with symptoms of a brain tumor who were discovered to have clinical signs of a ventricular septal defect Because of this association a diagnosis of cerebral abscess was made and confirmed by surgical exploration It is presumed though it is usually difficult to prove, that these cases of brain abscess are examples of paradoxical embolism in which the embolic material contains pyogenic organisms Because the abscess is a solitary one, it should be amenable to antibiotic and surgical cure if the diagnosis is made One such cure was reported by Smolik and associates[369]

Spontaneous *rupture of the aorta* in cases of congenital heart disease is usually a complication of coarctation or hypoplasia of the aorta or of medionecrosis of the aorta

Cerebral complications and their symptoms have been discussed (p 730)

THE COMMON TYPES OF CONGENITAL HEART DISEASE

From the practical viewpoint, it is particularly important to be familiar with those congenital cardiovascular lesions which are amenable to surgical treatment Fortunately, the commonest lesions, including those usually free from, as well as those associated with, cyanosis can be alleviated or cured by surgical means The common congenital cardiovascular lesions without cyanosis, which are usually amenable to surgery, are (1) atrial septal defects, (2) ventricular septal defects, (3) pulmonic stenosis, (4) patent ductus arteriosus (5) coarctation of the aorta, (6) double aortic arch and possibly (7) aortic and subaortic stenosis The common congenital lesions associated with cyanosis which are amenable to surgery include (1) tetralogy of Fallot, (2) pulmonic stenosis with interatrial septal defect (3) tricuspid atresia with hypoplastic pulmonary arteries (4) single ventricle with hypoplastic pulmonary artery and (5) pseudotruncus arteriosus with a single vessel supplying both systemic and bronchial arteries The lesions *not* amenable to surgery at present—all associated with cyanosis—are Eisenmenger complex complete transposition of the great vessels truncus arteriosus with the pulmonary artery arising from the common trunk tricuspid atresia with complete transposition of the great vessels transposition of the aorta with overriding pulmonary artery (Taussig Bing), hypoplasia or atresia of the aorta Among the non cyanotic forms of congenital cardiovascular disease not amenable to surgery are idiopathic hypertrophy of the heart, anomalous coronary artery arising from a pulmonary artery, Ebstein s disease and congenital dilatation of the pulmonary artery

ATRIAL SEPTAL DEFECTS

Uncomplicated interatrial septal defect is probably the commonest form of congenital heart disease, occurring in 15 to 20 per cent of cases[4 5] It occurs two to four times as frequently in females as in males

Embryology

About the fourth week of fetal life, a membrane, the *septum primum*, grows downward from the superior posterior wall of the atrium and divides it incompletely into right and left chambers The lower margin of the septum primum has a sickle-shaped defect which is the *ostium primum* Shortly afterward another opening the *ostium secundum*, appears in the upper portion of the septum primum Subsequently a second membrane the *septum secundum*, whose exact origin is uncertain develops slightly to the right of the septum primum and fuses with it It embraces the ostium secundum, leaving an oval opening the foramen ovale which functions as a circulatory pathway in the fetus but usually closes shortly after birth The ostium primum is normally closed during the fifth or sixth week by the downward growth of the septum primum and its fusion with the endocardial cushions which divide the atrioventricular canal into left and right channels Occasionally, however the ostium primum is not

closed and persists in adult life as a defect at the lower end of the interatrial septum An arrest in development of the endocardial cushions with failure to close the gap between the interatrial and interventricular septa results in a common atrioventricular canal the so-called *persistent atrioventricularis communis*

Despite the fusion of the septum secundum and septum primum, the foramen ovale is patent throughout fetal life and for some time after birth During fetal life the mixed blood containing the oxygenated blood from the placenta enters the right atrium and is directed by the sinus valve through the foramen ovale into the left atrium After birth the higher pressure in the left atrium as compared with that in the right causes the valve-like fold about the foramen ovale to occlude the opening But anatomically the foramen is still patent in many individuals until the second year of postnatal life According to Patten[309] functional closure of the foramen ovale occurs in only 35 per cent of subjects by two weeks of age but at six weeks 90 per cent and at three months 98 per cent of individuals have a functionally closed foramen ovale On the other hand complete anatomic closure of the foramen ovale is found in only 18 per cent of subjects at one year in 50 per cent at two years Even among adults 20 to 25 per cent of hearts at necropsy are found to possess an anatomically open foramen ovale In most instances it is only a slit like aperture which just permits a probe to be passed obliquely from the right atrium anteriorly to the left atrium posteriorly (probe-patent foramen ovale)

Pathology

A patent foramen ovale may be of clinical significance only when it is of sufficient size to permit the passage of blood between the two atria In the series of 1100 necropsies studied by Thompson and Evans[40] 6 per cent of the hearts revealed a foramen ovale more than 7 mm in diameter while 29 per cent contained merely a probe-patent opening Usually the atrial septal defect in the adult is large with a diameter of 2 to 3 cm Multiple defects may be present

A knowledge of the variety of atrial septal defects with respect to their size location and complexity of structure is important, not only because they present differences in circulatory disturbance but also because they impose different problems for the surgeon undertaking their closure.[31] There may be only an insignificant probe-patency but with competence of the valve of the foramen in about 25 per cent of cases In cases of valvular incompetent foramen ovale the posterior rim may be complete or incomplete When the rim is incomplete the defect may be continuous with the orifice of the superior vena cava and associated with partial anomalous pulmonary venous drainage especially from the right lung The atrial septal defect may have its lateral margins continuous with the valve of the inferior vena cava to form a false lower margin These defects are generally located high in the septum and there is a rim of septal tissue below them and above the mitral and tricuspid valve rings In another group, the defect is due to a *persistence of ostium primum* and lies on the valve rings In a third group the defect represents an absence in the lower part of the atrial septum and is associated with an opening in the upper part of the ventricular septum perhaps with fusion of the mitral and tricuspid valves or with a single atrioventricular canal

The entire atrial septum may be lacking In such cases if the ventricular septum is present, the subject has a *cor triloculare biventriculare*[113] This condition is rare is usually associated with other lesions and offers a very poor prognosis rarely an individual with this defect lives to the age of 30 with relatively few symptoms There is a striking tendency for Mongolian idiocy to be associated with defects at the lower end of the atrial septum (persistent ostium primum) which are sometimes combined with a common (undivided) atrioventricular canal[332]

Many cases with a significant atrial septal defect are complicated by a valvular lesion this association was encountered in more than three quarters of the 61 cases analyzed by Roesler[331] More recent observations suggest that the incidence of significant associated valvular lesions is much less, probably well below 25 per cent There may be a mitral stenosis less commonly an aortic valvular lesion or both The combination of an atrial septal defect with mitral stenosis is known as Lutembacher s disease[349] According to Nadas and Alimurung[297] Lutembacher s syndrome is rarer than previously thought and occurs in only 6 per cent of all atrial septal defects

When the atrial septal defect is a persistent

ostium primum deformity of the subjacent mitral valve is usual and results in mitral regurgitation [431, 436] Occasionally the tricuspid valve is deformed and incompetent in cases of persistent ostium primum When persistent ostium primum is associated with deformities of the atrioventricular valves the condition resembles or may be identical with a partial common atrioventricular canal In the latter however a defect in the ventricular septum should be demonstrable

Atrial septal defects are common in association with a variety of congenital cardiovascular lesions associated with cyanosis serving as the sole or major route for blood from the right side of the circulation to reach the left The most common associated congenital lesions include tricuspid atresia pulmonic stenosis transposition of the great vessels Eisenmenger s syndrome and Ebstein s disease

The heart is very large and averages 550 to 600 gm in weight But there may be no significant enlargement of the heart with small septal defects The enlargement involves particularly the right ventricle and right atrium which are exceedingly dilated and hypertrophied Almost the entire anterior aspect of the heart in situ is formed by the dilated right chambers, while the left ventricle appears as a small appendage which is just visible near the apex Even with associated mitral stenosis the left atrium is usually of normal size or only slightly enlarged because the flow of blood has free egress through the septal defect and because the mitral stenosis is not severe But in persistent ostium primum with mitral regurgitation, the left ventricle may be enlarged and hypertrophied

The pulmonary artery, whose diameter is normally less than that of the aorta is relatively larger in this disease Occasionally the pulmonary artery and its branches are greatly dilated and may reach aneurysmal proportions This exaggerated pulmonary dilatation is an essential feature of the disease as described by Lutembacher [267] There may be pulmonary arteriolar sclerosis and narrowing, or, occasionally gross thrombosis of the main pulmonary arteries [88] The aorta is hypoplastic

Pathologic Physiology

In uncomplicated atrial septal defect, the shunt is from left to right since the left atrial pressure exceeds that within the right atrium [72, 80] However, right to left shunts of small magnitude may occur intermittently with changes in pressure relationships [339, 356] That such right to-left shunts occur is indicated by an average arterial oxygen saturation of 85 per cent in a group of patients with atrial septal defect whose pulmonary artery and right ventricular pressure were normal [48] When pulmonary arterial hypertension was associated with atrial septal defect, the average oxygen saturation was 71 per cent and, [illegible] course most of the patients in this group were cyanotic

The *pulmonary blood flow*, i e, the right ventricular minute output, is strikingly increased to between 7 and 22 liters per minute,[189] instead of a normal of about liters This is the result of the increased blood flow into the right ventricle from the right atrium, which receives blood both from the vena caval systems and from the left atrium The work of the right ventricle is thus increased and this chamber becomes enlarged and hypertrophied The systemic blood flow is normal or slightly decreased, hence the pulmonic blood flow ranges from somewhat greater than, to more than four times the systemic blood flow according to the varying magnitude of the shunt

The *pulmonary artery blood pressure* may be normal or elevated usually without relation to pulmonary blood flow Blount et al [48] found the pulmonary blood flow averaged 13 2 liters in a group with normal pulmonary blood pressure and 8 0 liters in a group with elevated pulmonary blood pressure Occasionally the pulmonary blood pressure is equal to the systemic blood pressure Although the pulmonary artery pressure may rise because of very increased blood flow (e g when three or more times normal), the major cause for the pulmonary hypertension is an increase in pulmonary arteriolar resistance which averages 122 dynes/second/cm^{-5} in tho e with relatively normal pulmonary arterial pre ures and 770 in those with pulmonary hypertension It appears that the pulmonary arteriolar resistance is a major factor in determining the magnitude of the shunt and of the increased pulmonary blood flow [115] The pulmonary flow is large and the associated pulmonary artery pressure [illegible] normal in one group of cases because the pulmonary resistance is small and presumably therefore the pulmonary vascular bed distensible In the

and associated with a thrill, and the second sound is widely split

With the development of congestive heart failure the cervical veins become full In the presence of atrial fibrillation which occurs frequently there may be a systolic pulse in the liver and cervical veins (pp 72) with regular sinus rhythm there is a presystolic venous and hepatic wave (double pulse wave p 715)[171] just as in cases of tricuspid stenosis The radial pulse is often small

Roentgenology[303]

The essential features are

1 A prominent main pulmonary artery (Fig 129)

2 A small aortic knob or absence of the aortic knob

3 Prominent hilar shadows and large sharply defined branches of the pulmonary artery These are not invariable findings increased pulmonary vascular markings are almost always present in the acyanotic cases absent in the cyanotic[106] The hilar vessels may clearly pulsate (hilum dance) The larger hilar vessels may be mistaken for a mediastinal tumor or lymphoma and needless surgery or radiotherapy undertaken There is increased pulmonary vascularity The left atrium is usually of normal size but may be slightly enlarged The barium filled esophagus may be displaced as in uncomplicated acquired mitral stenosis

4 There is often a prominent right atrial shadow in the posteroanterior and left anterior oblique views and there may be evidence of right ventricular enlargement Sometimes there is a large globular cardiac shadow without striking enlargement of the pulmonary artery or hilar vessels When there is a persistent ostium primum with mitral regurgitation the left ventricle may be enlarged as well as the right

Pulmonic stenosis may be associated with a prominent pulmonary artery due to post stenotic dilatation but the pulmonary fields are clear A high interventricular septal defect may also be accompanied by a prominent pulmonary artery but the left as well as right ventricle is enlarged Patent ductus arteriosus may be differentiated as it is usually associated with a normal or large aortic knob

Angiocardiography

Atrial septal defects may be demonstrated angiocardiographically by means of a special technique involving synchronous radiography in two planes at right angles (right and left anterior oblique) at the rate of 10 to 12 exposures per second in each plane with precise timing of the exposures on a simultaneously recorded electrocardiogram[60] If the defect is not large its demonstration requires that the contrast medium be injected from below to reach the inferior vena cava whence it is most likely to pass through the defect into the left atrium

The speed of exposures yields films demonstrating the actual passage of the contrast substance through the septal defect immediately after it reaches the right atrium If the shunt is from left to right the contrast material is shunted into the left atrium chiefly during diastole If the shunt is demonstrated in atrial systole it indicates a right-to left shunt By this technique Lind and Wegelius[261] demonstrated atrial septal defects in 30 (20%) of 150 infants believed to have congenital heart disease This is the most direct method of demonstrating the septal defect by angiocardiography But even by conventional angiocardiography the presence of an interatrial septal defect may be indicated by the early opacification of the left atrium by maintained opacification of the right heart or occasionally by actual reopacification of the right heart

Electrocardiogram

There is usually a right axis deviation and almost always evidence of right ventricular hypertrophy or more commonly of incomplete right bundle branch block as revealed by the precordial leads[30, 370] The electrocardiographic pattern is that attributed to diastolic overloading of the right ventricle[70] The typical rSr pattern seen in cases of atrial septal defect has been attributed to hypertrophy of the crista supraventricularis and not to right bundle branch block[47] In the ostium primum defect there is more likely to be a left axis deviation in extremity leads and signs of right ventricular hypertrophy in the precordial leads The QRS complexes may be of high voltage notched and frequently widened[7] High P waves are often present especially in V_1 The P R interval is sometimes prolonged Atrial fibrillation is common toward the end of the disease Incomplete right bundle branch block in a case of congenital heart disease should suggest the presence of an interatrial septal defect

group of cases with increased pulmonary resistance distensibility is limited increased pulmonary blood flows are more difficult to accommodate and then only by a rise in pulmonary blood pressure The cause of the increased pulmonary arteriolar resistance is uncertain but in some cases examined at autopsy there were associated anatomic lesions with narrowing of the small pulmonary arteries and arterioles or occasionally with thrombosis of the major pulmonary arteries [88]

Clinical Features

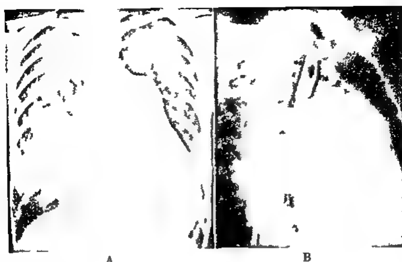
There may be no significant symptoms and no interference with a normal or even a long life span When symptoms are present, the most common are exertional dyspnea palpitation fatigability or weakness In infants and children there may be feeding difficulties recurrent respiratory infections and retardation of growth [1?] Often symptoms are precipitated by an upper respiratory infection Recurrent attacks of pneumonia pulmonary infarction and pulmonary congestion (left sided heart failure) are characteristic in some cases Cyanosis is usually absent throughout most or all of the course of the disease because the shunt of blood is from the arterial to the venous side of the heart but cyanosis was encountered in 7 per cent of 180 proven autopsy cases [89] Late or terminal cyanosis (cyanose tardive) may appear with a reversal of the shunt if the pressure in the right atrium is made to exceed that in the left because of pulmonary complications pulmonary vascular disease or heart failure Clubbing is absent except in rare instances in which there is persistent cyanosis [359]

The patients are sometimes underdeveloped slender or even infantile (habitus gracilis) The skin may be semitranslucent the bony structure light, puberty delayed and menstruation abnormal Arachnodactyly may be a significant association (p 728) The underdevelopment is attributed to the diminished blood flow through the aorta into the systemic circulation

Eventually the clinical course is terminated most often by symptoms of right-sided congestive heart failure with evidences of venous engorgement, subcutaneous edema ascites and hydrothorax Dexter also noted left ventricular failure in 14 of 60 cases of atrial septal defect [116] Subacute bacterial endocarditis is a rare complication [43] The occurrence of paradoxical embolism has been mentioned Furthermore an atrial septal defect represents the only congenital cardiac anomaly which is frequently associated with paroxysmal tachycardia and atrial fibrillation Extrasystoles atrial flutter ventricular escape and atrioventricular dissociation also have been noted

Hoarseness may result from paralysis of the left recurrent laryngeal nerve due to giant dilatation of the pulmonary artery [417]

In cases of ostium primum the clinical picture is similar to that of other atrial septal defects but the symptoms tend to occur earlier and to be more incapacitating



Physical Examination

There may be a left-sided deformity of the chest due to forward pressure of the right ventricle against the precordium Palpation and percussion reveal enlargement of the heart the apex being displaced downward and to the left while the right border is extended to the right of the sternum

A systolic murmur is present in most cases but its location is variable Most often there is a loud systolic murmur only occasionally accompanied by a thrill, in the second or third interspace near the left border of the sternum But it may also be heard lower near the sternum or at the apex It is thought to be due to increased blood flow through the pulmonary valve orifice (relative pulmonic stenosis) In about one third of the cases there is an apical diastolic murmur not due to an associated mitral stenosis, since it disappears after surgical closure of the septal defect, but possibly due to a functional (relative) tricuspid stenosis caused by the large blood flow through the tricuspid orifice In advanced cases there may be a diastolic murmur of pulmonic insufficiency The second pulmonic sound often is accentuated but wide splitting of the second sound is more diagnostic according to Barber et al [20] and Leatham and Gray [474]

In cases of ostium primum which are associated with mitral valvular incompetence there is a loud, high pitched blowing murmur over the apical and lower left sternal regions A low pitched diastolic rumble in the tricuspid region is usual in these cases, probably because of the very marked increase in blood flow with consequent functional tricuspid stenosis

When pulmonic stenosis is associated with interatrial septal defect the systolic murmur in the second and third interspace is very loud

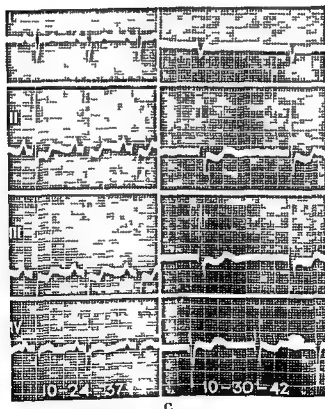


Fig. 129 Interatrial septal defect. *A* Posteroanterior view. Huge pulmonary artery and branches.
B Right oblique view. Rounding and compression of esophagus by large left atrium due to associated mitral stenosis.
C Electrocardiogram of same case 10/24/37. Pronounced right ventricular strain. 10/30/42 developed atrial fibrillation. This arrhythmia in congenital heart disease suggests interatrial septal defect.

Cardiac Catheterization and Diagnosis

The diagnosis is based on the finding of a loud systolic murmur in association with pronounced globular enlargement of the cardiac silhouette especially the right chambers, with small aortic knob and prominent pulmonary artery and branches Confirmation may be presented by intracardiac catheterization, which reveals a distinctly higher oxygen concentration in the right atrium than in the superior vena cava [3,7] This sharp rise in oxygen content may be missed if the catheter is too near the coronary sinus On the other hand, similar oxygen findings occur with partial transposition of the pulmonary veins into the right atrium Occasionally the catheter slips through the interatrial opening into the left atrium and arterial blood is obtained This gives a more positive diagnosis of interatrial defect than the oxygen findings In cases of ostium primum the catheter crosses over in a low position into the left atrium and readily enters the left ventricle The differential diagnosis of this and other congenital lesions is discussed in more detail at the end of the chapter (p 793)

Prognosis

The prognosis is relatively favorable as compared with that in other congenital cardiac lesions The average age at death is about 35 but half the patients live beyond the age of 50 The disease may be extremely well tolerated as in Firket's[156] patient, who lived to be 74 and had eleven pregnancies, Lutembacher's [67] patient who survived seven pregnancies and died at the age of 61 and a patient who survived to the age of 82 [14]

Surgical Treatment

Atrial septal defects may be corrected by atrioseptopexy the use of an atrial well, or under direct vision using hypothermia with inflow stasis cross circulation or an 'artificial heart' (pump oxygenator)

Patients are considered for these operations if they have significant disability due to exertional dyspnea or recurrent episodes of heart failure There should be evidence of right ventricular hypertrophy and catheterization studies should show pulmonary blood flows at least twice the systemic blood flow With even larger pulmonary blood flows operation is probably indicated even in asymptomatic patients An elevated pulmonary artery pressure is not always a contraindication, but suggests care in excluding associated anomalies The combination of pulmonary hypertension and a large left to right interatrial shunt is regarded as a strong operative indication But pulmonary hypertension with a right-to left interatrial shunt is generally a contraindication

In Bailey's technique of atrioseptopexy,[11] the left index finger is inserted through an opening in the right atrial appendage and the defect outlined by touch A portion of the lateral wall of the usually large redundant right atrium is sutured down to occlude the defect completely Associated anomalies of the pulmonary veins and significant mitral stenosis are corrected at the same time This technique limits repair generally to defects with complete rims in the middle of the septum It cannot be used in children below the age of four because the appendage is too small to admit the finger Among 50 patients operated on by Bailey's group there were 5 deaths (13 5%) in 37 patients with persistent ostium secundum and 8 deaths (61 5%) in 13 patients with persistent ostium primum [119]

Another "closed" method used by Crafoord[18] involves similar insertion of the finger in the right atrial appendage following a dissection in the groove between the right and left atrial walls With the finger as a guide a needle and suture are passed through the right atrial wall, then subendocardially in the rim of the defect through the upper portion of the interventricular septum and out again through the atrial wall The septal rim is thus drawn down to the ventricular septum and the defect closed The two ends of the suture are drawn taut over a piece of Fibrin Foam in the groove previously dissected between the superior vena cava and right pulmonary veins This technique was used in 12 patients with survival in 10, and is said to be applicable to all types of septal defects including those associated with a common atrioventricular canal [103]

The atrial well technique of Gross[242, 412] allows more freedom of exploration and repair The right atrium is approached by a right anterolateral thoracotomy through the fifth interspace the incision curving around under the right breast A large rubber well (truncated cone) about 15 cm tall, 13 cm in diameter at the top and 4 cm at bottom, is sutured onto an incision in the right atrium A clamp on the atrium is released and the blood

in that chamber rises into the well to a height equal to the intra atrial pressure This loss of blood is compensated by a slow transfusion of 300 to 500 cc blood given prior to opening the well As the blood is kept fluid by heparin dripped into it the surgeon is able to explore the defect and repair it with his hand beneath the surface of the blood Small defects are repaired by direct sutures and approximation of the septal margins Larger defects are closed by a piece of polyvinyl (Ivalon) sponge or other plastic cut to the proper shape and size placed on the left side of the septal remnant and secured in place by interrupted mattress sutures Eventually the atrial clamp is reapplied the atrial well cut away the right atrial incision sutured and the clamp removed Kirklin and associates [illegible] reported 33 such operations with only one death and an excellent result in 29[84a] Muller and associates[93] used the technique of atriopexy or the atrial well in 18 patients in 14 of whom a successful closure and good clinical result were obtained The operation is contraindicated in patients with pulmonary hypertension and an elevated right atrial pressure

Operation under direct vision in a dry field is possible by refrigeration of the anesthetized patient whose rectal temperature is reduced to 28 C, and by occluding the body inflow fo up to 15 minutes[282, 285] (See Hypothermia p 1112) During this period the right atrium is opened and the defect closed Lewis et al[281] reported operation with this procedure on 31 patients 4 of whom died Postoperative physiologic studies[43] of patients operated on by the technique of hypothermia and direct vision have shown a marked reduction of pulmonary blood flows to levels equaling systemic blood flow Clinical symptoms such as dyspnea and fatigability were greatly ameliorated The pulmonic systolic murmur disappeared in some diminished in intensity but persisted in others Its persistence despite closure of the septal defect suggested that the murmur was not due to the septal defect but to some other factor possibly a functional pulmonic stenosis The apical diastolic murmur disappeared in all cases indicating that it was not due to mitral stenosis but to a functional tricuspid stenosis caused by the immense preoperative pulmonary blood flow Reduplication of the second pulmonic sound and the bundle branch block pattern in the electrocardiogram persisted An extracorporeal pump-oxygenator circuit has been used to repair experimental interatrial septal defects[35] and more recently clinical atrial septal defects in humans[132, 257] (pp 1114 1115)

Operation under direct vision would appear to be more desirable than the closed methods, especially for complex defects and those low in the septum involving the atrioventricular valve or associated with interventricular septal lesions or persistent atrioventricularis communis One would also be more certain of an accurate and complete repair under direct vision and of finding and repairing associated anomalous veins or multiple defects Two factors militate against the general acceptance of the open procedures at present (1) Excellent results have been obtained without direct vision using the well technique sometimes even in cases of the more complex defects (2) Hypothermia is still associated with some serious risk especially of ventricular fibrillation and imposes limitations on the time permitted for repair Extracorporeal pump oxygenator techniques still suffer from technical and physiologic difficulties which, however should be overcome shortly Regardless of the type of procedure there still appears to be difficulty in obtaining consistently satisfactory results or avoiding complications or fatalities in the cases of ostium primum and related complex lesions

PERSISTENT ATRIOVENTRICULARIS COMMUNIS

There is an arrest of development of the ventral and dorsal endocardial cushions and the atrial and ventricular septa fail to meet resulting in low atrial and high ventricular septal defects and a more or less common atrioventricular canal The atrioventricular cusps are deformed and incompetent The shunt is predominantly from left to right and there is usually no cyanosis There is an apical systolic murmur The right atrium right ventricle and to a lesser extent the left ventricle are enlarged Angiocardiography shows early filling of all four chambers There is continuous opacification of both sides of the heart Heart failure often develops at an early age Most of these patients succumb in the first year of life but some reach adult life Mongolism may be associated

COR TRIATRIUM[305, 315]

A transverse septum with a single small opening runs across the left atrium separating

the openings of the pulmonary veins from the mitral orifice There may be stenosis of the common pulmonary vein causing obstruction resembling that of mitral stenosis The clinical picture is characterized by progressive pulmonary congestion with respiratory distress, progressive cardiac enlargement and signs of congestive heart failure Roentgenographic examination shows enlargement of the middle left cardiac salient and of the right ventricle and the electrocardiogram reveals right ventricular hypertrophy The course depends in part on the size of the opening in the transverse septum A triatrial heart was repaired by open cardiotomy in a 29 year old man, with the aid of hypothermia and venous inflow occlusion [25,8] The third atrial chamber was opened while a finger in the left atrium invaginated the abnormal septum into the third chamber The septum was then divided under direct vision

ANOMALOUS ENTRANCE OF THE PULMONARY VEINS[371, 06, 186, 10, 416, 91, 92, 184]

This is discussed here because of its common association with atrial septal defects and because surgical treatment is undertaken at the same time as that for the atrial defect It is one of the more frequent congenital cardiovascular anomalies There may be *total anomalous pulmonary venous drainage*,[395] all the veins draining into the left innominate vein the right atrium the superior vena cava, or a persistent left superior vena cava,[416] or *partial anomalous venous drainage*, in which one or more pulmonary veins drain into the right atrium or superior vena cava, or more rarely into the coronary sinus, left innominate vein vena azygos portal vein persistent left superior vena cava [187] or other veins From the viewpoint of surgical correction in cases of total anomalous pulmonary venous drainage, it is important to know that the pulmonary veins from both lungs usually converge to form a chamber or sinus from which a single anomalous vein emerges to join the systemic venous circulation [63]

There is usually an atrial septal defect or occasionally a common atrial chamber or a patent ductus in the total form life being thus maintained by a right to-left shunt Actually there is first a left to right shunt at the level of the superior vena cava or right atrium, the blood in the right atrium thus receiving oxygenated as well as unoxygenated blood then there is a right to left shunt through the atrial septal defect (or patent ductus) whereby this unoxygenated as well as oxygenated blood reaches the systemic arteries Hence the diagnostic feature which distinguishes total from partial pulmonary anomalous venous drainage or uncomplicated atrial septal defect, is that the right atrial blood is not only significantly more oxygenated than that in the inferior vena cava but also the right atrial oxygen saturation is equal to that of systemic arterial blood The latter is subnormal in oxygen saturation Since a functionally common atrium without pulmonary venous connection could produce the same findings, it is preferable to study the blood in the right ventricle as well as the right atrium In total anomalous pulmonary drainage the right ventricular oxygen saturation equals that in a peripheral artery

An atrial septal defect is also found commonly in cases of partial anomalous pulmonary venous drainage but in such cases of combined interatrial septal defect and anomalous venous drainage, the shunt is from left to right except where most of the pulmonary venous blood drains into the right atrium

Total anomalous pulmonary venous drainage [34, 287, 367] is characterized by slight cyanosis, increasing dyspnea and fatigue, progressive enlargement of the right cardiac chambers and pulmonary artery, increased right atrial pressure, high oxygen saturation of the blood in the right atrium and identical but subnormal oxygen saturation of the peripheral arterial blood and of that in the right ventricle or pulmonary artery There are signs of chronic pulmonary congestion repeated pulmonary infections and eventual right sided heart failure Death occurs usually in infancy or early childhood, but patients have survived into young adult life

Partial anomalous pulmonary drainage is now being commonly diagnosed by cardiac catheterization angiocardiography, selective angiocardiography,[11] dye dilution curves (p 798), or by careful exploration during operations for atrial septal defects The condition is usually benign and may remain asymptomatic, depending on the quantity of anomalous drainage When a large proportion of the pulmonary venous blood drains into the right superior vena cava or right atrium, the clinical picture resembles that described for uncomplicated atrial septal defect There is an

increase in pulmonary blood flow, enlargement of the right cardiac chambers and pulmonary artery, accentuated second pulmonic sound and occasional systolic murmur. The electrocardiogram shows right ventricular hypertrophy or bundle branch block.

On roentgenographic examination[65] the anomalous veins produce a crescentic saber-shaped shadow of vascular density parallel to or behind the right side of the heart, directed into the right atrium or inferior vena cava. Tomography may show the vessels more clearly. The main pulmonary arteries are large and pulsate vigorously, and the right cardiac chambers are enlarged. The pulmonary fields are greatly engorged. The heart is often shifted to the right. There is a diminution in size of one hemithorax due to hypogenesis or agenesis of the lung or bronchi on the side of the involved veins. When all the pulmonary veins empty into the right side of the heart, their shadows form a typical figure of 8 pattern.[34, 380] The anomalous veins often enter a persistent left superior vena cava, which appears as a distinctive wide mediastinal shadow enveloping the aortic knob and pulmonary arc.

Angiocardiographic study has frequently disclosed a constant filling defect at the site of insertion of the anomalous pulmonary veins, thought to be due to turbulent inflow of blood impinging against the contrast material.[380]

A diagnosis of partial anomalous pulmonary circulation may be made if the catheter passes directly into the pulmonary vein before entering the right atrium (i.e., the catheter reaches the pulmonary field without traversing the cardiac shadow) and if a sample of arterialized blood is obtained. But if the anomalous vein empties into the right atrium directly, it may be difficult to distinguish the findings from those of an atrial septal defect. Diagnosis may be aided by the differences in time-dilution curves of Evans blue (T 1824) during its initial circulation after injection into the right and left pulmonary arteries, or by the differences in the curves after injection of the dye into the pulmonary vein and the venae cavae.[387]

Partial anomalous pulmonary venous drainage is associated with a high incidence of pulmonary disease. If a lobectomy or pneumonectomy is to be performed, it is important to be certain that the remaining pulmonary veins drain into the left atrium.

Surgical Treatment

Because of the unfavorable outlook for anomalous pulmonary venous drainage, surgical treatment should be considered if studies indicate the presence of a vessel which is suitable for transplantation into the left atrium.[10-34] Complete correction of the anomaly requires operation under direct vision with the aid of hypothermia, cross circulation, or a pump-oxygenator heart-lung by-pass. Operation is indicated in cases of partial anomalous drainage only if there are disabling symptoms or evidence of considerable enlargement of the heart or a large left-to-right shunt and excessive pulmonary blood flow, as in atrial septal defect. During operations to repair an interatrial septal defect, consideration should be given to the simultaneous implantation of the anomalous veins into the left atrium.[172] If the septal defect is closed by a plastic prosthesis with the aid of an atrial well, the prosthesis can be so placed that the anomalous pulmonary veins are to its left and now enter the left atrium. In the procedure of atrioseptopexy (p. 740) the right atrial wall with the anomalous pulmonary veins can be invaginated through the atrial septal defect, thereby closing the defect and causing the veins to drain into the left atrium. A case of anomalous pulmonary venous drainage into the left innominate vein in association with mitral stenosis was reported.[381] Mitral commissurotomy and transplantation of the anomalous vein into the left atrial appendage were successfully performed at one operation.

In 10 cases in which an atrial septal defect was repaired by atrioseptopexy, the procedure was modified to correct simultaneously partial anomalous pulmonary venous drainage into the right atrium and/or superior vena cava. Lewis et al[15-a] repaired the total anomalous pulmonary venous drainage entering the right atrium by open cardiotomy with the aid of hypothermia and venous inflow occlusion. Burroughs and Kirklin[164] reported 3 cases of total anomalous pulmonary venous drainage in which corrective operations were performed, in 1 with the atrial well technique and in 2 with the aid of an extracorporeal circulation.

LEFT SIDED SUPERIOR VENA CAVA[77, 380]

Persistence of the fetal left superior vena cava is now commonly recognized, especially by cardiac catheterization or angiocardiography. It may appear as an isolated anom

aly but is also likely to occur in the presence of some degree of transposition of the viscera or in association with atrial or ventricular septal defect tetralogy of Fallot, mitral atresia or Taussig Bing heart As a rule, there is a superior vena cava on the right as well as the left side the latter draining into the right atrium by way of the coronary sinus In the less common type the left superior vena cava drains into the left side of a single atrium and the right superior vena cava into the right side of this chamber In this type there may be no inferior vena cava Occasionally a left superior vena cava empties into the left atrium and then other malformations are associated Persistence of the left superior vena cava is due to failure of the upper part of the left anterior cardinal vein to become obliterated The persistent left superior vena cava may be seen in the conventional posteroanterior roentgenogram as a para mediastinal bulge below the aortic arch[303] The vessel is visualized by angiocardiograms if the contrast material is injected in the left arm

Rarely the inferior vena cava opens into the left atrium[186]

Prenatal closure of the interatrial foramen[88] results in atrophy of the left atrium and ventricle After birth the atrophic left atrium cannot accommodate to the large pulmonary venous return with resulting pulmonary congestion dyspnea cyanosis and occasional generalized edema A similar disturbance and clinical picture may arise in cases of aortic atresia congenital mitral stenosis or hypoplasia of the left ventricle[201]

VENTRICULAR SEPTAL DEFECTS

Defects of the interventricular septum have been regarded as the second most frequent cardiac anomaly but this is probable only if all cases with associated lesions are included Only 6 per cent of Abbott s congenital cardiac cases were of uncomplicated ventricular septal defect In a recent series of 750 cases of congenital heart disease isolated ventricular septal defects occurred in 8 per cent[45] Ventricular septal defect also occurred as part of the tetralogy of Fallot in 11 per cent as part of the Eisenmenger complex in another 2 5 per cent, with pulmonic stenosis and a normal aortic root in 2 per cent with pulmonary atresia in 1 5 per cent and transposition of the great vessels in 1 per cent However since more recent studies with cardiac catheterization and other diagnostic techniques, it appears probable that many cases of so-called ventricular septal defect have been incorrectly diagnosed[45]

The cases of uncomplicated ventricular septal defect are known as Roger s disease, Roger[32] described the characteristic murmur associated with this lesion According to Wood et al[45] the term, Roger s disease, if used at all should be applied only to the mild asymptomatic cases characterized solely by Roger's murmur and thrill On the other hand there are also uncomplicated ventricular septal lesions of moderate and great severity with significant circulatory disturbances and clinical symptoms

Embryology

During the second month of fetal life the ventricle is divided into two chambers by a septum which grows upward along the anterior and posterior margins The posterior margin is completed above by joining the posterior endocardial cushion of the atrioventricular canal The anterior margin is incomplete above leaving an interventricular foramen Normally this foramen is closed at about the eighth week by a downward extension of the proximal end of the septum of the bulbus arteriosus The bulbar septum fuses with the incompleted upper end of the interventricular septum and with the posterior endocardial cushion The major primary portion of the interventricular septum is a muscular structure The later segment which closes the interventricular foramen is thin and membranous (septum membranaceum) and is situated in the so-called undefended space of Peacock

Pathology and Pathologic Physiology

A ventricular septal defect usually results from failure of the bulbar septum to close completely the interventricular foramen This deficiency of the bulbar septum may be associated also with some abnormality in the division of the truncus arteriosus into aorta and pulmonary artery and in the position of these great vessels (see below, p 755) For this reason a defect in the ventricular membranous septum is often combined with a dextraposition of the aorta and stenosis of the pulmonary artery The juxtaposition of the septal leaflet of the tricuspid valve to the fetal interventricular foramen accounts for relatively frequent associated anomalies of that

valve including fenestration of the valve with consequent tricuspid regurgitation In such cases of defective tricuspid septal leaflet and high ventricular septal defect there is a virtual direct shunt from the left ventricle to the right atrium[376] If the disturbances in growth are only slight the ventricular septal defect may appear as an isolated lesion Sometimes ventricular septal defects are classified into two types (1) the type in the septum proper responsible for so-called Roger s disease and (2) high ventricular septal defects in the membranous portion of the septum immediately below the aortic valve (p 747) due to failure of the aortic and ventricular septa to meet Often there are associated anomalies such as transposition of the great vessels atrial septal defects[170] or pulmonic stenosis

The uncomplicated ventricular septal defect may be so small as to permit only the entrance of a probe or it may be large enough to admit the thumb It is situated usually in the upper part of the septum just anterior to the septum membranaceum[367] Its margins may be thickened owing to the tension of the blood stream Similar sclerosis may appear on the endocardium of the right ventricle opposite the septal defect Both of these sites may become infected with bacterial vegetations The heart itself is only slightly enlarged the enlargement involving chiefly the right ventricle in cases of small defects But with large (high) interventricular septal defects the left ventricle is more dilated and hypertrophied than the right However the right ventricle is hypertrophied when there is associated pulmonary hypertension The pulmonary artery is dilated in large high ventricular septal defects

The flow of blood through the interventricular opening is from the left to the right ventricle owing to the higher pressure in the former Hence the systemic blood is not contaminated by unoxygenated blood and there is no cyanosis In mild cases the left-to-right shunt is small and the pulmonary blood flow may be only slightly more than the systemic flow In severe cases the pulmonary blood flow may be three to five times that through the systemic circulation[4,5] In such cases there is a high pulmonary vascular resistance and pulmonary hypertension This may represent a persistence of the high pulmonary resistance in the fetus and usually there are pulmonary vascular obliterative lesions in the small arteries and arterioles[37] When the pulmonary hypertension is very marked i e the pulmonary artery pressure is equal to or slightly greater than the systemic there is a bidirectional or reversed shunt[35] These latter cases represent the Eisenmenger complex[47] although to be accurate the Eisenmenger complex includes an overriding aorta There is some evidence that bidirectional shunting or a right-to-left shunt in isolated ventricular septal defect occurs only if there is an associated overriding of the aorta[50] Lesser degrees of pulmonary hypertension not sufficient to cause a right to-left shunt may occur as a result of increased pulmonary blood flow without markedly increased pulmonary resistance Usually the pulmonary blood flow must be at least three times normal to produce so-called hyperkinetic hypertension When there is marked pulmonary hypertension due to increased pulmonary resistance but the right ventricular pressure is slightly less than the left ventricular pressure throughout the cardiac cycle there may be only a small left to-right shunt

When a ventricular septal defect is associated with pulmonic stenosis and overriding aorta (tetralogy of Fallot) the shunt is almost always from right to-left However there are cases of ventricular septal defect with pulmonic stenosis in which there is a left to-right shunt through the septal defect and an increased pulmonary blood flow despite the pulmonic stenosis[10, 11]

Clinical Features

Only the mild cases with small shunts are associated with the classic picture of Roger s disease and are characterized as asymptomatic acyanotic and having a very favorable prognosis On the other hand in patients with large ventricular septal defects and large shunts there may be evidence of underdevelopment recurrent pulmonary infections and early congestive heart failure with death due directly to the septal defect[71] Cyanosis may be present in patients with marked pulmonary hypertension and intermittent or continuous reversal of the shunt usually associated with overriding aorta (Eisenmenger complex) It may also occur in some patients only during exercise pulmonary infections or the development of heart failure Although the muscular defects in the ventricular septum are usually small and asymptomatic they

may be rarely associated with pulmonary hypertension and severe symptoms [99]

The characteristic *physical sign* in cases with a small ventricular septal lesion is a distinctive prolonged usually loud and harsh systolic murmur with maximum intensity in the third or fourth left interspace near the sternum The murmur is very loud at this site in the center of the precordium and becomes progressively fainter as the examiner moves the stethoscope toward the apex or toward the left clavicle Rarely the murmur is loudest at the left of the xiphoid process Often it is transmitted to the back where it is heard in the left interscapular or subscapular region The murmur of an uncomplicated ventricular septal defect is said to be not usually transmitted to the cervical vessels, in contrast with the murmur of the tetralogy of Fallot But there are occasional exceptions The murmur may endure through part of diastole and obscure the second sound A *thrill* accompanies the murmur in about 90 per cent of the cases [4,5]

In cases with large ventricular septal lesions the nature of the systolic murmur is more variable A thrill may be absent An apical diastolic murmur may be heard in cases with severe defects and very large pulmonary blood flows probably due to functional tricuspid stenosis A pulmonic diastolic murmur may be present as a result of pulmonary hypertension and functional pulmonic insufficiency

The second pulmonic sound may be accentuated and split in the cases with large septal defects

Course and Complications

Frequently in asymptomatic subjects a normal life is terminated by some intercurrent disease Right-sided heart failure with terminal cyanosis is not uncommon in subjects with large defects In Abbott's[1] autopsied series of cases, 37 per cent died of a complicating bacterial endocarditis The vegetations are usually situated in the pulmonary conus of the right ventricle where the shunted stream of blood strikes most forcibly Brain abscess occurs occasionally, more often with uncomplicated ventricular septal defect or tetralogy of Fallot than with any other congenital cardiac anomaly [4,9]

Of interest is the uncommon association of *congenital heart block* [4,8] probably due to a developmental defect of the bundle of His In most cases of congenital heart block there is found a defect of the membranous portion of the interventricular septum [31] Of 14 cases with this conduction disturbance collected by Yater Lyon and McNabb,[423] 26 had a ventricular septal defect and one had no ventricular septum The association of congenital heart block with a ventricular septal defect is attributed to the proximity of the bundle of His to the usual site of the defect near the undefended space, so that the same developmental disturbance is likely to cause both lesions In a recent report of [illegible] cases of congenital heart block, the ventricular septal defect was part of the tetralogy of Fallot in 3, and of Eisenmenger's complex in one [97] Occasionally an atrial septal defect is also present Congenital heart block in itself is not a serious lesion and does not interfere with life The serious prognosis in some cases is determined by associated cardiac anomalies Rarely, Adams Stokes syndrome occurs [98] In the series of 44 cases collected by Yater et al ,[423] symptoms were uncommon and cyanosis was absent in 24 and slight or occasional in 14

Roentgenology

In the cases of small, low interventricular septal defects there is no distinctive cardiac silhouette, but there may be slight enlargement of the right ventricle Occasionally, moderate increases in pulmonary blood flow may be indicated by engorgement of the pulmonary vessels

With large and high interventricular septal defects there are some features similar to those of atrial septal defect with left-to-right shunt, but more striking are features resembling those of patent ductus arteriosus or aortic pulmonic septal defect For as in these conditions blood is transferred from the higher pressure area of the left ventricle to the right ventricle and pulmonary artery Because of the high position and large size of the defect blood passes through the septal defect and pulmonary conus into the pulmonary artery Hence the left ventricular load is increased and the left ventricle becomes enlarged, the pulmonary artery prominent and its smaller branches engorged The aortic knob is small

When pulmonary hypertension is marked or there is an associated overriding of the aorta, there is a right-to left shunt through the

ventricular septal defect, and the roentgenologic findings are those of the Eisenmenger complex (p 749)

Angiocardiography

Even with small shunts the septal defect may be demonstrable by selective angiocardiography (p 15) or rapid biplane angiocardiography With larger high ventricular septal defects conventional angiocardiography discloses continuous reopacification of the right ventricle and pulmonary artery Or the pulmonary artery alone may show reopacification if the contrast material is shunted from the left ventricle through the high defect more directly toward the pulmonary artery than toward the right ventricle proper

Electrocardiogram

There is no significant change in cases with small defects With larger defects incomplete right bundle branch block occurs commonly In cases with high pulmonary arterial pressure the electrocardiogram usually shows evidence of both left and right ventricular hypertrophy [77] Even in the presence of right bundle branch block a deep S wave in V_1 suggests the presence of left ventricular hypertrophy

Cardiac catheterization discloses a significantly higher oxygen content of the right ventricular blood than of the blood in the right atrium owing to the shunt of arterial blood from the left to the right ventricle There is usually an elevation of the pulmonary artery and right ventricular pressures

Surgical Treatment

Methods Ventricular septal defects have been repaired by so-called closed methods or under direct vision [39] In the former a purse string suture is placed in the anterior wall of the right ventricle and through an incision in its center the index finger of the left hand explores the right ventricular chamber for other defects With a large needle a non absorbable suture is passed into the region of the pulmonary conus and directed by the index finger in the ventricular cavity to approximate the anterior and posterior lips of the septal defect The needle and suture are then brought out through the ventricular wall After the septal defect is sutured the myotomy incision is closed by interrupted sutures

Lillehei and associates [56] have employed donors to create a cross circulation (p 1111) and have repaired ventricular septal defects successfully under direct vision with survival of 18 of 25 operated patients Swan and associates [289] refrigerated patients to about 28° and repaired ventricular septal defects under direct vision Du Shane et al [133] repaired ventricular septal defects in 20 children under direct vision with the aid of a mechanical pump oxygenator (p 1114) Sixteen of the 20 survived The period of open cardiotomy varied from 10 to 45 minutes Repair of the ventricular septal defect was accomplished by direct suture in 3 patients and by insertion and suture of a non absorbable polyvinyl (Ivalon) sponge into the opening in the other 17 patients The 16 patients who survived showed pronounced improvement in appetite weight gain increased exercise tolerance and a reduction in pulmonary arterial pressure postoperatively Atrioventricular and intraventricular conduction disturbances occurred in 9 patients

Indications for Surgical Repair There is no indication to repair small ventricular septal defects in patients in whom the left to-right shunt is small and there is no significant pulmonary hypertension At the other extreme also there is no surgical indication in patients with very large defects in whom pulmonary hypertension is so great that the right ventricular pressure is only slightly less than equal to or occasionally exceeds the pressure in the left ventricle and the magnitude of the shunt is very small Operation is indicated in patients with large ventricular septal defects in whom there is a large left to right shunt and pulmonary hypertension is of mild to moderate degree In such cases there will usually be disturbing clinical symptoms and electrocardiographic evidence of right and left ventricular hypertrophy

VENTRICULAR SEPTAL DEFECT WITH AORTIC INSUFFICIENCY

Occasionally a high ventricular septal defect situated just below the aortic valve is associated with a fibrous band which distorts the valve by drawing down one of the cusps and thus renders the valve incompetent [340] Or aortic insufficiency may be due to incomplete support of the medial cusp The physical signs are those of the ventricular septal defect (thrill and loud holosystolic murmur in the second third and fourth left interspace) plus a high pitched diastolic murmur of aortic insufficiency There is a low diastolic pressure due to the aortic insufficiency The electro-

cardiogram shows evidence of left ventricular hypertrophy and sometimes a prolonged P R interval Right ventricular hypertrophy and right bundle branch block patterns have been described in some cases [4, 1] Roentgenologic examination reveals enlargement of the left ventricle and perhaps also of the right and *prominent pulsations of the aorta and pulmonary* arteries Cardiac catheterization may disclose increased oxygenation of blood in the pulmonary arteries Because of the presence of a relatively high oxygen saturation in pulmonary artery blood together with the systolic and diastolic murmurs and evidence of left ventricular hypertrophy, the diagnosis of patent ductus may be made erroneously The clinical course is that of aortic insufficiency with eventual heart failure Bacterial endocarditis may also occur

COR TRILOCULARE BIATRIUM

There is complete or virtually complete absence of the interventricular septum [130] An atrial septum is present but may have a patent foramen ovale or other defect [3, 6] Other congenital cardiac lesions are often present [101, 246] The clinical picture and course *when uncomplicated* are those of a large ventricular septal defect but at least mild cyanosis is usually present

COR BILOCULARE

This occurs rarely About half of the patients with cor biloculare are Mongolian idiots Both the atrial and ventricular septa fail to develop or are vestigial and there is a single atrium a single ventricle and a common atrioventricular canal and valve There may be associated anomalies of the great vessels such as pulmonary atresia [80] common truncus arteriosus anomalous pulmonary veins and persistent left superior vena cava It is amazing that sometimes cyanosis fails to develop in patients with normal arterial trunks, presumably because of a functional if not an anatomic segregation of arterial and venous blood within a single atrium and ventricle As a rule cyanosis is present dyspnea develops and there is evidence of right ventricular hypertrophy

EISENMENGER S COMPLEX[141, 35, 180, 64, 148]

In its narrowest sense this refers to the combination of a ventricular septal defect overriding aorta, right ventricular hypertrophy and a normal or dilated pulmonary artery In the latter item it differs from the tetralogy of Fallot in which the pulmonary artery, valve or infundibulum is stenotic There is now a tendency to include in the Eisenmenger complex also cases of *ventricular septal defect* with a normal aortic root, but with a right to left shunt through the septal defect due to an associated pulmonary hypertension The latter is caused by an increased pulmonary arteriolar resistance of uncertain origin Thus the Eisenmenger complex represents essentially cases with ventricular septal defect and a right to-left shunt either because of pulmonary and right ventricular hypertension (right ventricular pressure equal to left ventricular) or because of an overriding aorta with unoxygenated right ventricular blood entering the aorta and thus reaching the systemic circulation In these cases also pulmonary hypertension is at least a contributory factor It should be noted that cases of the Eisenmenger complex resemble in their pathological physiology (a) cases of patent ductus arteriosus with right to left (reversed) shunt due to pulmonic hypertension and (b) cases of aortic pulmonic septal defect with pulmonary hypertension Furthermore, they resemble also cases of interatrial septal defect with pulmonary hypertension and right to left shunt but in these cases unlike the above there is no increase in left ventricular work and no left ventricular hypertrophy Cases of interatrial septal defect in which a right to left shunt occurs because of associated pulmonic stenosis (with high right ventricular but low pulmonary arterial pressure) are not included in the category of the Eisenmenger complex

There is clinical evidence and evidence from cardiac catheterization that the pulmonary hypertension in Eisenmenger's complex occurs progressively after birth, and that it becomes high enough to cause a reversal in a previous left-to right shunt some time between the ages of 6 and 12 or occasionally later Eisenmenger s complex occurs in those large and high ventricular septal defects in which there is an early large left to-right shunt with augmented pulmonary blood flow and enlargement of the left and right ventricles and pulmonary artery even before the shunt is reversed by severe pulmonary hypertension

The reversal of shunt may occur in infancy or early childhood if there is dextraposition of the aorta

The *clinical picture* is characterized by the relatively late appearance of cyanosis in childhood adolescence or early adult life The cyanosis is usually not as intense as in the tetralogy of Fallot and may occur only on exertion Otherwise the clinical picture is that described under high septal defect

Roentgenologic examination shows enlargement of the right and left ventricles prominent main pulmonary artery with increased vascularity of the mid and peripheral lung fields although the engorgement is often less than that in similar cases with left to right shunts[4]

Angiocardiography shows early opacification of the left ventricle and/or of the ascending aorta simultaneously with the pulmonary artery The increased vascularity of the lung fields distinguishes the Eisenmenger complex from the tetralogy of Fallot The enlarged pulmonary artery of Eisenmenger's complex may not be distinctive because there may be a post stenotic dilatation in Fallot s tetralogy

The *electrocardiogram* shows left or right axis deviation and may disclose evidence of right and left ventricular hypertrophy

Eisenmenger's complex is not amenable to surgical therapy

ISOLATED PULMONIC STENOSIS

Definition

Pulmonic stenosis denotes an impediment to the flow of blood from the right ventricle to the pulmonary vessels at the level of the infundibulum the valve or the main pulmonary artery

Pulmonic stenosis, as part of the tetralogy of Fallot, was always regarded as a common congenital cardiovascular lesion but isolated pulmonic stenosis was formerly considered to be a rare anomaly Largely as a result of cardiac catheterization studies, isolated pulmonic stenosis has now come to be recognized as one of the more common congenital cardiac abnormalities[184, 144, 129, 4, 4, 74, 73, 365] It represents 10 to 12 per cent of cases of congenital heart disease Many relatively large series of cases have been studied and reported[8, 270, 57, [illegible], 358, [illegible], 365]

Isolated pulmonic stenosis also termed pure or solitary' pulmonic stenosis denotes that *the ventricular septum is intact* but according to usage has included the cases with atrial septal defect or patent foramen ovale as well as those with intact atrial septum Pulmonic stenosis with interatrial septal defect (and right ventricular hypertrophy) is sometimes termed the trilogy of Fallot.[2, 8] After the tetralogy of Fallot isolated pulmonic stenosis with interatrial septal communication is the commonest cause of cyanotic congenital heart disease

Age and Sex

Most of the patients are between the ages of 20 and 30 and some between 30 and 50 when the lesion is recognized In the latter group the patients are more likely to be acyanotic Acyanotic patients with isolated pulmonic stenosis below the age of five are rarely seen probably because such patients are asymptomatic and there is no cyanosis to stimulate cardiac investigation There is no significant difference in sex incidence

Pathology

As a rule isolated pulmonic stenosis is the result of stenosis of the pulmonary valve, characterized by a dome like or conical fusion of the pulmonary cusps with a central perforation often only 2 to 4 mm in diameter Or pulmonary stenosis may be caused by scarring and narrowing of the pulmonary annulus and leaflets A bicuspid pulmonic valve is a common finding in valvular stenosis Isolated pulmonic stenosis with intact ventricular septum may also be due to infundibular stenosis[8, 57] In a series of 25 cases of isolated pulmonic stenosis operated by Glover et al [179] there were six instances of infundibular stenosis or of combined valvular and infundibular stenosis, the remaining were purely valvular Stenosis of the main pulmonary artery trunk has been reported and occasionally the narrowing may extend to the left main branch, less often to the right but not beyond

The infundibular stenosis may be located high low or intermediate in the outflow tract and occasionally there is more than one stenosis There is a *membranous type* characterized by a short localized fibrous diaphragm just below the pulmonic valve or more commonly a *fibromuscular type* characterized by a long narrow channel (myocardial infundibular stenosis) In the latter variety the outflow tract is hypertrophied in the membranous type there is a thin walled infundibular chamber In cases of combined infundibular and valvular stenosis the pul

monary artery is frequently hypoplastic The pulmonic valve is frequently bicuspid

The pulmonary artery is usually thin walled and dilated beyond the stenosis (poststenotic dilatation) and the right ventricle is hypertrophied The pathogenesis of the poststenotic dilatation is uncertain It may be due to atrophy of the wall because of the low pulmonary artery pressure, with secondary distention of the atrophic wall Or the distention may be caused by eddies of alternating high and low pressure distal to the stenosis, consequent to the ejection of blood through a constriction at high velocity [12] On the other hand, angiocardiographic and catheterization studies have disclosed that the diameter of the pulmonary artery in pulmonic stenosis varied widely, and that its width could not be correlated with the severity of the pulmonic stenosis as indicated by the pressure in the right ventricle or by the right ventricular pulmonary artery gradient [404] These findings suggested that the dilatation of the pulmonary artery in pulmonic stenosis was a coincident not a related lesion and that the combination represented two different congenital lesions, namely congenital pulmonic stenosis and congenital idiopathic dilatation of the pulmonary artery

The right ventricle is hypertrophied and its wall may be as thick as or thicker than that of the left ventricle The right atrium is usually dilated In fatal cases the organs frequently show signs of passive congestion, cardiac cirrhosis of the liver is especially common

The opening in the atrial septum, when present, was a patent foramen ovale in all the cases reported by Selzer and Carnes,[358] but Campbell[74] observed that true interatrial septal defects occurred with equal frequency There may also be anomalous pulmonary veins draining into the right atrium, in addition to the atrial septal defect Patent ductus arteriosus may be associated with isolated pulmonic stenosis or with pulmonic stenosis and an interventricular septal defect [269, 50a]

The cases of isolated pulmonic stenosis with and without atrial septal communication are presented as a unit because they have essentially similar clinical features, except for the presence of cyanosis in most cases with a septal communication However, this is inadequate to permit an absolute differentiation because cyanosis may be absent despite the communication in cases in which the interatrial shunt is from left to right [269]

Pathologic Physiology[144, 270]

The essential disturbance is an increased pressure in the right ventricle with a normal or diminished pressure in the pulmonary artery (see Catheterization, p 752) The right ventricular hypertension leads to right ventricular hypertrophy Normal cardiac output is maintained despite the obstruction Eventually the right side of the heart may fail, in consequence the cardiac output falls and the right ventricular diastolic, right atrial and systemic venous pressures rise The blood follows its normal pathway when the atrial septum is intact

In cases with patency of the foramen ovale or atrial septal defect there may be no significant shunt or the shunt may be from left to right if there is no rise in right atrial pressure Pressure changes during the cardiac cycle may be such as to produce minor varying left-to-right and right-to-left intermittent shunts In other cases distinct shunts from right to left occur during exercise only and in still others there is a continuous significant right-to-left shunt

In cases of pulmonic stenosis with associated extracardiac aortic pulmonary shunts such as patent ductus with or without ventricular septal defect, the blood flow in the extracardiac shunt is from left to right despite an elevated right ventricular pressure [50a]

Clinical Features

Symptoms and Course In the cases without atrial septal defect, the disease is usually asymptomatic for a long time [3] Sooner or later dyspnea on exertion or fatigability may occur and these are the commonest symptoms Sudden decompensation with right sided heart failure develops commonly in such cases Occasionally there is chest pain or syncope on effort, presumably due to inability of the right ventricle to increase its output during exertion [383, 212] In cases with atrial septal defect cyanosis occurs frequently especially with exertion Continuous cyanosis may appear shortly after birth but most often it appears later, occasionally after puberty or in adult life Cyanosis which appears only on exertion may later become persistent Clubbing of fingers and toes and polycythemia may accompany the cyanosis Squatting occurs occasionally in the cyanotic patients but not nearly as often as in cases of tetralogy of Fal

lot Inadequate weight gain is a common finding in the cyanotic children Pulmonary infections including tuberculosis occur more commonly in association with this lesion than with other congenital cardiac lesions but these have become less important since improvement in public health measures and the advent of antibiotics Right-sided heart failure usually appears in the third or fourth decade and is the chief cause of death The average age at death was 26 years in the series reported by Greene et al [183] but about 10 per cent survive the age of 50 and some live beyond 70 [177] Bacterial endocarditis occurs occasionally Cerebral abscess may be a cause of death in cases in which there is an associated atrial communication

Physical Signs There is a long rough *systolic murmur*, usually maximal in the second left interspace transmitted toward the left cervical region and occasionally to the back Occasionally it is loudest in the third left interspace Stenosis of the infundibulum is more likely to be represented by a systolic murmur in the fourth or third left interspace valvular stenosis by a murmur in the second or third Almost always there is a palpable thrill in the area of maximal intensity of the murmur The second sound may be normal but it is often weak or absent It is usually single sometimes split Occasionally there is a diastolic murmur of pulmonary insufficiency

Roentgenology[207, 139, 49]

In mild cases or early stages of the disease the heart is of normal size in more severe or advanced cases there may be evidence of right ventricular enlargement and the right atrium may also be enlarged if there is a significant atrial septal defect In these cases also the pulmonary vascular markings are diminished and the pulmonary fields may appear unusually clear However in the occasional cases of pulmonic stenosis and interventricular septal defect in which the shunt is from left to right the pulmonary fields may show normal or increased vascularization [10, 141] This applies also to occasional cases of pulmonary stenosis with interatrial septal defect in which a left to-right shunt is associated with an increased pulmonary blood flow [141]

In cases with valvular stenosis the usually associated post stenotic dilatation of the pulmonary artery produces a *marked convexity of the middle left cardiac salient* just below the aortic knob Its pulsations are prominent Rarely this is of aneurysmal size The main branches of the pulmonary artery are usually of normal or diminished size and their pulsations diminished The association of a prominent main pulmonary artery of increased pulsation, with diminished pulsation of the left and right pulmonary arteries and clear lung fields is diagnostic of pulmonic stenosis In occasional cases of valvular stenosis without post stenotic dilatation the pulmonary artery salient is normal In the rare instance of isolated pulmonary infundibular stenosis the pulmonary artery segment is usually small Post stenotic dilatation may involve the distal portion of the infundibulum and the pulmonary conus may form a prominent convexity on the left border above the left ventricular contour

When pulmonic stenosis is associated with post stenotic dilatation and a prominent pulmonary artery shadow, its roentgenologic appearance simulates the various conditions associated with pulmonary hypertension and a large pulmonary artery namely atrial or ventricular septal defect or patent ductus Fluoroscopic study of the pulmonary artery pulsations and of the peripheral pulmonary vascular field aids in diagnosis (p 795)

Angiocardiography

This is not usually of major diagnostic importance except to determine the presence of complicating lesions However the stenosis itself is more commonly demonstrable in cases in which it is isolated than when associated with interventricular septal defects [183] This is seen as an interruption in the flow of contrast medium at the site of the pulmonic valve or a narrowing in the infundibulum The actual site of the stenosis may be demonstrable more regularly by the rapid biplane method of Lind (p 15) or by selective angiocardiography after direct injection of the contrast medium into the outflow tract of the right ventricle (Fig 10 p 16) Angiocardiography confirms the presence of right ventricular enlargement and dilatation of the main pulmonary artery It may also indicate the presence of an interatrial shunt by early opacification of the left atrium from the right

Electrocardiography

This usually shows right axis deviation (occasionally left axis deviation) [5] right ventricular hypertrophy or incomplete right bundle branch block [1, 8] [5] In mild cases there may be no axis deviation In severe cases

with right ventricular hypertrophy there is usually a tall R wave, S-T segment depression and T wave inversion in V_1 and other right precordial leads. The height of the R wave diminishes after successful operation.[185, 44, 46, 24] There may be tall P waves especially in lead II suggesting atrial hypertrophy.

Cardiac Catheterization: Pressures and Oximetry

The striking and *diagnostic finding* is the *elevation of right ventricular pressure with a relatively low pulmonary artery systolic pressure, and with a consequent significantly increased gradient between them.* Normally the gradient is minimal, the pulmonary artery and ventricular systolic pressures being virtually identical. As the catheter is withdrawn from the pulmonary artery to the right ventricle, a ventricular septum because in the presence of a large ventricular septal defect right and left ventricular pressures are equal. Although the pulmonary artery pressures are relatively less, their absolute values are normal or very slightly diminished. In the presence of infundibular stenosis, as the catheter is withdrawn, the systolic pressure in the pulmonary artery and that in the infundibulum distal to the stenosis are the same (Fig. 130). Proximal to the stenosis there is a rise in systolic pressure in the infundibulum and this remains the same in the rest of the right ventricle. The diastolic pressure falls as the catheter is withdrawn from the pulmonary artery past the pulmonic valve and remains constant in the right ventricle both proximal and distal to the infundibular stenosis.

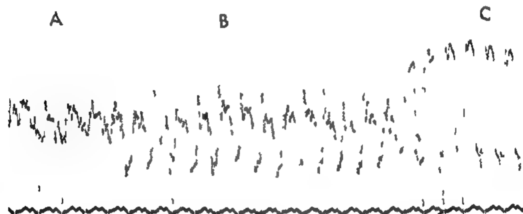

Fig. 130. Pressure readings in a case of pulmonary valvular stenosis as intracardiac catheter is withdrawn from pulmonary artery (A) to infundibulum (B) to right ventricle (C). Pulmonary pressure 37/13, infundibular pressure 38/7, right ventricular pressure 61/6 mm. Hg.

characteristic pressure curve, showing a sharp rise, is produced. In mild or moderate cases the right ventricular systolic pressure ranges from 40 to 100 mm. Hg, and in very severe cases it is usually above 100 mm. Hg. However, there is no close correlation between clinical severity and right ventricular pressures in individual cases; asymptomatic patients may have right ventricular systolic pressures exceeding 100 mm. Hg. In the relatively milder cases reported by Joos et al.[274] it ranges from 28 to 134 mm. Hg; in the severe cases reported by Blount et al.[46] from 110 to 221, with an average of 168 mm. Hg. In the acyanotic cases the right ventricular systolic pressure occasionally exceeds that in the systemic arteries. This denotes closure of the

In combined valvular and infundibular stenosis, there is a rise in systolic pressure when the catheter is withdrawn from the pulmonary artery into the infundibulum (between the valvular and infundibular stenoses) and a further rise as the catheter is drawn proximal to the infundibular stenosis. The right atrial pressure is usually normal unless there is right sided heart failure. In cases with atrial septal defect the right atrial pressure may be slightly elevated. Occasionally the catheter passes through the atrial septal communication, then it may be determined that left and right atrial pressures are approximately equal, or one or the other is slightly higher.

Oxygen saturation is normal in the various

chambers if the atrial septum is intact When there is an atrial septal communication the oxygen content of right atrial blood is significantly higher than that in the vena cava Identical oxygen concentrations in the right atrial and right ventricular blood exclude a ventricular septal defect

Surgical Treatment

Surgical treatment is generally effective and consists of direct enlargement of the stenotic passage sufficiently to diminish greatly or abolish the ventricular infundibular or ventricular pulmonic gradient [254, 55, 55b, 318, 4, 75, 365]

Exact *indications* have not become stabilized but are being extended as the technical procedures and results improve and as surgical mortality diminishes Operation is indicated in isolated pulmonic stenosis in which cyanosis is caused by a right to left interatrial shunt It is indicated in patients with or without cyanosis if the pulmonic stenosis produces considerable disability due to exertional dyspnea or fatigability Finally it may be indicated whether or not cyanosis or symptoms are present if severe hemodynamic disturbances are present as denoted by a right ventricular systolic pressure of more than 75 to 100 mm Hg or a gradient of more than 45 to 70 mm Hg or if there is electrocardiographic evidence of marked right ventricular hypertrophy On the other hand there is no indication for operation at present on acyanotic asymptomatic patients with right ventricular pressures of less than 75 mm Hg Silverman et al [365] observed a good correlation between the electrocardiographic findings and right ventricular systolic pressures below and above 100 mm Hg All 20 of their 50 patients with pressures of 100 mm Hg or more showed one or several of the following (1) an R wave in V_{4R} or V_1 of 20 mm or over (2) P pulmonale" i e peaked P waves of 3 0 mm or more in lead II and right precordial leads (3) S T segment depressions and T wave inversions in right precordial leads Those with right ventricular pressures below 100 mm Hg sometimes had tall R waves in right precordial leads but less than 20 mm there were no S T and T wave alterations or P pulmonale

The preferred age for operation appears to be between 5 and 20 since operative mortality has been higher in cases outside this age range But sometimes it is necessary to operate during infancy when severe pulmonary stenosis is associated with right sided congestive heart failure Medical measures to control the heart failure should be administered preoperatively but only for a brief period

Surgical Procedure Until recently the preferred operative procedure was the Brock type of transventricular valvulotomy The Brock procedure refers to resection and dilatation of the pulmonary valve[55] or resection of an infundibular stenosis[55b] through an incision in the right ventricle without direct palpation or visualization of the stenosis More recently, open' procedures permitting correction of the lesion under direct vision have been used with the aid of hypothermia or of a donor cross circulation with venous inflow occlusion or by a pump to by pass the right heart The Blalock subclavian pulmonic or the Potts aortic pulmonic shunt type of operation employed in cases of the tetralogy of Fallot is contraindicated in isolated pulmonic stenosis Cyanotic patients with pulmonic stenosis and atrial septal defect in whom a Blalock operation was performed because of a mistaken diagnosis of tetralogy of Fallot eventually suffered severe heart failure with pulmonary congestion This was due to the fact that the left atrium postoperatively received not only right atrial blood through the septal defect but also a greatly increased pulmonary venous return due to the improved pulmonary circulation

Access to the heart is obtained by a parabolic inframammary incision through the third left anterior intercostal space The presence and site of valvular or infundibular stenosis are readily ascertained In valvular stenosis the post-stenotic dilatation of the main pulmonary artery is observed and a systolic thrill is palpable just distal to the valve The thrill may be abolished by digital invagination of the pulmonary artery with obliteration of the valve In infundibular stenosis the thrill is felt over the wall of the outflow tract distal to the infundibular stenosis and proximal to the valve A thin walled infundibular chamber but no post stenotic dilatation of the pulmonary artery, is seen in isolated infundibular stenosis

Valvular stenosis is corrected by making a small incision through the right ventricular wall inserting a probe to explore the stenotic area and following with a valvulotome designed with a spearhead blade with a short

blunt tip With the latter instrument the valve is repeatedly resected with progressively wider blades and further dilated by a series of sounds A similar procedure has been performed by retrograde approach to the valve through an incision in the pulmonary artery[389]

Infundibular stenosis is corrected by first passing a resecting rongeur through a right ventricular incision and exploring the ventricle with it to ascertain the site and nature of the stenosis Then the jaws of the resector are opened to engage the full crest of protruding tissue and the tissue cut away repeatedly For adolescents and older patients a more thorough resection has been claimed by use of a guillotine type of knife such as is used in mitral valve surgery, and by use of a large dilator for the valvular stenosis, such as is used in the surgical treatment of aortic stenosis

A successful surgical procedure should be checked at the time of operation by demonstrating that the ventricular pulmonary or ventricular infundibular gradient has been minimized (to less than 10 mm Hg) or abolished There should also be apparent an increased pressure of the infundibulum and pulmonary artery and generalization of the previously localized thrill

Open valvuloplasty has been used to correct pulmonic stenosis, because of dissatisfaction with the blind approach of the Brock procedure Dodrill and associates[1,3] reported the performance of pulmonary valvuloplasty under direct vision using a mechanical heart for a complete by pass of the right side of the heart, in a case of pulmonic stenosis Swan and associates[389] have corrected pulmonic stenosis by a transarterial (pulmonary artery) approach after hypothermia has been induced (p 1112) to permit cessation of the circulation and direct visualization of the lesion

The chest is entered by a transverse sternum splitting incision through the fourth intercostal space on the right and the third intercostal space on the left The azygos vein is ligated and ligatures placed around the venae cavae The pulmonary artery is clamped distally to avoid back bleeding A Potts curve-toothed aortic clamp is placed longitudinally on a bite of the main pulmonary artery just distal to the valve ring a small incision is made into this bite of aorta and the ligatures on the venae cavae are promptly tened to cut off the blood flow into the heart The heart beats at a slow rate of 4 to 10 per minute and after a few beats the right ventricle is emptied of blood and the operative field is dry The conical stenotic valve is clearly visualized its tip grasped with a toothed forceps and an incision made with a scissors from the lumen of the valve to the valve ring A second incision is made 180 degrees away again extending from the valve opening clear to the base of the valve The valve is thus divided into two cusps with commissures If the valve rim is too thick or the cone very long the distal segment of the valve is excised The finger or an instrument is inserted through the valve into the right ventricle to exclude the presence of an associated infundibular stenosis The entire chest and especially the entire heart is flooded with Ringer s solution to expel air through the open pulmonary artery and thus to avoid air embolism The ligature on the superior vena cava is released to allow blood to mix with the Ringer s solution then the clamps on the aorta and pulmonary artery are removed and finally the ligature on the inferior vena cava Blood flow is now restored The incision in the pulmonary artery is sutured hemostasis effected the thorax closed and postoperative pleural drainage set up The patient is then rewarmed (p 1113) The entire operative procedure can usually be performed during three or four minutes of total occlusion and an additional minute for occlusion of the inferior vena cava

Operative Mortality and Results The mortality rate is equally low in the closed and open procedures for *valvular stenosis*, generally below 10 per cent but more recently well below 5 per cent[56, 173, 41, 388, 216, 21a] However resection of an infundibular stenosis by the Brock technique is associated with a mortality rate of about 15 per cent

Clinical improvement in terms of disappearance of cyanosis, amelioration of other symptoms and increased exercise tolerance has likewise been excellent in the great majority of cases, regardless of technical approach On the other hand comparative preoperative and postoperative hemodynamic studies have disclosed inconstant and frequently inadequate reductions in right ventricular pressure and insufficient diminution of the ventricular pulmonary gradient[268, 281, 46, 34, 216] (Fig 131) Swan et al[388] have reported that transpulmonary valvuloplasty under direct vision had afforded more uniformly satisfactory results with complete reduction of right ventricular pressure virtually to normal and complete or almost complete elimination of the gradient across the obstruction Thus in operations by the closed technique Blount et al[46] reported that the right ventricular systolic pressure *fell from* an average of 168 mm Hg preoperatively to an average of 65 mm Hg postoperatively *still* leaving a persistent postoperative gradient which averaged 43 mm In the group operated on transarterially under direct vision, the

average preoperative right ventricular systolic pressure was 116 mm Hg and fell postoperatively to normal in every case The average postoperative systolic pressure was 28 mm Hg Since the average postoperative pulmonary arterial pressure was [illegible] mm Hg the average gradient was only about 6 mm Hg after operation

Diminution in the intensity of the systolic murmur increased intensity of the second pulmonic sound occasional appearance of a pulmonic diastolic murmur presumed to be due to induced pulmonary insufficiency of no clinical significance, slight postoperative increase in transverse diameter of the heart and diminution in electrocardiographic signs of

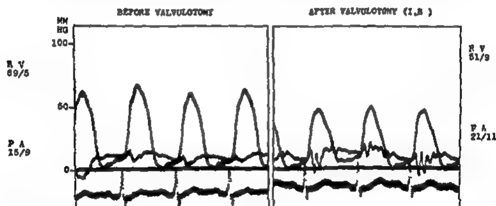

Fig 131 Simultaneous pressure pulses in a case of pulmonary valvular stenosis before and after valvulotomy Note systolic right ventricular pulmonary artery gradient of 54 mm Hg moderately reduced to 30 mm Hg following Brock type of valvulotomy (Courtesy Dr A Gordon)

right ventricular hypertrophy are among some of the results of the operation Transient heart failure and subacute bacterial endocarditis have been observed postoperatively

THE TETRALOGY OF FALLOT

The combination of a ventricular septal defect with pulmonic stenosis dextroposition of the aorta and right ventricular hypertrophy is known as the tetralogy of Fallot [153] It is the commonest clinical form of congenital heart disease in adult life which is associated with cyanosis and clubbed fingers Tetralogy of Fallot does not refer to a sharply defined pathologic entity since the location and character of the pulmonic stenosis the nature and size of the ventricular septal defect and the degree of dextroposition vary greatly, individually and in combination

Embryology and Pathogenesis

Cephalad to the primitive ventricle and separated by a fold is another chamber termed the bulbus arteriosus, this in turn is similarly demarcated cephalad from the truncus arteriosus During the fifth to the eighth weeks the proximal (caudal) portion of the bulbus is absorbed into the right ventricle as the infundibulum or the pulmonary conus arteriosus The remainder of the bulbus and the truncus arteriosus are divided by a spirally (clockwise) twisted septum to form the pulmonary artery and the aorta As noted above (p 744) this septum also grows caudally to help form the membranous part of the interventricular septum and thereby to close the interventricular foramen The normal growth and twist of the truncus bulbar septum is such as to cause the pulmonary artery to arise from the right ventricle and the aorta from the left ventricle

The pathogenesis of the lesions forming the tetralogy of Fallot and similar combinations of malposition of the great vessels has been the subject of controversial theories which have been reviewed by Lev and Saphir [249] These authors applied the studies of Pernkopf and Wirtinger[318] to their own cases and reached the conclusion that the basic abnormality is a disturbance in the absorption of the bulbus as first postulated by Keith [232] This disturbance is said to be due to an excessive backward torsion of the proximal portion of the bulbus

An ingenious theory supported by many

case studies was formulated by Spitzer[375] who attributed the lesions in the tetralogy of Fallot to two essential factors (1) An inadequate clockwise torsion or even a counter clockwise torsion of the truncus and bulbus arteriosus (see above) and of the septum which divides this vascular tube (2) Persistence of the reptilian right aorta which should atrophy if development is normal

A new ontogenetic theory has recently been proposed by de la Cruz and da Rocha[115]

Pathology[16]

Since the proper development of the truncus and bulbus arteriosus and their common septum determines the normal position and size of the aorta and pulmonary artery and the completion of the interventricular septum it is obvious that a disturbance in that development would cause not a single but multiple defects Hence the frequency of the tetralogy of Fallot as compared with uncomplicated malposition of the great vessels Most often the aorta appears displaced to the right so as to arise from both ventricles (reitende or riding aorta), or it may arise from the right ventricle alone (simple transposition or dextroposition of the aorta) Occasionally the origin of both vessels is transposed the aorta arising from the right and the pulmonary artery from the left ventricle (crossed or complete transposition of the great vessels) (p 762) The positions of the aorta and pulmonary artery may appear reversed with respect to each other, but their origin is from the proper ventricle (corrected transposition)[37] The degree of dextroposition of the aorta in the tetralogy of Fallot is very variable The operative results have been poor when most of the aorta arises to the right of the ventricular septum

The pathology of pulmonary valvular, pulmonary infundibular and pulmonary arterial stenosis has been described (p 749) In an anatomic study of 48 hearts with the tetralogy of Fallot,[68] there was infundibular stenosis alone in 16 combined infundibular and valvular stenosis in an additional 27 In 2 there was only valvular stenosis and in 3 only pulmonary atresia Surgical experience indicates a considerably higher incidence of solitary or predominant valvular stenosis in cases of tetralogy of Fallot

If the pulmonic stenosis is severe or the pulmonary artery or valve is completely occluded (pulmonary atresia), the ductus arteriosus must be patent to permit life The ductus may communicate with the pulmonary artery, which is patent distal to the atretic portion Death usually supervenes after a few months as the ductus becomes obliterated Rarely a blood supply to the lungs is maintained by the development of a remarkable collateral circulation arising from the aorta or its branches[6] as in cases of persistent truncus arteriosus with bronchial arteries supplying the lungs The collaterals consist of dilated bronchial, esophageal, thyroid mediastinal or other vessels

The ventricular septal defect, the third element in the tetralogy of Fallot, is usually at the upper portion of the interventricular septum, anterior to the undefended space Occasionally the entire septum is lacking

The right ventricle is considerably hypertrophied In most cases its wall is thicker than that of the left ventricle When the site of the pulmonary stenosis is in the infundibulum a third (accessory) ventricular chamber may be formed in the right ventricle just above the stenosis

In about three quarters of the cases of tetralogy, the aortic arch is on the left, in one quarter on the right In 12 to 20 per cent of the cases there is an associated aberrant right subclavian artery[318]

A tendency to the development of widespread pulmonary thrombosis has been reported by Rich[3]

The so called *pentalogy of Fallot* refers to the four elements of the tetralogy in combination with patency of the foramen ovale or interatrial septal defect[149] In a series of 25 necropsy cases of tetralogy of Fallot, 10 were found to have a functional atrial septal defect, averaging 9 by [illegible] mm, but not correlated with any of the clinical features[52]

Pathologic Physiology

As a result of the pulmonic stenosis, the right ventricular pressure and the work of the right ventricle are increased and the chamber becomes enlarged and its wall hypertrophied (See Cardiac catheterization p 759) Right ventricular venous blood is shunted through the interventricular septal defect into the overriding aorta The aorta also receives oxygenated blood from the left ventricle and the total systemic blood flow exceeds that through the narrowed pulmonary artery The subnormal pulmonary blood flow[35] and consequent deficiency in arterial oxygenation are

fundamental elements in the circulatory disturbance (See p 732 for cardiac output and size of shunt) Arterial oxygen unsaturation results in cyanosis and in polycythemia

Clinical Features

The tetralogy of Fallot is the one form of congenital heart disease which accounts for the great majority of cases of persistent cyanosis and clubbing in adolescence and adult life (morbus caeruleus) *Cyanosis* is present from infancy It may be absent or slight in the first few months of life while the ductus arteriosus is still patent and serves as an accessory route for blood (from the aorta) to reach the pulmonary circulation However there are cases of tetralogy of Fallot called acyanotic because of the absence or virtual absence of a right to left shunt at rest There were ten such cases among 80 collected by Wood et al [4,5] Rowe et al [342] reported four cases of atypical tetralogy of Fallot without cyanosis and with increased pulmonary vascularity despite pulmonic stenosis *Clubbed fingers* usually appear months or years after the appearance of cyanosis Eventually clubbing may be marked while the cyanosis is only slight The cyanosis may become intensified during exercise pulmonary infections and late in the course of the disease when right sided heart failure develops The increased cyanosis on exercise may be due to the inability of the increased venous return to pass the pulmonary stenosis hence more of the venous return is shunted from right to left into the aorta *Cyanosis retinae* is usually present and occurs early *Suffusion of the eyeballs* is often associated with secondary *polycythemia*

The pathogenesis of cyanosis and clubbing *in congenital heart disease was discussed* above (p 731 732)

Dyspnea on exertion is a common complaint Paroxysmal attacks of dyspnea may occur generally after exercise, and accompanied by an intensification of cyanosis Exercise may induce syncope Orthopnea is absent in fact the dyspnea may be intensified when the patient is erect (orthostatic dyspnea) Fatigability and weakness are frequent symptoms Characteristically the child with tetralogy of Fallot assumes the squatting or knee-chest position when dyspneic or tired from exertion The physiology of the squatting position is uncertain It is presumed that the peripheral systemic resistance is somehow increased the aortic and left ventricular pressure raised and thereby the right-to left shunt diminished Or else the venous return is diminished and a greater percentage of the unoxygenated blood passes by way of the pulmonary artery Arterial oxygen saturation is promptly increased by squatting

Polycythemia often of intense degree is usually present The blood volume is increased primarily due to an increase in red cell volume [398] The hematocrit is very high Quite frequently and especially in the late stages of the disease patients suffer from dizziness, syncopal attacks epileptiform convulsions and transient or permanent paralyses Death may occur during a syncopal attack These cerebral symptoms are secondary to anoxia of the brain and are probably related to the vascular disturbances associated with polycythemia Cerebral thrombosis, encephalomalacia and cerebral hemorrhage may occur Epistaxis hemoptysis and hematemesis have also been reported as resulting from the polycythemia Brain abscess is more often associated with this than with any other congenital cardiac lesion [3,9] Orthostatic albuminuria due to disturbance of the renal circulation has been noted The patients with tetralogy of Fallot may be of normal intelligence or they may be mentally and physically retarded

Cardiac Signs Usually there is a *systolic murmur* to the left of the sternum in the second or third interspace occasionally in the fourth It has been claimed that the lower location corresponds to an infundibular stenosis the higher to a pulmonary valvular or arterial stenosis The murmur may or may not radiate to the cervical vessels The *systolic murmur is usually absent in pulmonary atresia*

A systolic *thrill* is often present but less frequently than in uncomplicated cases of pulmonic stenosis or ventricular septal defects

The *second pulmonic sound* is weak or absent but occasionally it is normal In pulmonary atresia and occasionally in pulmonary stenosis the second pulmonic sound is normal or loud and clear and presumably represents the second aortic sound transmitted from the dextroposed aorta There is no diastolic murmur The presence of the latter suggests some other lesion or an additional lesion besides the tetralogy of Fallot

Precordial bulging systolic pulsation in the

second and third interspaces and epigastric pulsation may result from the hypertrophy of the right ventricle

Roentgenology

The roentgenologic findings have been described by Pipp[307] The following are the usual features after the first few years of life when the heart appears small or only slightly enlarged

Fig 132 *A* Tetralogy of Fallot Coeur en sabot configuration
B Angiocardiogram of same case Simultaneous opacification of aorta and pulmonary artery

Fig 133 Tetralogy of Fallot *A* Posteroanterior view Note coeur en sabot configuration is not present
B Angiocardiogram of same case Left oblique view Simultaneous opacification of aorta and pulmonary artery

1 The left lower contour is plump and prominent and the apex is elevated and blunted resembling a sheep's nose The blunting of the left contour, often associated with a transverse rectangular enlargement gives rise to the description of *coeur en sabot* (like a wooden shoe) (Fig 132) This contour represents the hypertrophied and rotated right ventricle This differs from the aortic configuration (p 689) in which the left lower contour is elliptical and not cut off, and in which oblique views disclose enlargement of the left ventricle not of the right In general the cardiac enlargement in tetralogy of Fallot is not pronounced, and the coeur en sabot

configuration is usually absent in children (Fig 133)

2 In some cases the waist of the heart forms a concave depression i e, *the left mid dle contour formed by the pulmonary artery* is small or absent In the left anterior oblique view the pulmonary window is abnormally clear There is no pulmonary congestion The hilar pulmonary vessels are usually small and their pulsations are not visible These findings contrast with the prominent pulmonary arterial shadow in Eisenmenger's tetralogy and in atrial septal defect In other cases the left border of the heart is straight or convex and the pulmonary salient may be prominent This depends on the size of the pulmonary artery In valvular stenosis with post stenotic dilatation the latter causes a prominence of the pulmonary salient But in these cases also the pulmonary branches are small and the pulmonary fields are clear owing to dimin ished vascular markings

3 The shadow of the great vessels may be narrow in the anterior posterior view but the aortic shadow becomes wider and prominent in the left-anterior-oblique view

4 In about 20 to 25 per cent of cases there is a right aortic arch (p 781) visible as a prominence of the aortic knob to the right of the sternum within the shadow of the su perior vena cava

Angiocardiography[1, 8, 210]

There is a prompt passage of the Diodrast from the right ventricle simultaneously into the aorta and pulmonary artery The aorta and all its branches are visualized within 3 seconds after injection instead of in 5 or 6 seconds as is normal Relatively little of the contrast media enters the pulmonary artery whereas a normal or large pulmonary artery is visualized in Eisenmenger's tetralogy

The opacification of the aorta is not only prompt but dense in contrast with the early but faint opacification which may occur with atrial septal defects The exact site and na ture of the stenosis are demonstrable in not more than 20 to 50 per cent of cases and somewhat better with rapid biplane angio cardiography[211] Angiocardiography is of value also in disclosing the anatomy of the aortic arch and subclavian arteries in differentiating other cyanotic cardiac anomalies (such as pul monic stenosis with interatrial communica tion Eisenmenger complex and transposition of the great vessels) and in detecting as sociated anomalies such as a *persistent left* superior vena cava which may obscure the operative field It is also of value in disclosing *the availability of a pulmonary artery to be used for the Blalock anastomosis*

The left anterior oblique or left lateral views are ordinarily used in angiocardiography to visualize the two sides of the heart simul taneously but in some cases the opacified superior vena cava or dextroposed aorta ob scures the outflow tract of the right ven tricle in these projections Marder and Scott[212] found that the right anterior oblique projec tion provided unobstructed visualization of the infundibulum of the right ventricle and was valuable in demonstrating the infundibu lar stenosis seen in the tetralogy of Fallot es pecially by the technique of biplane right-angle serial exposures

The Electrocardiogram

There is usually a pronounced right axis deviation and there may be an RS T de pression and an inverted T in leads II and III Electrocardiographic evidence of right ven tricular hypertrophy was found in all of a series of 52 cases studied by Woods[47] es pecially in the precordial leads (p 115) Tall pointed P waves were found in 35 per cent especially in lead II

The Circulation Time

The injection of 3 minims of ether diluted with 10 minims of saline produces pares thesias of the lips and extremities due to the drug's entrance into the systemic circulation[29] Arm to-tongue (saccharin) time may be abbreviated almost to the ether time since the saccharin passes directly into the systemic circulation by way of the shunt without traversing the pulmonary circulation as it usually does The right ventricle-to-ear time may be determined by injecting Evans blue dye (T 1824) into the catheter placed in the right ventricle and determining its time of ar rival in the ear by an ear oximeter Normally the time is 8 to 10 seconds In the tetralogy of Fallot it is less than 5 seconds In other right to-left shunts such as pulmonary stenosis with interatrial septal defect the time is usually be tween 6 and 8 seconds

Cardiac Catheterization

The right ventricular pressure is elevated *The pulmonary arterial pressure is lower than that in the right ventricle* denoting pulmonary stenosis Occasionally the catheter may pass through the ventricular septal defect from the

right ventricle into the aorta The establishment of the type of stenosis by successive pressure measurements as the catheter is withdrawn from the pulmonary artery to the infundibular region to the right ventricle has been described (p 752) The right ventricular aortic and systemic arterial pressures are equal when the septal opening is large and the aorta considerably dextroposed

The *oxygen concentration* in the right ventricle significantly exceeds that in the right atrium as in other cases of ventricular septal defects

In many cases of tetralogy of Fallot the flow in the pulmonary capillaries exceeds that in the pulmonary artery indicating a significant collateral circulation to the lungs,[35] but the effective pulmonary blood is still diminished The pulmonary blood flow in Eisenmenger's complex is normal or increased

Oximetry

The resting arterial oxygen saturation is usually between 70 and 85 per cent with a range between 45 and 90 During exercise, continuous recordings with the Millikan ear oximeter have disclosed a striking fall in oxygen saturation[289] which is associated with an increase in cyanosis In normal persons there is no reduction in oxygen saturation during exercise Furthermore, patients with the tetralogy of Fallot experience a fall in oxygen consumption per liter of *ventilation during exercise* whereas normal individuals consume more oxygen per liter of ventilation under the same conditions Patients with the tetralogy of *Eisenmenger may experience a fall in oxygen* saturation during exercise but their $\frac{\text{oxygen consumption}}{\text{ventilation}}$ ratio rises in normal fashion [illegible] When normal persons breathe 100 per cent oxygen the arterial oxygen saturation rises from about 97 per cent to 100 per cent within three minutes Patients with tetralogy of Fallot require 10 to 15 minutes under the same circumstances to reach maximum oxygen saturation (which is still below normal)[200]

Differential Diagnosis (p 793)

Course and Complications of Tetralogy of Fallot

Most patients with the tetralogy of Fallot die in the first two decades of life as a result of congestive heart failure cerebral lesions complicating polycythemia bacterial endocarditis or pulmonary infections including tuberculosis Occasionally, however, patients reach adult life and are capable of normal activity with few symptoms The greatest longevity was reported in the case of a famous American musician who died of a stroke at the age of 59[418] Middleton and Ritchie[285] reported another case of tetralogy of Fallot in which death from congestive heart failure occurred at 45

Surgical Treatment

Blalock Taussig Operation and Aortic Pulmonary Shunt The objective of these operations for Fallot's tetralogy is to increase the pulmonary blood flow and the oxygenation of *blood by anastomosing a systemic artery to a* pulmonary artery These operations are indicated for other congenital cardiac lesions with diminished pulmonary blood flow, including tricuspid atresia pseudotruncus arteriosus single ventricle with pulmonary stenosis and some cases of pulmonary atresia Shunt operations are feasible only if there is a pulmonary artery or branch of sufficient size to receive the blood flow from a systemic artery For this reason, among others, angiocardiography may be necessary to obtain exact anatomic knowledge of the anomalies especially if a direct attack is considered

In the procedure devised by Blalock and Taussig[43] a subclavian or innominate artery is anastomosed end to-side (occasionally end to end) to the right or left pulmonary artery, near its origin In the procedure of Potts *Smith and Gibson*[319] a direct side-to-side anastomosis is made between the aorta and pulmonary artery, with the aid of a clamp which does not completely interrupt the circulation *in these vessels during* the anastomosis Blalock usually makes his incision in the third right interspace but when preoperative examination reveals a right aortic arch, the incision is on the *left side* Potts performs an aortic pulmonary anastomosis on the left side if there is a normal left aortic arch a subclavian pulmonary anastomosis also on the left side if there is a right aortic arch

Ideally patients should be operated upon between the ages of three and twelve The severity of anoxemia incapacity, dyspnea and degree of reduction in pulmonary blood flow response to exercise and failure to gain weight are factors determining the urgency of the operative procedure

The *results* of successful operation are often dramatic and the clinical improvement

striking[307, 317] The pulmonary blood flow and oxygen saturation are increased Cyanosis disappears and exercise tolerance is greatly improved so that previously incapacitated children can run and play However there is some enlargement of the heart postoperatively It is theoretically probable that many of these operated patients will subsequently succumb to congestive heart failure as do patients with congenital patent ductus arteriosus or other arteriovenous shunts However during the period that has elapsed there have been remarkably few instances of heart failure due to this cause

The mortality rate in the first 857 operations performed by Blalock varied from 11 to 25 per cent according to the age group with an over all mortality of 15 7 per cent and an additional 2 per cent mortality in the 8 months following the operation[307] The clinical result was good in 77 3 per cent and fair in an additional 3 9 per cent only 3 1 per cent being unimproved Operative complications included cardiac arrest hemorrhage cerebral thrombosis hemorrhagic pleural effusions pulmonary edema pneumothorax and local thrombosis at the anastomotic site In some cases the operation could not be completed because the pulmonary pressure was too high there was a single pulmonary artery the pulmonary arteries were too small or the systemic artery was too short to permit anastomosis In 4 per cent there was an incorrect preoperative diagnosis of tetralogy in patients found to be suffering from complete transposition of the aorta a single ventricle with pulmonic stenosis pseudotruncus arteriosus and others Bacterial endocarditis or cerebral abscess occurred occasionally in the first few months or first few years after the operation In a series of 500 operations for cyanotic heart disease Potts[318] reported a mortality of 15 per cent among children from 2 weeks to 3 years of age but only 2 8 to 4 6 per cent in those beyond the age of 3 years

In a report of 200 cases of cyanotic congenital heart disease essentially the tetralogy of Fallot operated on over a 4 year period Campbell and Deuchar[76] noted an operative mortality of 12 per cent and good or very good results in 68 per cent In the 165 cases of tetralogy of Fallot alone the operative mortality was 8 5 per cent and good results were obtained in over 75 per cent They commented that the improvement in comparison with the preoperative state was especially dramatic at first but that in time it appeared less striking because of comparison with the state of the normal child

Valvulotomy and Infundibular Resection for Tetralogy of Fallot The Blalock anastomosis does not alleviate the anatomic abnormalities in the tetralogy of Fallot and produces an additional anomaly a patent ductus Therefore, despite the encouraging and often dramatic results observed with that procedure efforts have been made to attack the tetralogy directly and to repair the anatomic disturbances responsible This has been accomplished primarily by pulmonary valvulotomy when the stenosis was located at the valve or by infundibular resection in cases of infundibular stenosis or by both The procedures have been described (p 753) In 30 cases thus treated there was an over all mortality of 23 3 per cent 20 per cent in cases of valvular and 33 3 per cent in cases of infundibular stenosis This was regarded as not significantly higher than the mortality in the early series of cases operated on by the Blalock procedure Campbell Deuchar and Brock[78] reported the results in 100 patients with Fallot s tetralogy operated on by the direct procedure 45 of them had infundibular resection alone and 55 a pulmonary valvulotomy but 18 of these required an infundibular resection as well The gross mortality was 11 per cent in cases operated on by valvulotomy 18 per cent in those operated on by infundibular resection These compared with an 8 per cent mortality rate found by the same authors in 165 cases of Fallot s tetralogy treated by the Blalock shunting procedure Two thirds of the patients treated by the direct procedures obtained good or very good results the results being better in those who had an infundibular resection and survived than in those subjected to valvulotomy An Eisenmenger syndrome is not produced by the operation possibly because considerable stenosis persists and there is still a large ventricular pulmonary pressure gradient across the site of stenosis It is dubious that these incomplete direct procedures are preferable to the Blalock shunting operation as long as the operative risk is greater in the former

Intracardiac Surgical Correction by Direct Vision Pulmonary valvulotomy and infundibular resection attempt correction of only

one part of Fallot's tetralogy and this is imperfect because the procedure is relatively blind (p 753) Lillehei and associates[55] reported the correction of both the pulmonic stenosis and the interventricular septal defect under direct vision with the aid of cross circulation and by complete by pass of the heart and lungs with the aid of a pump oxygenator[67] Apparently the septal defect can be closed despite some persistent overriding of the aorta In a case of pentology of Fallot the atrial as well as the ventricular septal defect was closed and the pulmonic stenosis relieved by valvulotomy Direct vision intracardiac correction of the defect may also be accomplished by the aid of hypothermia but the use of a pump-oxygenator heart lung by pass is now replacing all other techniques (p 1113)

PULMONARY ATRESIA (SINGLE OUTFLOW TRACT)[6]

Pulmonary atresia instead of pulmonary stenosis may form one of the elements of a tetralogy of Fallot Life is maintained (a) by a patent ductus arteriosus which carries blood from the aorta to a branch of the pulmonary artery distal to the atresia, or (b) through hugely dilated bronchial arteries which come off the dextroposed aorta An atrial septal defect is often present Extreme cyanosis is usual Attacks of dyspnea are common and may be fatal Syncopal attacks occur with exertion There may be no significant murmur or a loud systolic murmur in the pulmonic area or occasionally a continuous murmur The second 'pulmonic sound referred from the dextroposed aorta, is loud and clear, i e not split Inability to introduce the cardiac catheter into the pulmonary artery although it can be made to enter the dextroposed aorta, suggests the presence of pulmonary atresia Angiocardiography shows early opacification of the aorta of which the root may be displaced and the arch abnormally large There is an enlarged displaced ascending aorta and no main pulmonary artery which differs from the appearance in the usual Fallot s tetralogy Angiocardiography discloses whether pulmonary arteries are available for anastomoses There may be a distinctive vascular pattern characterized by coarse stippling of the hilar vascular markings when there are enlarged bronchial arteries, with absence of the hilar comma[79]

If the associated dextroposition of the aorta is not extreme and a rudimentary pulmonary vessel of sufficient size can be found the Blalock operation may be successful As a rule the operative mortality is very high largely because the patient s life depends on the collateral vessels and some of these are divided during the operation In addition the postatretic pulmonary artery is thin walled and poor for anastomosis Lillehei et al[55] reported the successful correction of a case of pulmonary atresia by intracardiac surgery under direct vision, using a donor for cross circulation The ventricular septal defect was closed, a new opening was created at the top of the outflow tract of the right ventricle and the pulmonary artery distal to the atresia was anastomosed to this newly created orifice

COMPLETE TRANSPOSITION OF THE GREAT VESSELS[18 11 233]

This is one of the leading causes of death from the cyanotic forms of congenital heart disease The aorta arises entirely from the right ventricle and the pulmonary artery from the left ventricle Thus unoxygenated blood from the peripheral veins reaches the right atrium and right ventricle and is thence pumped by way of the aorta into the general circulation without passing through the lungs Another circulation is formed by oxygenated blood flowing from the pulmonary veins left atrium and left ventricle into the pulmonary artery and through the lungs again Life depends on the degree of cross flow between these circulations by way of a patent ductus arteriosus in more than half of the cases by way of an interventricular septal defect in one third or by way of a patent foramen ovale or interatrial septal defect in the others In the majority of cases the aorta and pulmonary artery are of equal size in some the pulmonary artery is larger and occasionally the aorta has the greater diameter An anatomic problem, which is of importance if surgical correction is contemplated is the origin of the left coronary artery from a position close to the pulmonary artery Therefore, at least one coronary artery must be transplanted to arise from the aorta when the position of the great vessels is surgically restored

Transposition of the great vessels occurs at least two or three times as often in males as in females At present the outlook for life is ex

tremely grave since about 50 per cent of the infants die in the first month of life and the average age at death has been found to vary from 3 to 19 months.[41, 223] Because of this and because of the promise that an effective surgical repair may become available, diagnosis in the first months of life is especially important. However, a considerable number of children with this disturbance survive beyond the age of three, usually because there is a large ventricular septal defect permitting adequate mixing of blood from both sides of the circulation.

Clinical Features

Cyanosis is usually prominent from birth and is more intense than in Fallot's tetralogy. Characteristically, the cyanosis is intensified by crying and is incompletely relieved by oxygen. In cases of complete transposition with patent ductus arteriosus the cyanosis is said to be deeper in the upper than in the lower half of the body, since the more oxygenated blood in the left ventricle is transported by way of the transposed pulmonary artery and the patent ductus arteriosus to the descending aorta. However, this distinction in degree of cyanosis is either not mentioned or has been overlooked in most reported cases. Feeding is poor and weight gain inadequate. Dyspnea is common, usually in exertion, and may be associated with syncope of effort. Cough occurs in many but squatting is rare or absent. Polycythemia may appear after several months, but not clubbing unless the infant survives at least six months. Congestive heart failure, with distention of the cervical veins and hepatic enlargement, develops frequently.

In at least one third of the cases there are no murmurs. When present, the murmur is soft, systolic and located in the third left interspace, and occasionally it is accompanied by a thrill. It is most likely to occur when there is an associated ventricular septal defect. A pulmonary diastolic murmur is occasionally present. The second pulmonic sound is usually very loud in contrast with that in Fallot's tetralogy. Gallop rhythm is common. Cardiac enlargement is prominent and occurs regularly. The relatively normal cardiac size at birth, with rapid progressive enlargement even within the first three or four weeks of life, is diagnostic of complete transposition.

Roentgenologic Examination[4, 11]

The heart is enlarged and may be egg shaped with the narrow end at the apex. The left border may form a peculiar long bulge in its middle salient and show an aortic pulsation. But more often there is a concave left middle segment. A diagnostic feature, though present in only one third of the cases, is a narrow vascular pedicle. The peripheral pulmonary vessels are engorged and the pulmonary markings increased. When the lung fields appear oligemic in the presence of other evidence suggesting complete transposition, it is probable that there is a complicating pulmonic stenosis. The varied appearance in different cases limits the diagnostic value of roentgenologic examination in this disease.

Angiocardiography[59, 11, 104, 170] is usually necessary to make or confirm the diagnosis. The aorta fills promptly with dye and is seen to arise directly from the right ventricle. The aorta may be seen to form the left upper mediastinal border, lying in the usual position of the pulmonary artery and right ventricular outflow tract.

Electrocardiography usually shows evidence of right ventricular hypertrophy and tall P waves in lead II.

Cardiac Catheterization may be helpful in demonstrating other defects. The catheter may pass through an atrial or ventricular septal defect or occasionally into both the aorta and pulmonary artery. Pressure relationships and oxygen contents depend on the nature of the communication between the left and right sides of the circulation.

If the communication is by way of a ductus arteriosus, then the more oxygenated blood from the pulmonary artery (arising from the left ventricle) reaches the lower half of the body and the femoral arterial oxygen is higher than the brachial. Such patients may have a worse prognosis because the coronary arteries receive the less oxygenated blood from the ascending aorta.

Surgical Treatment

Blalock and Hanlon[41] attempted to improve the cross over of oxygenated blood (1) by an anastomosis of the right superior pulmonic vein to the right atrium, (2) by creating an interatrial septal defect and in addition anastomosing the proximal end of the subclavian artery to the distal end of the pulmonary artery. They reported improvement in

two thirds of the children who survived, but the mortality was high Experimental studies of surgical possibilities for treating complete transposition were reported by Lillehei and Varco[268] and by Bjork and Bouckaert[37] Mustard and associates[296] described a surgical method using a Cowan perfusion pump and a monkey lung as an oxygenator, which they employed in operation on seven infants none of whom survived Hypothermia and mechanical pump oxygenators have been employed Cross and associates[109] described a technique whereby external plastic shunts were used to by pass the circulation around the aortic and pulmonic valves and the proximal great vessels while repair of the great vessels or valves can be undertaken Murphy et al[94] reported that 7 of 32 infants or children operated on for transposition of the great vessels had survived and showed significant improvements after a follow up period of 15 to 36 months Baffes[15] described a new technique which utilized a homologous aortic graft to transpose the inferior vena cava to the left atrium while the right pulmonary veins were transposed to enter the right atrium This was satisfactorily applied in one case involving an infant who showed considerable improvement postoperatively

THE TAUSSIG BING SYNDROME[398, 271]

The aorta is completely transposed and arises from the right venticle and there is levoposition of a large pulmonary artery which overrides the left ventricle but does not arise completely from it The aorta is situated anteriorly the pulmonary artery posteriorly There are also a high ventricular septal defect and right ventricular hypertrophy The prognosis for life is fair and much better than with complete transposition

The syndrome is characterized by cyanosis from birth, underdevelopment dyspnea on exertion, cardiac enlargement systolic murmur in the left third intercostal space, loud second pulmonic sound, moderate polycythemia electrocardiographic evidence of right ventricular hypertrophy or incomplete bundle branch block, and large pulsating hilar vessels and increased pulmonary vascular markings on fluoroscopy

Angiocardiography shows that the aorta fills directly from the right ventricle but unlike its situation in complete transposition the pulmonary artery is seen to override both ventricles and fills simultaneously with the aorta Subsequent films show poor filling of the left ventricle and reopacification of the pulmonary artery On the basis of angiocardiography the diagnosis has been made in vivo and confirmed anatomically[284]

Cardiac catheterization[15] shows the catheter passing into the aorta from the right ventricle but also into the pulmonary artery The oxygen content is higher in the pulmonary artery than in the aorta Equality of pressures in the right ventricle, aorta and pulmonary artery indicates the presence of a large ventricular septal defect The syndrome is usually confused with the Eisenmenger complex, but in the latter cyanosis does not start at birth and catheterization studies do not show the oxygen content in the pulmonary artery higher than in the aorta

SINGLE VENTRICLE WITH PULMONARY STENOSIS[84]

These are cases in which the ventricular septum fails to develop normally and there is a single ventricle with one or two atrioventricular orifices The atrial septum may be intact but more often has a defect The clinical picture resembles that of the tetralogy of Fallot and like this syndrome it is amenable to surgery by the Blalock procedure

A single ventricle may be associated with mitral or tricuspid atresia or with transposition of the great vessels

PATENT DUCTUS ARTERIOSUS

Patent ductus arteriosus is important because it is one of the frequent clinically significant congenital cardiovascular lesions and because it is completely curable by surgery According to Abbott s[1] figures for autopsied cases, a patent ductus arteriosus occurred 150 times among 1000 cases of congenital heart disease of which 92 were uncomplicated, it was exceeded in frequency only by atrial and ventricular septal defects In the series of Wood et al[4-5] it was encountered as an isolated lesion in 12 5 per cent of their cases of congenital heart disease and was only exceeded in frequency by interatrial septal communications and slightly by isolated pulmonic stenosis Patent ductus arteriosus occurs about three times as frequently among females as among males[238, 50]

Embryology and Pathogenesis

The ductus arteriosus arises from the sixth left aortic arch and connects the main or left pulmonary artery with the descending arch of the aorta just below the origin of the left sub clavian artery at the termination of the so called isthmus of the aortic arch In fetal life the blood from the right atrium which comes from the superior vena cava and which does not pass through the foramen ovale is ex pelled into the right ventricle and the pul monary artery Almost all the blood from the pulmonary artery passes through the wide patent ductus arteriosus to the descending aorta and its branches to supply the lower half of the body Only a minute portion of the pulmonary arterial blood reaches the non functioning lungs

According to Patten [309] however the blood supply to the lungs increa es gradually in fetal life until shortly before birth a fair pulmonary circulation develops But it is only after birth when the lungs assume their respiratory func tion and their alveoli and the pulmonary vessels expand that the major quantity of blood from the main pulmonary artery tra verses the pulmonary circulation while less and less is shunted through the ductus ar teriosus It is uncertain whether the ductus ceases to function immediately after birth[21] or gradually after an interval of weeks [348] Ana tomic closure usually occurs by the end of the third month (in about 80 per cent of cases) and at the end of one year the ductus is ob literated in 95 per cent of cases Rarely closure has been reported to occur later in life [86] When the ductus closes it is converted into a fibrous cord known as the ligamentum arteriosum

Many theories have been offered to explain the mechanism of closure of the ductus ar teriosus The mechanical theory as indicated by Klotz [43] maintains that the ductus closes because of a fall in its blood pressure as the pulmonary arterial stream is deviated to the functioning lungs According to Klotz [243] when the blood pressure has fallen the extremely muscular walls obliterate the lumen by their tonic contraction and initiate the process of fibrosis On the other hand persistent patency of the ductus arteriosus results from the main tenance of a relatively high pressure in this canal According to the studies of Kennedy and Clark [36] the oxygen in the blood is the im portant factor in closure of the ductus ar teriosus

Pathology

From the standpoint of surgical manage ment it is important to recognize two groups, namely patent ductus arteriosus with as sociated cardiac anomalies and uncompli cated patent ductus Patent ductus ar teriosus with aorta to pulmonary artery shunt has been distinguished from patent ductus arteriosus with reversal of shunt (pulmonary artery to-aorta) due to pulmonary hyperten sion (p 769) Among the associated lesions are infantile coarctation of the aorta complete transposition of the great vessels pulmonary atresia or pulmonary stenosis [60] interatrial or interventricular septal defect In some of these cases patency of the ductus is essential to the maintenance of life

The patent ductus arteriosus usually forms a cylindrical tube of variable caliber and most often less than 1 cm long in the adult Or the communication may be of the window type in which there is merely a fistula between the aorta and pulmonary artery In such cases surgical ligation or section may be impossible The ductus is sometimes funnel shaped and wider at the aortic end it may be aneurysmal and its lumen filled with thrombus Rarely the pulmonic end is incompletely closed by a membrane

The pulmonary artery and its branches be come widened Rarely there may be an aneurysmal dilatation of the pulmonary artery Both ventricles are somewhat dilated and hypertrophied

Pathologic Physiology (See also Cardiac Catheterization p 768)

In uncomplicated patency of the ductus ar teriosus the higher pressure in the aorta shunts blood from that vessel into the pul monary artery during both systole and diastole Since the pulmonary artery receives blood from the aorta as well as from the right ventricle the pulmonary blood flow is above normal the vessel becomes dilated and its pulsations may be exaggerated

According to the measurements of Burwell Eppinger and Gross[59] the shunt was of great magnitude from 4 to 19 liters of blood flowing per minute from the high pre sure area in the aorta to the low pressure area in the pulmon ary artery The aortic pulmonary shunt also results in increased work for the left ventricle

According to Eppinger, Burwell and Gross[148] the cardiac output is two to four times normal Eppinger and his associates calculated that 45 to 75 per cent of the blood pumped by the left ventricle into the aorta is shunted through the ductus and lungs back to the left side of the heart without supplying the periphery of the body However the shunt is probably much less in many asymptomatic cases[160]

Dilatation and hypertrophy of the left ventricle are usually present although in most asymptomatic cases this is not demonstrable clinically On the other hand Eppinger and Burwell[148] observed a moderate degree of left ventricular enlargement roentgenographically in 8 of 9 patients who were operated upon for a patent ductus The presence and extent of left ventricular enlargement depend on the degree of left ventricular strain The leakage of blood from the aorta to the pulmonary artery is accompanied by a fall in diastolic pressure similar to that in cases of aortic regurgitation

In infants there may be a reversal of flow with a venous arterial shunt during crying sucking or coughing Such a reversal with transient or terminal cyanosis may occur also during pulmonary infections and heart failure A reversal of flow with cyanosis occurs also *when there are certain associated anomalies* such as complete transposition of the great vessels or whenever there is marked pulmonary hypertension (p 769)

The following clinical discussion applies to the cases of uncomplicated patency of the ductus arteriosus

Clinical Features

Symptoms In many if not most cases there are no symptoms due to the lesion Cyanosis is absent although it may occur rarely with pulmonary vascular disease and pulmonary hypertension (p 770) When symptoms appear they are most often exertional dyspnea and palpitation or fatigability Occasionally the subjects with a patent ductus are slender undersized and underdeveloped (habitus gracilis) and pale The underdevelopment is attributed to a diminished systemic arterial *blood supply as denoted anatomically by* hypoplasia of the aorta This results from the short circuit of a large portion of the aortic blood through the pulmonary circuit (supra) Cardiac failure develops sooner or later in most patients but it is emphasized that even in infancy or early childhood heart failure may be due to a patent ductus[229]

Physical Signs The physical signs are characteristic The pathognomonic sign is the *Gibson murmur*[175] which is variously described as continuous machinery like train in tunnel, humming top, churning sawing etc It is a long and rumbling murmur which occupies most of systole and diastole (Fig 134*D*) There is often an accentuation in late systole[203] The murmur may be diffuse but usually is localized or loudest in the second left interspace near the sternum the site of the dilated pulmonary artery Occasionally it may be heard in the third left interspace near the sternum The systolic element radiates to the cervical vessels and often posteriorly *A systolic thrill* is usually and a diastolic or continuous thrill is rarely palpable over the site of maximal intensity of the murmur

As a rule, if there is no continuous murmur, there is a rough long *systolic murmur* with maximum intensity in the second left interspace *near the sternum, or occasionally in the* first or third left interspace An increasing number of patients with patent ductus arteriosus are being seen who have no murmur or only a systolic murmur[314] As a rule such patients are either in congestive heart failure or have an associated pulmonary hypertension In infants only a systolic murmur is usually audible, although a machinery murmur may be heard in the first few months of life The presence and character of the murmur depend on the development of a significant shunt and the height of the aortic pulmonary artery pressure difference (gradient) In young infants the gradient may be very small or insignificant in diastole or both systole and diastole

Occasionally there is an apical diastolic murmur,[11] due to functional mitral or tricuspid stenosis (excessive blood flow) and there may be a diastolic murmur along the left border of the sternum due to pulmonary insufficiency

The *second pulmonic sound* is accentuated and may be reduplicated

Percussion may reveal a thin, rectangular area of dullness in the second and third left interspace (Gerhardt's dullness) overlying the dilated pulmonary artery This is inconstant or difficult to demonstrate by physical examination

When the ductus arteriosus is widely patent and there is a considerable arteriovenous shunt one often encounters the peripheral circulatory phenomena seen in cases of free aortic regurgitation (p 690) These result from the aortic regurgitation of blood into the pulmonary artery during diastole There is a *high pulse pressure* which may be due in part to an elevation of the systolic pressure but chiefly to a sharp drop in the diastolic pressure The diastolic pressure may fall sharply during exercise In addition to the high pulse pressure there may be a stenosis of the orifice of the left subclavian artery An infrequent sign is the *pulsus paradoxus*

Roentgenology

1 The size of the cardiac silhouette is usually normal when the shunt is small With large shunts there is an enlargement of the left ventricle and occasionally to a lesser extent of the right ventricle[230a]

2 The characteristic feature although not invariably present is a prominence of the pulmonary arc in the left upper portion of the cardiac silhouette[1 6] (Fig 134 A) This is known

Fig 134 Patent ductus arteriosus *A* Conventional posteroanterior view Prominent pulmonary artery segment

B Angiocardiogram Left oblique view Fusiform dilatation just beyond aortic isthmus where ductus is attached (arrow)

C Diagram of angiocardiogram

D Machinery type continuous systolic-diastolic murmur

Corrigan pulse *capillary pulsation* *Duroziez s sign* (pistol shot femorals) and other circulatory phenomena often associated with aortic insufficiency *Microplethysmography* usually discloses characteristic changes in the pulse wave of the finger, including blunting of the apex of the wave loss of differentiation between systolic rise and diastolic fall and loss of dicrotic notch[8] Occasionally the blood pressure is higher in the right arm than in the left and the *radial pulses are unequal* but this probably represents an associated coarctation of the aorta with as the x ray cap of Zinn The bulging cap of Zinn represents the dilated pulmonary artery In other cases the pulmonary artery is only slightly dilated and the pulmonary arc less conspicuous roentgenoscopically Prominence of the pulmonary artery with prominent pulmonary vascularity is observed also in cases of interatrial and interventricular septal defects but in the latter conditions there is right not left ventricular enlargement The post stenotic pulmonary artery enlargement in pulmonic stenosis is distinguished by the association of relatively avascular lung fields

3 Not only is the pulmonary arc prominent in most cases but its pulsation is considerably exaggerated The hilar shadows are also prominent both in size and pulsation These pulsations are rarely as striking and much less frequent than in cases of atrial septal defect

4 Increased fullness of the peripheral pulmonary vessels may be present if the shunt is of considerable size

5 There may be evidence of left ventricular and left atrial enlargement and this is especially frequent in infants

The enlargement of the pulmonary artery may be observed most readily in the right oblique view In the left anterior oblique view, a large ductus arteriosus may partially obscure the window of the aorta A valuable diagnostic sign, occasionally present is a calcified plaque near the caudal end of the arch of the aorta (i e the site of junction of the ductus and aorta)[344] in young persons in whom arteriosclerotic calcification of the aorta is otherwise rare

Angiocardiography is not usually of diagnostic importance It may reveal a localized dilatation of the descending aorta just beyond the isthmus (Fig 134*B* and *C*) In the early films the pulmonary artery shows weak contrast material presumably due to dilution by blood shunted from the aorta

Retrograde aortography (p 16) not only discloses simultaneous opacification of the aorta and pulmonary artery but also visualizes the ductus directly However the procedure is rarely indicated Sometimes patency of the ductus is indicated by prolonged or renewed visualization of the pulmonary artery after there is no longer any contrast medium in the right ventricle [31]

Electrocardiogram

The electrocardiogram is often normal There is generally no axis deviation These negative findings are important in differential diagnosis In infants there is commonly electrocardiographic as well as roentgenologic evidence of left ventricular hypertrophy As age increases left and right hypertrophy become balanced In cases with moderate pulmonary hypertension there may be evidence of both left and right ventricular hypertrophy Left ventricular hypertrophy may be associated with electrocardiographic changes of right bundle branch block

Cardiac Catheterization

The blood oxygen content is significantly higher in the pulmonary artery than in the right ventricle[116,117] (usually by more than 2 vols per cent)[illegible] The pulmonary arterial pressure and that in the right ventricle may be normal, or moderately or greatly elevated [illegible] Manometric studies in 24 cases showed a normal pulmonary artery pressure in 10, slight elevation in 6 and moderate elevation in 6, but not high enough to alter the left to-right (aortic to pulmonic) shunt[35] (p 770) In about one third of cases of patent ductus, the cardiac catheter may pass through the ductus [7] The pulmonary capillary flow exceeds that in the pulmonary artery, since the pulmonary capillaries also receive blood through the aortic pulmonary shunt

Diagnosis

The diagnosis of patent ductus arteriosus is based essentially on the presence of the typical machinery like murmur Confirmation is supplied by roentgenologic findings of a prominent pulmonary artery and especially by cardiac catheterization which reveals a higher oxygen concentration in the blood of the pulmonary artery than in that of the right ventricle and by passage of the catheter into the ductus in some cases Associated complicating lesions should be excluded

Course and Complications

Many patients never have symptoms referable to the patent ductus and die of independent causes Unfortunately the available statistics which are based on autopsied cases usually reported because of some special complication are misleading in so far as they are not likely to include the more favorable asymptomatic cases [30] According to Abbott[1] the average age at death is 24 years and according to Keys and Shapiro [231] 37 years, but some patients have a normal life span, and death has occurred at the age of 75 [157]

The commonest complications and causes of death are *congestive heart failure* and *bacterial arteritis or endocarditis* Other complications are less common Occasionally the dilated or even aneurysmal pulmonary artery or ductus arteriosus ruptures causing thoracic hemorrhage and death A dissecting aneurysm of the pulmonary artery may develop Thrombosis *of the ductus arteriosus* occasionally *leads to* pulmonary embolism Paradoxical embolism rarely results from the passage of thrombotic

material from the left atrium by way of the aorta and patent ductus to the lung. Occasionally there is hoarseness or aphonia due to paralysis of the left recurrent laryngeal nerve probably caused by the pressure of the dilated ductus arteriosus or pulmonary artery.[91]

Surgical Treatment

Surgical closure of the patent ductus corrects the abnormalities in circulatory dynamics, restores normal cardiac size, and eliminates the clinical symptoms and the risk of heart failure, bacterial endocarditis or other complications of a patent ductus.[194] Following operation the patient's hands and feet become warmer and the capacity for ordinary activity or physical exertion is increased. Patients with exertional dyspnea, palpitation, fatigability, weakness and chest pain are completely or almost completely relieved of these symptoms. Children who were malnourished and underdeveloped gain weight and improve in growth. The murmur and thrill disappear. The diastolic pressure rises and the pulse pressure falls. The heart rate is slowed as after the obliteration of other arteriovenous aneurysms (p. 694). The work of the heart as well as its size is diminished.

The technique of the operation has been described by Gross,[192] Potts,[315] Cade[71] and others. At first the ductus was closed by multiple ligatures, but recanalization occurred in about 10 per cent of cases. To avoid this Gross resorted to cutting the ductus and suturing the cut ends. Occasionally section of the ductus or even passing of ligatures cannot be performed because the ductus is too short. The mortality rate in uncomplicated cases should be well under 1 per cent. There are many short series of cases without a mortality. Potts[315] reported that there was no mortality in 250 consecutive surgical closures of the patent ductus arteriosus.

The most suitable time for operation is between the ages of 3 and 15. However operation may be necessary and successfully performed in infancy.[295] It may be performed in adults, but with greater difficulty than in children.

Indications for Operation. Prompt operation is indicated if there is evidence of a large circulatory shunt and cardiac strain as suggested by cardiac enlargement, pulmonary vascular engorgement and a high pulse pressure. It is indicated in patients with symptoms of diminished cardiac reserve, and with present or previous heart failure as soon as medical treatment for heart failure has accomplished as much as it can. It is indicated in cases of patent ductus with bacterial arteritis after the bacterial infection has been controlled by antibiotics or if a satisfactory clinical response cannot be obtained with antibiotics. Finally, because of the poor prognosis without operation, and with the operative risk minimized, I recommend that the operation should be performed as soon as convenient *on all children with a patent ductus*, as a prophylactic measure. Sometimes there is rewarding improvement postoperatively even when there were no apparent clinical symptoms preoperatively. Among adults with patent ductus, section or ligation should be performed only if there is evidence of cardiac strain or failure.

Ligation or section of the ductus arteriosus is contraindicated when this anomaly is associated with other congenital cardiac defects for which the ductus circulation is a compensation. This group can usually be distinguished by the presence of cyanosis and, if doubtful, with the aid of angiocardiography and intracardiac catheterization.

PATENT DUCTUS ARTERIOSUS WITH PULMONARY HYPERTENSION AND REVERSED SHUNT[81, 110, 215, 284, 427, 505]

In uncomplicated patency of the ductus arteriosus there is a flow of arterialized blood from the aorta to the low pressure pulmonary artery. When there is an associated pulmonary hypertension, which occurs in about 10 per cent of cases of patent ductus,[275] the pulmonary artery pressure may exceed that of the aorta and unoxygenated blood flows from the pulmonary artery to the aorta. The clinical picture in such cases differs strikingly from that of patent ductus, notably in the usual absence of the machinery murmur and in the presence of cyanosis.

Pathology

The right ventricle is hypertrophied. The pulmonary artery may be wider in diameter than the aorta. The ductus arteriosus is patent and usually large. The pulmonary arteries and arterioles may show no significant abnormality or they may present lesions of an occlusive nature.[81, 126] The arteriolar walls are thickened and their lumina narrowed or closed. The small muscular pul

monary arteries may disclose medial hypertrophy, increase of the elastica and subintimal fibrosis Medial hypertrophy and thrombosis of medium sized pulmonary arteries have been noted The possibility that the occlusions may be due to embolization is not excluded

Pathologic Physiology

The pressures in the pulmonary artery and systemic circulation are fairly equal in fetal life With the onset of pulmonary respiration at birth, the right ventricle pumps blood against the low resistance of the pulmonary vessels, in contrast with the left ventricle which works against the higher resistance of the systemic circulation Since the output from both ventricles is identical the pressure in the right ventricle and pulmonary artery is lower than that in the left ventricle and aorta If the ductus fails to close, the flow is from the higher pressure area in the aorta to the lower pressure area in the pulmonary artery If however, the pulmonary resistance is elevated at birth as a result of narrowing or occlusion of the small pulmonary arteries and arterioles there is no fall in resistance to right ventricular work with the onset of pulmonary respiration, and the pressure in the pulmonary artery does not fall normally If the pulmonary resistance and blood pressure remain higher than those in the systemic circulation the ductus arteriosus which normally closes as pulmonary arterial blood is detoured from it through the pulmonary vessels, now continues as an active channel because of the persistent high pressure in the pulmonary artery This hypothesis assumes that the patency of the ductus is actually secondary to the increased pulmonary resistance and pulmonary hypertension This is supported by the observation that cyanosis in these cases is present from birth If one regards the patency of the ductus and the pulmonary hypertension as due to two different mechanisms, then the pulmonary hypertension merely determines the direction of flow in a ductus which is patent for other reasons

Exertion tends to increase the pressure in the pulmonary artery relative to that in the aorta and thereby to increase the shunt of pulmonary (unoxygenated) blood through the ductus This probably results from the fall in systemic resistance as the blood flow increases with exercise On the other hand the increased blood flow cannot be handled by opening of vascular channels in the obstructed pulmonary vascular bed, hence the pulmonary resistance is unchanged or augmented as blood flow increases with exercise resulting in higher pulmonary blood pressure Sometimes the pulmonary artery pressure is elevated but is slightly less than aortic pressure at rest Under such circumstances, the pulmonary artery pressure may exceed that in the aorta only with exercise, and the reversal of flow may be intermittent [71]

The cause of the pulmonary hypertension in some cases or of the underlying vascular lesions in others is obscure

Clinical Features

The outstanding features are the cyanosis, usually present from birth, and dyspnea on exertion Squatting is present occasionally The cyanosis is increased with exercise and is distinctly more intense in the lower than in the upper half of the body and more in the left than in the right hand These local differences in intensity of cyanosis are accentuated by exercise The greater cyanosis in the lower half of the body is due to the fact that the head and upper extremities receive an oxygenated blood supply from the great vessels of the aortic arch, which come off before the site of the ductus On the other hand at the aortic end of the patent ductus, the oxygenated blood from the upper aorta becomes mixed with unoxygenated blood from the pulmonary artery and this relatively less oxygenated blood supplies the lower extremities But the left subclavian artery, which is close to or only a short distance above the ductus insertion in the aorta, receives some of this unoxygenated blood especially with exercise, and the left hand is more likely to appear cyanotic than the right

There is usually a loud systolic *murmur*, maximal in the third interspace along the left border of the sternum The murmur may be absent Occasionally there is a diastolic murmur along the left sternal border The second pulmonic sound is often accentuated and may be reduplicated

Roentgenologic Examination

The main pulmonary artery and the main pulmonary arterial branches are prominent and the former may show exaggerated pulsation The pulmonary fields are normally vascularized The right ventricle is enlarged (Fig 135*A*)

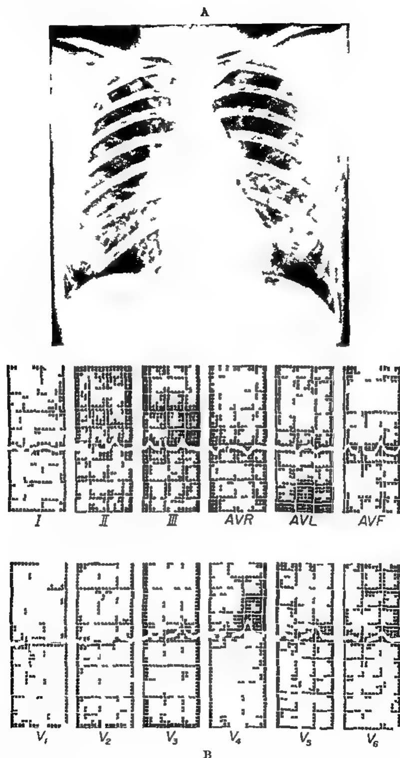

Fig 135 *A* Patent ductus arteriosus with pulmonary hypertension and reversed shunt Roentgenogram shows prominent pulmonary artery and increased vascularity of pulmonary fields

B Electrocardiogram shows right axis deviation vertical electrical axis but with insufficient evidence of right ventricular hypertrophy

Angiocardiography

A right-to left shunt through the ductus may be clearly indicated by visualization of the distal aorta simultaneously with the pulmonary artery while the ascending and transverse aorta are not yet visible Other sources for the shunt can be excluded by lack of visualization of the left cardiac chambers

Electrocardiogram (Fig 135*B*)

There is usually evidence suggesting right ventricular hypertrophy with tall R waves, ST segment depressions and T wave inversions in the right precordial leads Evidence of left ventricular hypertrophy is usually masked

Cardiac Catheterization Pressure Determinations and Oximetry

The catheter may enter the aorta by way of the pulmonary artery and patent ductus The pulmonary artery pressure is elevated and exceeds that in the systemic circulation Blood from the femoral artery shows an oxygen saturation considerably below normal, e g 60 to 70 per cent whereas that from the brachial artery is only moderately below normal saturation e g 90 per cent The pulmonary blood flow is normally or slightly diminished, whereas the maximal systemic flow (including the shunted blood) is two or three times as large

Diagnosis

Cyanosis frequently from birth the presence of a cardiac murmur and the localization of the cyanosis or of its greater intensity in the lower half of the body are clinically diagnostic The color of the left and right hands and of the right hand and right foot should be contrasted after exercise Arterial oxygen determinations of blood from the upper and lower extremities and findings on cardiac catheterization confirm the diagnosis and differentiate this from other forms of congenital heart disease with cyanosis

Prognosis

Patients may live for many years without heart failure although with moderate cyanosis

Treatment

Surgical closure in these cases appears to be contraindicated Usually such closure has resulted in a fairly prompt fatality[110, 268] Apparently the patent ductus serves as a compensatory safety valve for the right ventricle and its ligation is intolerable However in isolated cases the ductus has been successfully ligated[218, 3, 141b] In these the pressures in the pulmonary artery and aorta are about equal and reversal of flow occurs chiefly during exercise If ductal occlusion is contemplated at operation, it is important to occlude the ductus temporarily for 15 or 20 minutes and observe the pulmonary artery pressure If the pulmonary arterial pressure rises, the ductus should not be closed Antonius et al[8a] reported a case of patent ductus arteriosus with pulmonary hypertension and bidirectional shunt in which delayed closure was accomplished by partial ligation and wrapping with polyethylene sheeting

PERSISTENT TRUNCUS ARTERIOSUS COMMUNIS[99, 341]

Closely related to patency of the ductus arteriosus are the cases with a common arterial trunk, instead of distinct aorta and pulmonary artery, due to defective development of the bulbar septum There are two types (1) in the *true form of truncus arteriosus*, the trunk arises from both ventricles and gives off right and left pulmonary arteries from the ascending common trunk The pulmonary arteries are large and there is a good pulmonary blood flow (2) In *pseudotruncus arteriosus* there is no main pulmonary artery, there is atresia of the pulmonic valve, and the post atretic pulmonary artery is supplied with blood via a patent ductus, or more often bronchial arteries arising from the aorta supply the lungs with blood

If the pulmonary arteries arise directly from the truncus arteriosus, cyanosis is absent or minimal In the more frequent cases in which the circulation through the lungs is by way of dilated bronchial arteries cyanosis is usually intense as the pulmonary circulation and oxygenation are deficient There may be dyspnea In both types of cases there is often a harsh systolic murmur and thrill and cardiac enlargement but there may be no murmur The normal splitting of the second sound at the base is absent according to the phonocardiogram Death usually occurs early, but some patients reach adult life

Roentgen ray examination discloses a characteristic shelflike projection to the anterior chest wall in the left anterior oblique view a widened aortic shadow and absence of the contour of the pulmonary conus[111]

Angiocardiography shows the large common vascular trunk or a wide aorta arising *from* the right ventricle, but a similar picture may

be produced by pulmonary atresia The *electrocardiogram* usually shows right axis deviation, occasionally left axis deviation Postmortem examination discloses hypertrophy of both ventricles

If the pulmonary blood supply is by way of the bronchial arteries and a rudimentary pulmonary artery of sufficient size can be found, considerable clinical improvement results from anastomosis of a systemic artery (aorta innominate or subclavian) to the pulmonary artery (p 760)

A persistent truncus arteriosus is sometimes associated with a single ventricle [illegible] There may be a persistent left superior vena cava

AORTIC SEPTAL DEFECT—ANEURYSM OF SINUS OF VALSALVA

There is a small opening between the aorta and pulmonary artery about 1 cm above the semilunar valves [170, 15] The symptoms and signs may be insignificant or ill defined or may resemble those of a patent ductus arteriosus The diagnosis is suggested by finding all the manifestations of patent ductus, but the murmur is heard slightly lower and to the right of the site of the murmur in patent ductus Retrograde aortography has been used to make the diagnosis [168] The diagnosis was made by cardiac catheterization during life in two cases after study of films with the catheter in different positions in the aorta [319] Repair of an aortic septal defect has been reported [193]

In other cases the septum between the vessels is extremely thin leading to an aneurysm of the right sinus of Valsalva or more rarely of the posterior or left sinus [204, 159, 407, 59] Aneurysm of the sinus of Valsalva may be due to congenital disease of the aortic media sometimes associated with arachnodactyly (p 728) In a series of 15 cases of unruptured aortic sinus aneurysms reported by Steinberg and Finby [373] 6 were congenital (3 associated with arachnodactyly, 3 with coarctation of the aorta) and 9 were acquired and due to syphilitic aortitis or bacterial endocarditis These aneurysms may become clinically significant because of a tendency to perforation with a consequent defect between the right aortic sinus and the right ventricle (pulmonary conus) or pulmonary artery or between the posterior aortic sinus and the right atrium [illegible, 154] With perforation, the symptoms and signs resemble those of patency of the ductus but the murmur and thrill appear more superficial the murmur is situated lower (third or fourth left interspace) and there is more pronounced cardiac enlargement

The diagnosis is suggested by the sudden occurrence without apparent cause except exertion occasionally of symptoms of progressive heart failure and signs of a communication between the aorta and right side of the heart (continuous or harsh systolic murmur and thrill) In a personal case of sinus aneurysm with rupture into the right atrium, correctly diagnosed ante mortem, there were in addition to the sudden appearance of the murmur and thrill progressive congestive heart failure the development of right axis deviation not present in earlier electrocardiograms high pulse pressure and Corrigan pulse and a characteristic double pulsation in the cervical veins and over the liver At present the diagnosis of aortic sinus aneurysm is being made with increasing frequency, before rupture by means of angiocardiography [378] Surgical treatment of the ruptured aneurysm has been reported [63, 378]

Death may occur suddenly or within a few months or years but Abbott[1] has reported a case of survival for nine years after the perforation Bacterial endocarditis may complicate aortic septal defect or cause aneurysm of the sinus with rupture (p 868)

COARCTATION OF THE AORTA

Since Bonnet s[60] description, two forms of coarctation of the aorta are generally recognized the infantile and the adult As implied by these names the infantile form usually occurs in infants and is soon fatal while subjects with the adult form often reach mature life Exceptions occur in that the infantile form is encountered occasionally in adults and the adult form in subjects who die during infancy and childhood The *infantile form* is characterized by diffuse involvement of the aortic isthmus (from the origin of the left subclavian artery to the insertion of the ductus arteriosus with the constriction proximal to the isthmus) by the association of other congenital anomalies including a patent ductus and by cyanosis The *adult form* is characterized by a more localized constriction at or below the insertion of the ductus but distal to

the isthmus and left subclavian artery, by the absence of serious cardiac anomalies (except bicuspid aortic valve or subaortic stenosis), by a closed ductus, by a usually well developed collateral circulation and by the absence of cyanosis

Sex Incidence

There is a striking preponderance of males (4 to 1 or 5 to 1) among patients with coarctation of the aorta When it occurs in females, it may be associated with primary ovarian agenesis (Turner's syndrome)

Embryology and Pathology

The aorta in fetal life may be considered as divided into two functional units, the upper one extending from its cardiac origin to the insertion of the ductus at the lower end of the arch (i e, the isthmus) and a lower portion beginning at the insertion of the ductus and including the remainder of the descending aorta The upper unit receives the more oxygenated blood which, arriving in the right atrium from the placenta and inferior vena cava, is directed by the sinus valve through the foramen ovale to the left side of the heart and ascending aorta This oxygenated blood supplies the head the heart and the upper extremities Because this circuit contains only about half the venous return, it may be presumed that the aortic pressure is only sufficient to supply the upper unit and that the blood flow in this upper unit does not extend significantly beyond the isthmus The low pressure at the termination of the upper unit may account for the normal narrowing at the isthmus of the aorta

The unoxygenated blood from the superior vena cava, after relatively little mixing with the oxygenated blood in the right atrium is directed to the right ventricle, pulmonary artery and thence through the ductus arteriosus into the lower unit of the aorta This division of the circulation has been demonstrated roentgenographically in sheep fetuses after the injection of radiopaque material into the inferior and superior vena cava, respectively [1] Furthermore, the division into upper and lower units of the aorta may be an anatomic as well as a functional one, for there are cases in which the aortic arch and isthmus supplied by the left ventricle, are completely severed from the descending aorta beyond the isthmus, this unit receiving blood from the right ventricle through the ductus arteriosus [150]

Adult coarctation of the aorta, unlike the infantile form, is a late fetal or a neonatal anomaly [16] It occurs after and may be related to closure of the ductus arteriosus Normally an adequate pressure in the upper unit of the aorta prevents the constriction of the aorta at its ductal insertion when the ductus closes In instances of "adult" coarctation this constriction occurs because the aortic pressure in the upper unit is, at the time of ductus closure, insufficient to maintain the continuity between upper and lower aortic units This may be due to maldevelopment of the aortic valve and left ventricle as suggested by the frequent association of bicuspid aortic valve and subaortic stenosis

The *infantile type of coarctation is probably an early, primary developmental anomaly of the fourth left aortic arch,* occurring in the second month of fetal life Thus this lesion, unlike the usual adult type is associated with other developmental anomalies such as a septal defect or transposition of the arterial trunks Whatever the mechanism, the blood flow and pressure in the upper unit of the aorta is low leading to an exaggeration of the normally slight narrowing of the isthmus and to hypoplasia of the entire upper portion of the aorta Furthermore, owing to the associated cardiac anomalies or pulmonary vascular lesions,[137] there is often an elevated pulmonary pressure so that even when the lungs develop there is enough of a pulmonary pressure to keep the ductus open Hence patency of the ductus arteriosus almost always accompanies an infantile coarctation [354] Patent ductus arteriosus has been encountered in about 7 per cent of all cases of coarctation of the aorta which were treated surgically [108]

The *heart* reveals hypertrophy of the left ventricle in all cases The adult form of coarctation is not infrequently associated at necropsy with a bicuspid aortic valve which may be congenital or rheumatic (p 864) Congenital subaortic stenosis and aortic insufficiency occur occasionally in cases of adult coarctation, with or without bicuspid valves Miliary aneurysms of the small cerebral vessels are not infrequent especially at their bifurcation in the region of the circle of Willis Forbus[158] found the media of the vessels at the site of the aneurysm either very thin or absent The cerebral aneurysms may be due to the high tension in the upper half of the body (including the brain) which appears in

infancy as well as to a developmental defect Post stenotic aortic dilatation or aneurysm may occur just below the coarctation[255] Aneurysm of the aortic sinus may be associated with coarctation of the aorta[131]

Schwartz and Greene[352] described cases of coarctation of the aorta in children with involvement of the origin of the left subclavian An atypical form of coarctation of the aorta has been described in which the left subclavian artery is occluded but there is no obstruction of the blood flow in the thoracic aorta[47] Almost complete absence of the left radial pulse and a slow rise in pulse tracings were characteristic The diagnosis can be confirmed by angiocardiography

Pathologic Physiology in Adult Coarctation of the Aorta

There is a normal blood flow from the right side of the heart through the lungs and from the left ventricle into the aorta The blood flow to the head and upper extremities is normal or elevated[32] But because of the aortic constriction aortic blood to the lower half of the body is detoured A striking *collateral circulation* develops around the constriction in cases of adult coarctation[31] Branches of the subclavian artery above anastomose with branches of the descending aorta below the stenosis or occlusion The chief anastomoses are between (1) the superior intercostal branches of the subclavian artery and the first intercostal branches of the aorta within the thorax (2) the scapular branches of the subclavian artery and the aortic intercostal vessels in the chest wall (3) the internal mammary branches of the subclavian and the epigastric branches of the external iliac in the abdomen These anastomotic vessels become greatly dilated and the aortic intercostal vessels often erode the lower margins of the ribs posteriorly The collateral circulation may be limited to the interior of the chest wall and thus not visible or palpable clinically There are also mild cases of coarctation of the aorta with poorly developed collateral circulations

Detailed reviews of the anatomic and clinical features of coarctation of the aorta have been presented by Abbott[2] Blackford[25] King[233] Lewis[253] and Reifenstein et al[3]

Clinical Features

Symptoms are often absent The patient may be unaware of his disease until there is a sudden fatal complication such as rupture of the aorta or of a cerebral vessel or until cardiac failure or bacterial aortitis develops Certain symptoms may be associated with the hypertension which is usually present These include headaches dizziness tinnitus insomnia epistaxis and nervousness Neurologic symptoms may be the first manifestations due to cerebral complications (see below) The patient may complain of weakness coldness pallor *numbness or cramps in the legs due to* diminished circulation in the lower half of the body Occasionally there is intermittent claudication The temperature of the feet has been found diminished[■] *Symptoms of congestive heart failure* especially dyspnea may eventually result from the hypertension and left *ventricular enlargement* Occasionally there is palpitation and precordial distress Congestive heart failure commonly develops sooner or later But occasionally it occurs in infancy and coarctation must always be considered in the differential diagnosis of heart failure in infancy[17, 246a]

The *objective signs* are more striking and of diagnostic importance The subjects with adult coarctation are often robust muscular and intelligent There are striking bilateral supraclavicular pulsations due to large subclavian arteries Dilated tortuous *collateral vessels* may be visible or palpable Most often these are situated along the inner borders of and across the scapula in the axilla or less often along the sternum or in the epigastrium The vessels are more readily observed when the subject is in a warm room or has been active According to Campbell and Suzman[35] these collateral vessels are more readily observed if the patient leans forward Systolic bruits and thrills may be present over these dilated collateral vessels Cyanosis and clubbing are absent in the adult type of coarctation because there is no venous arterial shunt and the pulmonary blood flow ■ normal

Physical examination of the heart may reveal only a slight enlargement to the left and downward There is usually a moderately loud systolic murmur over the precordium most intense at the base but often heard also in the left interscapular region The murmur is occasionally loud and harsh and accompanied by a thrill Sometimes it is louder in the back than anteriorly The murmur may arise in the dilated collateral vessels or at the site of con

striction of the aorta There may also be murmurs of an associated subaortic or aortic stenosis and insufficiency

Arterial Pulses In contrast with the strong pulsations in the suprasternal and supraclavicular regions there is no palpable aortic pulsation in the abdomen The femoral pulses are weak or impalpable[384] The circuitous course of aortic blood flow to the femorals not only weakens the femoral pulse but also causes it to appear later than the radial pulse when simultaneous graphic records are made (Fig 136C) Normally the femoral pulse slightly precedes the radial

sure is considerably higher than the femoral systolic The arterial blood pressure in the upper and lower extremities has been measured directly by cannulization of the vessels and recorded by optical tracings[4 6 377 ...] These measurements revealed that whereas the systolic blood pressure was higher in the upper than in the lower extremity the diastolic pressures were equal or only slightly less in the lower than in the upper extremity The femoral systolic pressure was depressed but the femoral diastolic was usually slightly above normal From these observations Steele[377] concluded that the increased periph

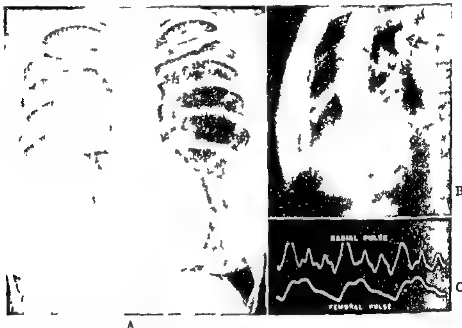

Fig 136 Coarctation of aorta *A* Notching of lower borders of ribs

B Angiocardiogram left lateral position Visualization of ascending aorta and arch At and beyond aortic isthmus irregularity and narrowing of aortic lumen (arrow)

C Simultaneous radial and femoral pulse to show delay of latter

Hypertension in Coarctation of the Aorta Hypertension is a characteristic feature of the adult type of aortic coarctation It may be absent if the anomaly is complicated by heart failure bacteremia and according to King[239] occasionally in uncomplicated cases The hypertension is chiefly systolic but the diastolic pressure may also be elevated to a variable degree *A diagnostic feature is the limitation of the hypertension to the upper extremities* the blood pressure in the lowers being normal or depressed Normally the systolic blood pressure in the femoral artery is about 20 mm higher than in the brachial In cases of adult coarctation the brachial systolic pres

eral resistance underlying the hypertension is generalized and involves lower as well as upper extremities However Bing and his associates[33] found the diastolic pressure elevated in the arms and not in the lower extremities and concluded that there was no *generalized* elevation of peripheral vascular resistance

Clinical studies of circulatory dynamics in cases of coarctation of the aorta[49] and animal experiments[305] have failed to elucidate the exact mechanism responsible for the hypertension and its limitation to the upper half of the body[204] The *mechanical theory* supposes that these abnormalities are purely the result of mechanical obstruction, ... but persistent

hypertension has not been produced experimentally in dogs by occluding the aortic isthmus at a level corresponding to the site of human adult coarctation The *humoral or renal theory* proposes that the hypertension is due to renal ischemia It is supported by studies of renal blood flow[164] and by the experiments in which hypertension in dogs[181] and in rabbits[345] was produced by means of constricting the aorta just above both renal arteries Hypertension did not follow similar obstruction below the origins of these vessels On the other hand the blood pressure in these experiments gradually fell to normal unless the aorta was clamped below as well as above the level of the renal vessels Studies by Scott et al [333] of experimental coarctation of the aorta favored a renal origin of the hypertension since transplantation of all functioning renal tissue above the site of the constriction caused a prompt reversion of the blood pressure to normal levels An observation which does not support the renal theory is supplied by a case reported by Maycock [79] in which there was pronounced brachial hypertension although the stenosis was below the level of the renal vessels The observations of Bing et al [37] (supra) and those of Hull[214] also indicate that the hypertension is not due to renal ischemia and a consequent humoral pressor substance but to the resistance of the aortic stenosis and the collateral vessels

Roentgenology

The heart is only slightly enlarged the enlargement involving the left ventricular contour as in cases of essential hypertension

The ascending aorta is dilated bulges somewhat to the right and shows increased pulsation

The aortic knob in the anteroposterior view is often small and may be absent and is in contrast with the prominent ascending aorta According to Fray [161] a pathognomonic feature is the presence of a localized defect or break in the continuity of the aortic arch on its convexity as viewed in the left anterior oblique view This break is situated at the junction of the transverse and descending portion of the arch and corresponds to the location of the coarctation at the point of insertion of the ligamentum arteriosum It is often difficult to outline the deformed and discontinuous descending aorta Gladnikoff[177] emphasized the recognition of a dilated left subclavian artery medial displacement of the aortic arch and indentation in the upper portion of the descending aorta as signs of coarctation

Attention has recently been directed to many accessory radiologic signs of coarctation of the aorta which have been neglected or insufficiently emphasized and which are of special diagnostic value in patients who have no rib notching [155] (1) Instead of a distinct aortic knob which is continuous laterally into the descending aorta the knob is small and indistinct and the transition to the descending aorta is vague and discontinuous [66] (2) There may be an indentation or concavity below the aortic knob at the site of coarctation (3) The descending aorta forms a lateral convexity below the aortic knob which simulates a second knob Occasionally this convexity is marked when it is the site of a post-stenotic aneurysm (4) The dilated left subclavian artery widens the left superior mediastinum which shows prominent pulsations The marked pulsations of the ascending aorta and left superior mediastinum contrast with the inconspicuous pulsations in the descending aorta (5) The internal mammary arteries may produce scalloped indentations in the anterior margins of the lungs suggesting multiple soft tissue masses especially in the left anterior oblique view [5 6] (6) In the lateral or left anterior oblique view an indentation in the posterosuperior aortic contour behind the tracheal air shadow denoting the coarctation site may be observed in 30 per cent of the cases [156]

Of at least equal diagnostic value and more readily discoverable is the *erosion of the lower borders of the ribs* by the large collateral vessels first noted roentgenoscopically by Roesler[321] and by Railsback and Dock[3 4] (Fig 136A) The erosions may involve a variable number of ribs from the third to the tenth usually on both sides and in their posterior portion The erosions are localized smooth and curvilinear They have been seen in patients aged 6 but as a rule do not become apparent before the age of 12[3 5] Since the collateral circulation and notching of the ribs should be well developed by the age of 13 to 14 absence of rib notching after that age is of surgical importance because it suggests that the collateral circulation is too poorly developed to allow the complete occlusion necessary for surgical repair or that the coarctation is too mild to require such repair

The normal curve of the barium filled esophagus may be absent and the esophagus, when viewed in the right anterior oblique position may be seen to be situated to the right of the aortic arch It is displaced anteriorly and to the right

Angiocardiography and Thoracic Aortography

These techniques show distinctly the site of occlusion or stenosis of the aorta and often its approximate length and caliber may be estimated (Fig 136B) Preoperative demonstration of the site and extent of the coarctation is of great importance to the surgeon and determines whether the lesion is amenable to surgical repair and whether grafting may be necessary It is likewise of value to depict the relation of the constriction to the subclavian artery At the same time angiocardiography may disclose the presence of associated congenital vascular lesions and the state of the collateral circulation particularly the size of the internal mammary arteries and the aortic branches proximal to the coarctation Nicolson[30] reported a case of coarctation of the aorta with arrested bacterial endocarditis in which a calcified mycotic aneurysm at the site of constriction was clearly filled by contrast medium *Thoracic aortography* has also been employed to demonstrate the coarctation (p 16) An F7 or F9 catheter is inserted through the upper part of the exposed radial artery into the subclavian artery or aortic arch and 50 cc of 70 per cent Diodrast rapidly injected while roentgen ray films are made The ulnar artery has also been used, or the injection may be made directly into the left common carotid artery

Electrocardiography

This is not diagnostic There may be a left axis deviation In young infants there may be a pattern of right ventricular hypertrophy or right bundle branch block[430]

Ballistocardiography

The ballistocardiogram shows an absence of the K wave (p 61) which is restored following successful operation[6, 301] This is diagnostic if other causes of obstruction of the lower end of the aorta can be excluded

Diagnosis

The diagnosis of coarctation of the aorta is discussed independently of the general diagnosis of congenital heart disease because the disease is often masked as essential or malignant hypertension neurologic disease or cardiac failure without suggesting the possibility of a congenital cardiac abnormality Therefore the finding of hypertension, particularly in a young adult or child, should always be followed by palpation of the femoral pulse and determination of the femoral blood pressure If the femoral pulse is weak or absent and the blood pressure less than in the upper extremity, a tentative diagnosis of coarctation of the aorta is warranted[384] Confirmatory signs are then sought e g, visible or palpable collateral vessels over the scapular and interscapular regions, the axilla, parasternal or lower anterior chest wall murmurs or thrills in these areas, particularly a systolic murmur which is as loud or louder in the interscapular region as over the precordium roentgenologic observation of erosion of the ribs or defect in the aortic arch Eisenberg[140] emphasizes the fact that in children with the adult form of coarctation, there may be no great collateral circulation and no erosion of the ribs Diagnosis in such cases depends essentially on the difference in brachial and femoral blood pressures on weakness or absence of the femoral pulse and on confirmation by angiocardiography Unfortunately only a small portion of the cases of coarctation of the aorta are diagnosed *before the age of 15,* the optimal time of operation is below that age when the blood vessels are still elastic and irreversible cardiovascular damage has not yet occurred as a rule

Coarctation of the aorta should also be considered in cases of cerebral accidents in young persons

Occasionally a loud interscapular murmur or the presence of large collateral vessels suggests the diagnosis of coarctation in the rare cases of coarctation without hypertension

A simultaneous recording of femoral and radial pulse waves revealing a lag in the former, and delayed build up of the femoral pulse also confirm coarctation of the aorta[55, 4, 6]

The finding of unequal radial pulses with weakness or absence of the left brachial and radial, should suggest the possibility of aortic coarctation The latter should also be sought in cases of congenital subaortic stenosis

Prognosis Complications and Cause of Death

A knowledge of the outlook for untreated cases of coarctation has assumed increased importance since a technique of surgical treatment has been developed

The adult form of coarctation is occasionally compatible not only with long life[3,4] (Reynaud's patient lived to the age of 92) but often also with normal physical activity. Nevertheless, in reported series of cases death occurred at a relatively early age and in most instances before the fortieth year.[2] In Blackford's[39] series of 323 cases only 68 patients survived the age of 40, 125 died in the first year, 142 (including the former 125) died in the first decade and 112 between the ages of 16 and 40. This series included cases of the infantile as well as of the adult form of coarctation. In a more recent study of 104 cases of the adult type of coarctation of the aorta 61 per cent died during or before the fortieth year of life and the average age at death was 35.[3] But about 25 per cent of the patients attained a relatively normal life span and died of incidental causes. It is probable that these series include the most severe cases of coarctation and that those with the least disability and complications and with the longest life are either overlooked or treated by the general practitioner, the latter therefore frequently do not enter into hospital and autopsy statistics. Nevertheless the over all outlook for a normal life appears to be poor.

The commonest *complications* and *causes of death* are congestive heart failure, bacterial endocarditis or aortitis, rupture of the aorta and cerebral hemorrhage (exclusive of that due to bacterial emboli sm). About one quarter of the patients succumb from aortic rupture, one quarter from bacterial endocarditis and one quarter from complications of hypertension, i.e., either heart failure or intracranial hemorrhage.[195]

Progressive cardiac failure occurred in 25 per cent of Abbott's[2] 200 cases and sudden cardiac death in 8 per cent. Aside from hypertension, congenital subaortic stenosis, rheumatic cardiovalvular disease, coronary atherosclerosis and myocardial infarction are contributory factors in the development of the heart failure.

Rupture of the aorta was the cause of death in 23 per cent of cases in the series of Reifenstein et al.[277] This appears as a linear or zigzag tear usually 1 to 4 cm. above the aortic valve or just below the site of the coarctation. Microscopic examination of the ascending aorta reveals defects, splitting and disorientation of the elastic tissue in the media possibly due to prolonged mechanical stress. The upper aortic rupture produces a dissecting aneurysm of the descending aorta which may rupture into the pericardium and cause fatal cardiac tamponade. Rupture at the lower site is into a bronchus, esophagus or left pleural cavity.

Cerebral accidents are responsible for death in 10 to 17 per cent of reported series of cases. Subarachnoid or cerebral hemorrhage results from perforation of cerebral miliary aneurysms probably of congenital origin. Hemorrhage and encephalomalacia may also be caused by mycotic emboli and aneurysms of the cerebral vessels secondary to a bacterial endocarditis or aortitis. Headache, convulsions, hemiplegia, coldness and numbness in the lower extremities, vertigo, tinnitus and transitory visual disturbances are among the more common neurologic manifestations of coarctation of the aorta.[4,3] In some cases a minute perforation of a cerebral miliary aneurysm with intermittent leakage of blood has been diagnosed on the basis of recurrent apoplectiform seizures occurring suddenly, associated with severe bursting headache and followed by transient neurologic signs.[114]

Bacterial endocarditis most commonly involves the aortic valve which is often bicuspid, or the site of congenital or rheumatic stenosis and insufficiency. A similar clinical picture results from a *bacterial aortitis* in which the bacterial vegetations are situated in the aortic intima just below the site of the coarctation or occasionally in the ascending aorta.

Surgical Treatment

Successful correction of coarctation of the aorta was first accomplished independently by Crafoord and Nylin[106] and by Gross and Hufnagel.[168] There were 15 fatalities in the first 100 and only 2 deaths in the last 100 of 270 patients operated for coarctation of the aorta by Gross.[195] Clagett et al.[95] reported a mortality of 5.6 per cent among 177 operated cases, including many that were complicated, with patients as young as 2 weeks and many over 30 and up to 50 years of age. After the application of special clamps above and below the constricted portion of the aorta, the latter is resected and the continuity of the artery reestablished by end-to-end anastomosis. A continuous mattress silk suture with an everting type of repair is less apt to cause later aortic dissection than an anatomic

layer to layer anastomosis In children, interrupted silk sutures are employed to permit enlargement of the aorta with growth of the child Often the third pair of intercostal arteries must be sacrificed by careful ligation and section Care must be taken in the dissection especially below the coarctation, not to injure the thin walled intercostal arteries and thus cause massive hemorrhage After the anastomosis has been effected, the clamps on the aorta and subclavian artery must be removed gradually in order to prevent sudden flooding of the vascular bed and acute cardiac dilatation There is a rapid reduction in the hypertension in a few days or a more gradual reduction within three weeks after the operation Simultaneously there is a restoration of normal pulsations in the lower extremities Preoperative headaches epistaxis or leg cramps usually disappear after the operation

Many complicating factors may cause a modification of the technique of transection and end to-end anastomosis [94] When it is not feasible the large left subclavian artery may be sectioned its distal portion ligated and its proximal end anastomosed with the aorta which has previously been sectioned distal to the coarctation [363, 174] In a variable number of cases in which simple resection and anastomosis are technically difficult or impossible, continuity of the resected aortic coarctation is reestablished by the use of homografts [187] Freeze dried arterial homografts saved in graft banks have been found suitable [347] Long term observations have shown no dilatation or aneurysm formation in the grafts but calcification has been observed roentgenologically [98] Tubes constructed from Vinyon N cloth a plastic have also been employed to bridge arterial defects [40] In inserting aortic grafts above the level of the renal arteries there is always the problem of the brief time that the aorta may be occluded Johnson et al [2 0] described a method for maintaining an adequate blood flow through the thoracic aorta while inserting the graft by use of a glass or plastic tube with flanges around each end The graft is placed around the tube the aorta is clamped off the appropriate area is resected and the tube is tied into one and then the other end of the resected aorta Blood flow is reestablished and the graft sewn with the tube in place The tube is removed just before suturing is completed Julian et al [5] used induced hypotension and hypothermia for resection of coarctation of the aorta in cases requiring grafts

Other problems arise in connection with the persistence of a patent ductus [219, 103] with pulmonary hypertension, in combination with coarctation of the aorta The aortic constriction should be repaired without, as a rule, occluding the ductus There may be multiple sites of constriction [135] abnormalities in the vessels of the aortic arch, and aneurysms of the aortic wall or intercostal arteries or diffuse hypoplasia of the aorta Fatalities have occurred postoperatively in cases with associated mitral stenosis or severe aortic insufficiency

Indication for Surgical Treatment In view of the poor prognosis for unoperated coarctation of the aorta, and the relatively low operative mortality which should be less than 5 per cent, surgical treatment should be undertaken in virtually all patients whose general condition permits Cardiac failure is no contraindication although a brief time may be spent in an effort to control the heart failure medically before undertaking the operation Often, and especially in infants and young children, it is heart failure which is the indication for operation, and compensation can not be restored by medical measures until the coarctation is repaired surgically

The optimum time of operation is between the ages of 10 and 15 or 10 and 20, but it should be done at any time before 10 or even in young infants[288] if progressive cardiac enlargement recurrent heart failure or other serious disturbances forbid delay In such cases it is undesirable to wait until growth is completed before performing the operation for fear that the site of anastomosis will not enlarge with the remainder of the aorta In a person beyond the age of 20 vascular elasticity diminishes and aortic atherosclerosis may be of sufficient degree to impair the ease and safety of surgical manipulation Nevertheless, age, even up to 50 or beyond, is no absolute contraindication, successful anastomoses with gratifying clinical results have been attained

OTHER CONGENITAL CARDIAC ANOMALIES

RIGHT SIDED OR DOUBLE AORTIC ARCH

Embryology and Pathology

In the five week embryo there are six pairs of aortic arches connecting the primitive ventral and dorsal aorta The first two disappear but their ventral roots form the external carotid arteries The third arches form part of the internal carotid arteries The right fourth arch normally disappears but its ventral root forms the innominate artery The left fourth arch forms the arch of the adult aorta The fifth arches disappear The sixth arches also disappear but the ventral root on the right forms the pulmonary artery and the dorsal root on the left forms the ductus arteriosus

A persistent right sided aortic arch is found when the fourth left arch disappears while the fourth right embryonic arch develops into the adult arch of the aorta [29] In cases of right aortic arch the ascending aorta lies normally at its origin but then instead of arching upward and to the left across the front of the trachea, as it does normally it ascends and turns posteriorly to the right of the trachea and esophagus and then descends in one of two ways (1) The descending aorta is on the right of the trachea and esophagus or (2) it starts by passing from right to left across the right bronchus behind the trachea and esophagus and descends as a left aorta The aorta crosses to the left when it is drawn over by a ductus arteriosus or a left subclavian artery which arises in its normal left sided pattern

The right sided aortic arch occurs most often in association with the tetralogy of Fallot and other conditions in which there is dextroposition of the aorta It is seen more commonly in males

Occasionally both fourth arches persist and give rise to a double aortic arch encircling the trachea and esophagus [9] one passing in front and to the left of the trachea the other to the right of the trachea and esophagus The two limbs then join to form the descending aorta which is usually on the left side of the spinal column The space between the two arches is so small that the trachea and esophagus are compressed

Clinical Features

As a rule a persistent right aortic arch or less often a double aortic arch is clinically insignificant and is discovered accidentally by roentgen ray examination or at autopsy But they may become of clinical importance in three ways

First they occasionally produce symptoms, such as *dysphagia and dyspnea*, by compression of the esophagus or trachea at about the level of the third dorsal vertebra (dysphagia lusoria) These abnormal vascular structures are sometimes termed "vascular rings since they encircle the trachea and esophagus The trachea is particularly compressed by the double aortic arch with resulting respiratory distress and pulmonary infections Respiratory difficulty is likely to be intensified during or immediately after swallowing There may be wheezing respiration ("crowing stridor") due to tracheal obstruction A double aortic arch may itself produce a constricting vascular ring A right aortic arch may cause some bronchial compression but cannot alone produce compression of the trachea and esophagus However it is frequently associated with other structures such as a diverticulum formed from the vestige of the fourth left arch, or a left subclavian artery arising abnormally from a persistent right aortic arch or a ductus botalli which runs behind the esophagus or a right subclavian artery arising abnormally from the left descending arch any one of which helps to complete a constricting ring The term *arteria lusoria* has been applied to these abnormally situated vessels which may cause dysphagia In the cases in which the descending aorta crosses to the left attacks of croup and pulmonary infections are common in infancy and early childhood and brassy cough may result from compression of the left recurrent laryngeal nerve Noisy stridulous breathing mild dysphagia chronic cough and recurrent pulmonary infections are not infrequent in the cases in which a double aortic arch together with an aberrant left subclavian or patent ductus or ligamentum arteriosum forms a vascular ring around the trachea and esophagus [395] The onset of symptoms is usually later and the symptoms are usually less severe with

right aortic arch than with a double aortic arch

Second, the right sided aortic arch, especially when associated with pressure symptoms, has been diagnosed incorrectly as a mediastinal tumor lymphoma or aneurysm leading to the unwarranted administration of radiotherapy or to surgery

Third the possibility of these vascular anomalies and the close relationship of these aberrant vessels to the trachea and esophagus must be borne in mind when bronchoscopy or esophagoscopy is considered or when surgical correction of tetralogy of Fallot is contemplated

The *diagnosis* is made by *roentgen ray examination* (Fig 137) There is a pulsating shadow of the right aortic arch along the right border of the upper sternum and trachea extending to the right sternoclavicular joint On the other hand the aortic knob on the left is either missing or in cases of double aortic arch the left knob is small The trachea is slightly displaced to the left and in lateral views is seen to be narrowed in the lower segment During inspiration the lungs may not become completely aerated whereas in expiration they are hyperaerated indicating tracheal obstruction The barium filled esophagus is seen to be distinctly displaced to the left and indented This displacement distinguishes cases of right aortic arch from coarctation of the aorta and other congenital cardiac lesions associated with a small or absent aortic knob

In cases of right aortic arch with left descending aorta the barium filled esophagus is displaced forward and is characteristically kinked (Fig 137*B*) In double aortic arch, lateral films may show narrowing of the lumen and anterior displacement of the trachea, and indentation of the posterior wall of the barium filled esophagus

Angiocardiography portrays clearly the anatomic abnormalities of the aortic arch

The diagnosis of a compressing vascular ring should be suspected in any infant with stridor, cough or dysphagia and frequent respiratory infections

Fig 137 Right aortic arch *A* Posteroanterior view Absence of aortic knob on left A shadow is seen extending along right side in supracardiac area and caudad to right of spine (arrow) *B* Right lateral view Barium filled esophagus displaced anteriorly by right aortic arch

Treatment

Relief of the compression symptoms caused by a vascular ring of a double aortic arch has been effected by severance of the smaller aortic arch which is usually anterior Sometimes the ligamentum arteriosum is sectioned at the same time if it retrodisplaces the pulmonary artery Of 26 infants and children operated for a double aortic arch 21 survived and experienced extraordinary relief of symptoms [196]

In cases of right aortic arch the ligamentum arteriosum is sectioned in order to break the constricting ring and any other structures (e g a displaced left subclavian artery) or bands of tissue which contribute to the constriction must be cut The arch itself cannot of

course, be restored to a normal position Of 18 patients between 2 months and 12 years of age operated on for right aortic arch, there were no deaths and striking improvement in all[196]

OTHER ANOMALIES OF THE AORTIC ARCH

Aberrant Right Subclavian Artery

An aberrant right subclavian artery arising as the last branch of the arch of the aorta instead of normally from the innominate artery is a fairly frequent congenital anomaly It arises from the upper or medial aspect of the normal left sided aortic arch or it may arise at the junction of the arch and descending aorta It is frequently dilated at its origin or associated with an aortic diverticulum To reach the right arm the artery must cross the midline from left to right usually behind the esophagus occasionally between esophagus and trachea or rarely in front of the trachea

This partial "vascular ring" causes an oblique filling defect in the posterior esophageal wall at the level of the third or fourth thoracic vertebra which is demonstrable radiologically in the posterior anterior projection Or it causes a semicircular impression on the posterior esophageal wall and narrowing of the esophageal lumen, as seen in the lateral view This anomaly may be associated with other congenital cardiac lesions and was associated with tetralogy of Fallot in 4 of the 7 cases of Pattinson[310]

Although the aberrant right subclavian artery often produces no important symptoms it may cause such a delay in swallowing that feeding and nutrition are impaired Dyspnea is not a complaint but aspiration of food may occur Symptoms may not appear until late adult life[308] When significant disability is present, the anomalous subclavian artery can be freed from its bed doubly ligated and divided In a series of 12 such cases operated on by Gross[198] all patients survived and were freed of their dysphagia

Anomalous Innominate Artery

A leftward displacement of the origin of the innominate artery from the aorta may necessitate its passing anterior to the trachea with consequent tracheal compression Rarely it causes severe respiratory distress with stridor unrelated to feeding Roentgenologic examination in the lateral view shows an oblique indentation with narrowing of the anterior wall of the trachea The compression can be relieved surgically by tension sutures through the sternum raising the first part of the innominate artery and accompanying aortic arch anteriorly, and away from the trachea[196]

Anomalous Left Common Carotid Artery

Rarely this vessel arises from the aorta to the right of its normal position and compresses the anterior surface of the trachea as it courses upward and to the left toward the left side of the neck Roentgenologic examination in the lateral view discloses compression of the anterior wall of the trachea If this causes disturbing symptoms the first part of the carotid artery and accompanying arch is raised off the trachea by mattress tension sutures through the vessels and the sternum

Idiopathic Dilatation of the Pulmonary Artery

Dilatation of the pulmonary artery has been described in a variety of congenital cardiac anomalies with left-to-right shunts and in pulmonary stenosis with post-stenotic dilatation Occasionally dilatation of the pulmonary artery is observed and no other causative abnormality can be discovered The term "idiopathic" dilatation of the pulmonary artery has been applied to such cases[296, 401] The diagnosis is based on roentgenologic observation of a large pulmonary artery occasional prominence of the major branches, but normal vascularity of the peripheral lung fields and normal cardiac silhouette Other causes are excluded by the absence of clinical symptoms normal electrocardiograms and normal findings in cardiac catheterization Occasionally dyspnea on exertion and inconstant systolic murmurs and thrills have been reported

DEXTROCARDIA

Rarely the heart is situated outside the thoracic cavity, either in the abdomen or even outside the chest wall This is termed ectopia cordis The condition is almost always fatal in a few days or in a month or so Occasionally patients with ectopia cordis abdominalis survive into adult life Pectoral ectopia cordis through a fissure in the lower sternum permits viability if both pericardial layers are intact

Dextrocardia with Situs Inversus (Type I Dextrocardia)

True dextrocardia consists of a mirror like transposition of the heart so that the left chambers and apex are on the right and the

right chambers are on the left the apex being formed by the left ventricle There is a similar mirror like transposition of the other viscera (situs inversus), the spleen being on the right and the liver on the left There are no symptoms the condition is without clinical significance except in so far as it may complicate abdominal diagnosis However, there appears to be an increased incidence of severe bronchiectasis and sinusitis in cases of dextrocardia and situs inversus The association of situs inversus sinusitis and bronchiectasis is known as *Kartagener s triad or syndrome* [229, 191] There may be other congenital cardiac anomalies in cases of true dextrocardia

True dextrocardia with situs inversus may be recognized by physical examination, roentgenologically and by the electrocardiogram

Physical examination discloses the apical impulse on the right hepatic dullness on the left and the tympany of Traube s space on the right

Roentgen ray examination reveals the heart chiefly in the right chest with a mirror transposition of the silhouette so that the anterior view of the chest resembles the normal posterior view The stomach bubble is on the right side and the right leaf of the diaphragm is lower than the left

In the electrocardiogram lead I is a mirror image of the normal lead I, the P QRS and T waves are all inverted Lead II is identical with the usual lead III and lead III with the usual lead II If the leads to the arms are reversed, a normal electrocardiogram is obtained For this reason, whenever the electrocardiogram is that of dextrocardia it should be repeated to be sure that it was not due to improper connection of the leads Special problems arise in the interpretations of electrocardiograms when coronary occlusion or other cardiac disturbances are associated with situs inversus [361]

Isolated Dextrocardia (Type II Dextrocardia)

Occasionally there is an *isolated true dextrocardia*, with mirror image arrangement of the cardiac cavities the abdominal viscera retaining their usual position [343] This form of dextrocardia is almost always accompanied by other cardiac anomalies which may be of a serious nature e g especially cor triloculare biatrium but also pulmonary stenosis or atresia, and other conditions which produce persistent cyanosis A persistent left aortic arch is often associated In cases of isolated dextrocardia the P wave in lead I is usually upright, in contrast with its inversion in true dextrocardia with situs inversus [illegible] Isolated dextrocardia is occasionally associated with transposition of the aorta and pulmonary artery (dextrocardia with corrected transposition)

Corrected (False) Dextrocardia (Dextroversion of the Heart Type III Dextrocardia)

There are also cases of false congenital dextrocardia in which there is no mirror transposition the heart being merely displaced and rotated so that it lies in the right side of the chest But the left chambers are on the left and the right chambers are on the right and posterior There is usually an inverted T_1 and often a deep Q_2 or Q_3 but these may be modified by the effects of associated anomalies There are almost always serious associated cardiac anomalies which determine the clinical course, e g, pentalogy of Fallot, transposition of the great vessels pulmonary atresia, right sided aortic arch and defects or absence of the cardiac septa (cor biloculare) There may also be extracardiac anomalies such as congenital defects of the ribs or pectoral muscles or herniation of the lungs But Welsh and Felson[418] reported 6 cases of dextroversion of the heart without complicating anomalies

Dextroposition of the Heart (Secondary Dextrocardia Type IV Dextrocardia)

These are terms applied sometime to cases in which the heart is displaced into the right chest by some external and usually acquired disease of the lungs, pleura or diaphragm [211] There is no change in the electrocardiogram of lead I

Levocardia[1,4, 291, 350] denotes that the heart is normally on the left side but there is situs inversus of the other viscera As a rule there are associated cardiac anomalies, especially tetralogy of Fallot and interatrial septal defects ventricular septal defects, anomalies of the vena cava

CONGENITAL IDIOPATHIC HYPERTROPHY

Congenital idiopathic hypertrophy[339] includes a variety of different conditions which are gradually being segregated They have in common unexplained cardiac enlargement, usually absence of murmurs absence of cyanosis and often absence of any symptoms until

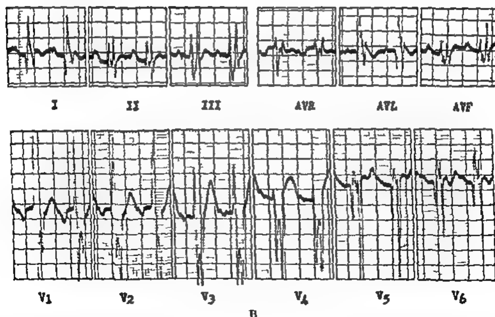

Fig 138 Idiopathic hypertrophy of the heart in an asymptomatic 26 year old man No murmurs Died suddenly six months later *A* Posteroanterior and right anterior oblique roentgenograms of the chest

B Electrocardiogram in above case Severe intraventricular conduction defect Q waves in leads I, aVL, V_1–V_6 suggesting anterolateral infarction

the patient develops heart failure a relatively short period before death

Congenital idiopathic hypertrophy includes cases of (1) endocardial fibroelastosis, (2) aberrant left coronary artery arising from the pulmonary artery, (3) glycogen storage disease of the heart, (4) rhabdomyoma, (5) interstitial (isolated, Fiedler's) myocarditis and (6) coronary artery lesions

1 Endocardial fibroelastosis[100, 401, 120, 151, 409, 234] is characterized by a gray, opaque thickening of the endocardium of one or more chambers the thickened areas being composed of layers of fibrous and elastic tissue There is little or no cellular infiltration The involved chambers are enlarged, usually the left ventricle and left atrium and the heart as a whole are two to four times normal size It is questionable whether the fibroelastosis is the primary cause of the cardiac hypertrophy or whether it is a nonspecific development in cardiac hypertrophy and failure of varied etiology There are commonly associated anomalies such as a tricuspid aortic valve, aortic stenosis, hypoplasia of the aorta or infantile type of coarctation of the aorta[235] Fibroelastosis may implicate the mitral valve and cause mitral insufficiency[234] There may be a family history of congenital heart disease Fibroelastosis occurs in adults[165b]

Symptoms, usually starting a month or two before death, include dyspnea, tachycardia and failure to gain weight There are generalized cardiac enlargement, hepatomegaly and electrocardiographic changes suggesting left ventricular hypertrophy Death is usually due to progressive congestive heart failure Treatment includes measures to control heart failure and improve nutrition and the use of antibiotics

2 Aberrant left coronary artery arising from the pulmonary artery is described below on p 791 It is distinguished by the electrocardiogram, which indicates anterior wall infarction (Fig 138)

3 Glycogen storage disease of the heart[92, 121] **(Glycogen cardiomegaly)**

Cardiac enlargement is due to abnormal storage of glycogen in the heart There is also some abnormal glycogen storage in the liver and skeletal muscle But this condition appears to be independent of if not unrelated to von Gierke s disease with its extreme glycogen accumulation in the liver and other organs, hepatomegaly, morning ketonuria, fasting hypoglycemia, etc , all of which are absent in glycogen cardiomegaly The heart is greatly enlarged, the left ventricle more so than the right The myocardial cells are swollen and contain a central nucleus surrounded by a large vacuolated area which stains for glycogen

Symptoms start in the first few months of life, and death usually occurs within six months, although glycogen cardiomegaly has been found in older children and also in adults Poor feeding, listlessness and poor weight gain progressive and eventually intense dyspnea and tachycardia are the outstanding manifestations Roentgen ray examination shows a large globular heart with occasional dorsally compressed trachea and esophagus, and atelectasis of the left lower lobe of the lung

The *electrocardiogram* is often distinctive and shows left axis deviation *deeply depressed ST segments in the standard leads and left precordial leads,* T inverted in all standard and left precordial leads and occasional ST segment elevation in V_1

The *diagnosis* should be suspected whenever there is "idiopathic" cardiac hypertrophy with ST depressions and T wave inversions in the left precordial leads and may be confirmed by biopsy of skeletal muscle and finding glycogen storage by Best s carmine stain

4 Rhabdomyoma (p 1070)

5 Interstitial (Isolated, Fiedler s) Myocarditis[400, 419]

These cases are characterized by very marked cardiac enlargement and by mild to severe interstitial infiltration of round cells lymphocytes, macrophages, plasma cells and sometimes eosinophils Degenerative myocardial changes are also observed Symptoms are likely to appear later in infancy than with other forms of congenital idiopathic hypertrophy There may be a history of a preceding or present infection or fever or neither of these Tachycardia is common and prominent There may be distress at feeding dyspnea and cyanosis Left and right sided congestive heart failure often develop abruptly with rapid progression often terminating in sudden death[244] There is clinical and roentgenologic evidence of gross uniform cardiac enlargement Gallop rhythm may be present and the liver is enlarged owing to congestive heart failure Respiratory distress

and pulmonary signs due to heart failure are often misinterpreted as pneumonia

Electrocardiographic changes usually consist of evidence of left sided heart strain flat T waves in all standard leads, occasional prolongation of the P R interval and low voltage of the QRS

Unlike the other forms of idiopathic hypertrophy and heart failure this disease may respond following therapy with digitalis and other measures against heart failure

Coronary artery lesions including necrosis of the media or medial hypertrophy and intimal fibrosis of the smaller coronary vessels may be found in cases of idiopathic cardiac hypertrophy

CONGENITAL VALVULAR DEFECTS

Congenital valvular defects are relatively common in association with one or more of the anomalies already discussed But except possibly for the bicuspid aortic valve they are rare as isolated lesions Pulmonic stenosis is the only one that is relatively common as an isolated lesion

PULMONIC STENOSIS (p 749)

PULMONIC INSUFFICIENCY (p 719)

AORTIC VALVULAR DISEASE

A *bicuspid aortic valve* alone or in combination with other lesions, such as coarctation of the aorta or subaortic stenosis is not infrequent It is uncertain how often the bicuspid aortic valve is of congenital and how often of rheumatic origin (p 864) Its chief significance is the frequency of a complicating bacterial endocarditis

Aortic valvular stenosis is usually stated to be rare but my personal clinical and pathologic observations suggest otherwise Grishman and his associates[190] reported 23 cases of congenital aortic or subaortic stenosis Marquis and Logan [11] also reviewed 23 cases of congenital aortic stenosis Campbell and Kauntze[6] presented evidence for the view that many cases of aortic stenosis in adults (aside from subaortic stenosis) are of congenital origin with superimposed degenerative and calcific changes rather than of primary calcific origin They stress the observation that in one half of 40 cases of aortic stenosis a murmur was heard in early childhood although a history of rheumatic fever was present in only two None of the patients presented evidence of mitral stenosis

Aortic stenosis is often due to a firm raised endocardial ring of fibrous tissue a few millimeters below the aortic valve (Fig 139) known as *subaortic stenosis* This appears to be analogous to infundibular stenosis in the right ventricle Subaortic stenosis may be associated with a second stenosis of the valve itself, so called double aortic stenosis A post stenotic dilatation of the aorta may occur similar to the post stenotic dilatation of the pulmonary artery in pulmonic stenosis Coarctation of the aorta narrowing of the aortic isthmus and bicuspid aortic valve are not infrequently associated [87] Subaortic stenosis probably represents an arrest of involution of the bulbus cordis [3] The left ventricle becomes hypertrophied

There are usually no symptoms or disability There may be distinct underdevelopment with severe stenosis (aortic dwarfs) There may be wide splitting of the first sound at the apex [333] There is a loud harsh systolic murmur and thrill maximal in the second right interspace or Erb s point and radiating to the cervical region (Fig 140) But the murmur may be heard lower over the sternal region or toward the apex There may be an associated diastolic murmur The second aortic sound in subaortic stenosis is usually normal and may even be accentuated[3 4] since the valve itself is intact

Roentgen ray examination reveals a large left ventricle and slight prominence of the ascending aorta due to post stenotic dilatation

Electrocardiography discloses left axis deviation and left ventricular hypertrophy

Pulse tracings over the cervical arteries show a characteristic slow initial rise an anacrotic notch systolic vibrations (carotid shudder) and a systolic plateau (Fig 140) Since the aortic valve itself is usually functioning normally the arterial tracing shows a sharp incisura due to aortic valve closure which is absent in cases of aortic valvular stenosis congenital or acquired [59]

In many cases the clinical course is asymptomatic but occasionally death has occurred relatively early because of a complicating bacterial endocarditis or congestive heart failure In cases involving the aortic valve itself angina pectoris syncope and heart failure are more likely to occur

The *diagnosis* is based on the history or finding of a harsh systolic murmur and thrill in childhood the absence of cyanosis and left axis deviation of the electrocardiogram The characteristic *carotid* pulse tracing is diagnostic According to Brofman and Feil,[59] subaortic stenosis is distinguished from aortic stenosis by the presence in the former of a sharp incisura accompanied by an aortic second sound of good quality

Treatment Six of 23 cases reviewed by Marquis and Logan [4] were submitted to aortic valvulotomy The valve was approached through the left ventricle and was ruptured by an expanding dilator without previous incision There were no deaths, but in two cases significant aortic insufficiency and cardiac enlargement were produced In the others there was a striking decrease in physical signs and a change in the form of the arterial pressure wave Electrocardiographic evidence of left ventricular hypertrophy in growing children with signs of aortic stenosis and especially attacks of syncope were regarded as indications for valvulotomy

Aortic atresia is rare The left ventricle is hypoplastic or nonfunctioning and oxygenated blood from the left atrium reaches the right atrium through a defect in the atrial septum Mixed venous and arterial blood passing from the right atrium to the right ventricle and pulmonary artery reaches the aorta by way of a patent ductus Intense cyanosis dyspnea great right sided cardiac enlargement and early death characterize the clinical picture

TRICUSPID VALVULAR DISEASE

Tricuspid stenosis with or without insufficiency is very rare [4]

Ebstein's disease[131, 134, 136, 643] is a congenital downward displacement of the tricuspid valve into the right ventricle Consequently the leaflets, instead of arising normally from the annulus fibrosus arise below this from the wall of the right ventricle The valve leaflets are usually deformed Occasionally the anterior leaflets arise normally from the ring There is no tricuspid regurgitation The portion of the right ventricle above the valve becomes incorporated into the right atrium (atrialized right ventricle) The right atrium is grossly enlarged Little blood thus flows into the right ventricle and pulmonary artery The right ventricle is diminished in volume The blood may reach the right ventricle through a sphincter like aperture in one of the deformed

Fig 139 *Subaortic stenosis male aged 67 Left ventricle opened to show aortic valve and subjacent ridge causing subvalvular stenosis*

valve leaflets There is an associated patency of the foramen ovale in the majority of cases, or there is an interatrial septal defect, but the septum may be intact in some cases A patent ductus may be present

Symptoms When there is an associated interatrial communication there is a right-to-left shunt through the opening and a distinctive clinical picture Dyspnea is a constant symptom There is usually marked cyanosis and slight clubbing The cyanosis is usually delayed but it may appear at birth, disappear and reappear with increasing severity after a few years Fatigability is common Squatting is unusual Occasionally there is no significant circulatory disturbance, no cyanosis[3, 18] and no symptoms due to the lesion as in the case of a woman who survived to the age of 79[5]

Examination reveals marked enlargement of the heart There is a diffuse systolic and often also a diastolic murmur over most of the precordium Gallop rhythm is usual The liver is large There are prominent "a and c waves in the jugular venous tracing

Fluoroscopic and roentgenographic examination disclose enlargement of the heart especially to the right (large right atrium) with a concave pulmonary artery salient small pulmonary arteries and clear lung fields

The electrocardiogram may show right bundle branch block and prolonged P R interval[408] The P waves are tall and may be of increased duration in leads II and III Paroxysmal ventricular premature beats are common

Angiocardiography discloses an enormous right atrium with persistent opacification due to long retention of the contrast substance There is poor visualization of the right ventricle and pulmonary artery The left side of the heart is visualized early by way of the interatrial communication

Catheterization The catheter may loop into the upper part of the right ventricle and meet an obstruction The right ventricular pressure is not elevated as in pulmonic stenosis with atrial septal defect from which Ebstein's anomaly must be distinguished

Diagnosis The diagnosis has been made during life[374, 210, 26, 37] The late onset of cyanosis absence of squatting distinctive cardiac enlargement and roentgenographic appearance of the heart and the systolic and diastolic murmurs can be diagnostic It may be mistaken for Fallot's tetralogy or for pulmonic stenosis with interatrial septal defect If the clinical features are not sufficiently distinctive angiocardiography and cardiac catheterization will differentiate them

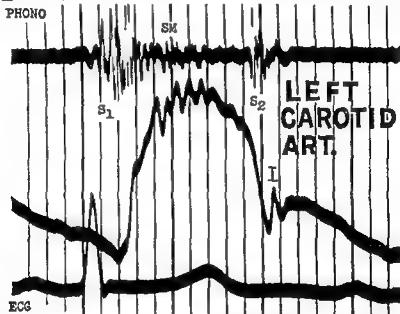

Fig 140 Subaortic stenosis Phonocardiogram and carotid artery tracing Prolonged high amplitude systolic murmur Anacrotic carotid pulse with systolic vibrations and plateau Sharp incisura (I) and normal second sound (S) indicate normal closure of aortic valve

Tricuspid atresia[12, 27, 87] results from faulty development, but its exact pathogenesis is uncertain Several varieties have been distinguished, but in all there is an atresia of the tricuspid valve, characterized by an imperforate atrioventricular canal, which is a simple membranous vault Therefore there is an interatrial communication to maintain the circulation There are two major forms of tricuspid atresia (1) *without transposition of the great vessels*, and (2), a less common form with a better prognosis, *with transposition of the great vessels*[13] Both forms are further subdivided into those with and those without pulmonic stenosis or atresia The group of tricuspid atresia without transposition but with pulmonic stenosis has a very high mortality during infancy but responds well to the Blalock ductus operation and therefore should be recognized early In the group without transposition a ventricular as well as atrial septal defect is present when the pulmonary artery is functioning but the ventricular septum is intact in cases with pulmonary atresia Dextrocardia and reversal of the aortic arch are often associated

In the cases without transposition of the great vessels the right ventricle is extremely small or rudimentary while the right atrium is greatly dilated The left ventricle is hypertrophied The pulmonary valve as well as the tricuspid may be atresic, since the right ventricle does not function

If the interatrial septal defect is small, the heart functions as a triloculate heart (pseudotriloculare-biatrium), blood passing from the right to the left atrium, thence to the left ventricle and aorta From the left ventricle some blood reaches the pulmonary artery and lungs by way of the ventricular septal defect If the ventricular septum is intact blood is supplied to the lungs from the aorta through a patent ductus arteriosus If the atrial septal defect is very large, both atria function as a single chamber and the heart as a biloculate chamber

When tricuspid atresia is associated with transposition of the great vessels, the aorta may arise from the right ventricle and be of small size, the patent pulmonary artery arising from the left ventricle The latter may also expel blood into the aorta through an interventricular septal defect Or the pulmonary artery, arising from the aorta, may be stenosed, and the aorta large and arising from the right ventricle The lung is then vascularized through an interventricular septal defect, patent ductus or bronchial arteries In general, there is little or no cyanosis in this group and a relatively favorable outlook

Clinical Features In the usual case, without transposition, cyanosis appears very early and death occurs in infancy Polycythemia and clubbing occur in those who survive long enough Attacks of syncope and exertional dyspnea are common There may be no murmur or a mesocardial systolic murmur which is heard all over the precordium In cases with a small atrial septal defect which offers resistance to the flow of blood from the right to the left atrium, blood is forced back to the inferior vena cava giving rise to a presystolic liver pulsation The cervical veins are prominent and show exaggerated pulsations

Roentgenology In the anteroposterior view examination reveals an enlarged globular heart with a sharp concavity in the region of the pulmonary conus which is rudimentary In the left anterior oblique view there is little or no shadow anteriorly where the right ventricle should be while the shadow of the left ventricle is enlarged There may be asynchronous pulsations of the anterior and posterior borders of the heart in this view, since the large right atrium replaces the right ventricle on the anterior border[272] The shadow of the great vessels is narrow and the pulmonic window is clear Clear lung fields are characteristic of tricuspid atresia without transposition of the great vessels but they may be obscured when there is an extensive bronchial collateral circulation in certain cases with transposition of the great vessel There may be a deficiency in the lower half of the right cardiac border (right ventricle) in posteroanterior and left anterior oblique views, which has been regarded as characteristic of tricuspid atresia But if the associated atrial septal defect is small relative to the size of the mitral orifice the right atrium may be so dilated and hypertrophied that the lower right cardiac contour is full not deficient[272]

Electrocardiogram The electrocardiogram reveals left axis deviation or the pattern of left ventricular hypertrophy The P waves may be enlarged due to atrial hypertrophy

Angiocardiography[135] discloses the dilated right atrium, interatrial communication (passage of contrast material from right to left

atrium) early filling of the aorta absence of the right ventricle and the position and chamber of origin of the great vessels

Cardiac Catheterization The catheter passes from the right atrium through the interatrial opening into the left atrium The pressure and oxygen concentration of right atrial blood are increased

The diagnosis of tricuspid atresia should be strongly suspected in a cyanotic patient with congenital heart disease if the left ventricle is enlarged and the electrocardiogram shows a left axis deviation or left ventricular hypertrophy

Treatment The cases of tricuspid atresia with rudimentary right ventricle and atrial septal defect as well as those of non functioning right ventricle with atrial septal defect pulmonary atresia and patent ductus are amenable to the Blalock Taussig (p 760) or Potts operation Essentially these are cases of tricuspid atresia without transposition of the great vessels but with pulmonic stenosis

Tricuspid insufficiency is a rare congenital lesion[24] It has been mentioned in association with ventricular septal defect (p 744) In the case described by Barrett and Urich[24] there were progressive cardiac enlargement small pulmonary artery shadows electrocardiographic evidence of right bundle branch block and atrial fibrillation a loud systolic murmur and thrill at the apex systolic pulsation of the cervical veins and liver, cyanosis, and eventual right heart failure

MITRAL VALVULAR DISEASE

Mitral stenosis is usually associated with an interatrial septal defect in so-called Lutembacher's syndrome (p 735) There is a difference of opinion as to whether the mitral lesion is of congenital or rheumatic origin but in my experience at least some cases are unequivocally congenital

A *congenital cleft of the mitral valve* with or without an atrial septal defect may produce the clinical picture of mitral regurgitation with left atrial and left ventricular enlargement systolic and diastolic apical murmurs and heart failure

Mitral atresia is associated with hypoplasia of the left cardiac chambers and aortic atresia and is combined with other defects such as complete absence of the interventricular septum (cor biatrium triloculare)[410] ventricular and atrial septal defects patent ductus arteriosus and with transposition of the great vessels Cyanosis may be absent or mild and intermittent until the onset of heart failure Roentgen ray examination discloses gross cardiac enlargement with enlargement of the right atrium and right ventricle and dilatation of the pulmonary arteries and superior vena cava[105]

ANOMALIES OF THE CORONARY ARTERIES

The most frequent coronary anomalies are the presence of more than two coronary ostia an unusual site of origin of some of the coronary arteries or an abnormal course The right coronary or the left coronary artery may be absent branches of the single coronary artery supplying all parts of the heart[330, 393, 394] In 3 of the 9 cases reported by Roberts and Loube[330] there was occlusion of the single coronary artery with ensuing myocardial infarction

Left Coronary from Pulmonary Artery Of grave clinical significance is the origin of the left coronary artery from the pulmonary artery, so that it carries venous blood to the heart[25] Necrosis and fibrosis of the left ventricle especially of the subendocardial region are consequences of the myocardial anoxia The small arteries or arterioles may be thrombosed Subendocardial fibroelastosis is usually present Marked dilatation of the heart is common and death usually occurs in infancy, though the patient occasionally reaches adult life if there are unusually good anastomoses between the branches of the left and right coronary arteries

Usually during the first month of life but occasionally later dyspnea and tachypnea prolonged time for feeding and diminished weight gain develop There then occur striking attacks of pain sweating and crying resembling angina pectoris with feeding or exertion Examination reveals tachycardia and rapid respirations but usually no murmurs or heart failure There is marked cardiac enlargement chiefly of the left ventricle The electrocardiogram usually shows changes indicative of anterior wall infarction The association of pain and distress on nursing cardiac enlargement without murmurs and the distinctive electrocardiographic changes should suggest the diagnosis Eidlow and

Mackenzie[133] made the correct diagnosis during life in a three months old infant on the basis of paroxysms of cardiac pain associated with sweating pallor cyanosis and dyspnea great enlargement of the heart, and inversion of T_1 and T_2 and deep Q_1 in the electrocardiogram In most of the cases in which the *right* coronary artery arises from the pulmonary artery there is no myocardial fibrosis cardiac enlargement or serious clinical consequences

Congenital arteriovenous fistula and aneurysm between the left circumflex artery and coronary sinus has been described[115] The clinical findings resembled those of a patent ductus arteriosus but the latter was excluded by cardiac catheterization, which showed that arterialized blood was entering the right atrium The patient died of congestive heart failure In a similar case simulating patent ductus arteriosus there was found at operation an anomalous left coronary artery communicating with the right ventricle[116]

PERICARDIAL DEFECTS

The parietal pericardium may be completely absent or only partially incomplete usually in the region of the pulmonary artery[117] In cases of ectopia cordis, the parietal pericardium may be missing or intact When the pericardium is missing, the fetus is usually non viable, when it is intact the outlook may be favorable The characteristic feature in the absence of the parietal pericardium is the complete mobility of the heart both on respiration and change of position of the body This may be demonstrable on physical and roentgenoscopic examination There may be no symptoms or thoracic pain circulatory disturbance and even death may result from kinking of the great vessels due to cardiac mobility An even more common complication in cases with partial or complete absence of the parietal pericardium is the frequency of pneumonia, pleurisy with effusion, empyema or pericarditis due to the juxtaposition of the heart and left lung without an intervening pericardial sac[154]

More rarely there is a diverticulum of the pericardium or failure of attachment of the parietal pericardium These are of no clinical significance unless the orifice of the diverticulum becomes occluded and the consequent distention of the diverticulum interferes with cardiac contraction

ANOMALOUS BANDS, CHORDAE AND PAPILLARY MUSCLES

Occasionally (2 to 3 per cent of hearts), there is a network of thread like strands or a fenestrated membrane in the right atrium continuous with the eustachian or thebesian valves[9] This is known as a Chiari network It may extend across the atrial cavity and be attached to the upper part of the interatrial septum It is believed to represent a residuum or persistence of the valvula venosa dextra together with the septum spurium It is usually an incidental postmortem finding, but it may be clinically significant in two ways First it may act as a favorable site for the formation of thrombi with consequent pulmonary embolism Second, it rarely gives rise to an unusual continuous or systolic murmur which may resemble a venous hum or be confused with the bruit de Roger

Anomalous chordae may extend across the left ventricular cavity from an individual papillary muscle to an attachment high up on a mitral cusp or to the left atrium They may cause confusing adventitious sounds or murmur Papillary muscles may have unusual sites or attachments, e g to a pulmonary valve

The left atrium may be subdivided into two chambers when the septum primum is deflected to the left leaving a cavity between it and the septum secundum Cardiac failure may supervene

CONGENITAL ARTERIOVENOUS ANEURYSM OR VARIX OF THE LUNG[118, 119] (CAVERNOUS HEMANGIOMA)

This condition is usually encountered among young adult males The lesion is usually single, but often there are multiple lesions Heredity may play a role, the anomaly has occurred in brothers[??] in a father and son[403] and in sisters[300] There may be a familial history of telangiectasia[??, 386] The clinical picture depends on the size of the shunt and there may be no abnormalities except roentgen ray findings with small shunts[121] With large shunts the lesion is characterized clinically by persistent cyanosis, polycythemia and clubbing of the fingers and toes by exertional dyspnea hemoptysis, chest pain,

dizziness syncopal or epileptiform seizures, Adams Stokes syndrome and occasionally by focal cerebral manifestations The clinical picture resembles and may be mistaken for that of cyanotic congenital heart disease or of advanced chronic pulmonary disease with cyanosis or polycythemia vera [414] The cyanosis is caused by the shunting of unoxygenated pulmonary artery blood into the pulmonary vein without passing through the pulmonary capillaries A continuous murmur may be heard over the site of the lesion

The heart does not usually become enlarged as in acquired arteriovenous fistula The cardiac output is essentially normal and there is no important change in circulatory dynamics in contrast with systemic arteriovenous fistulas [153] A bruit may be heard over the chest wall overlying the fistula Hemangiomata of the skin or mucous membranes are commonly associated Fluoroscopic and roentgenographic examination may disclose one or multiple nodular lobulated densities with branches into the pulmonary vascular markings [355 356] They are most common in the right lower lobe but occur frequently al o in the left lower lobe and less commonly in any other lobe The densities become larger during the Valsalva and smaller during the Muller experiment [6] They may or may not pulsate Hilar pulsations may be seen on the side of the aneurysms *Laminography* may distinctly how large vessels attached to a spherical lesion Angiocardiography is important in the differential diagnosis [381] Cure may be effected by resection of the aneurysms lobectomy or pneumonectomy [412] Bilateral resection of the involved pulmonary tissue for bilateral pulmonary arteriovenous fistulas has been reported [47]

DIAGNOSIS OF CONGENITAL HEART DISEASE

The diagnosis usually involves the recognition of the congenital nature of a cardiac lesion and the determination of the site and character of the lesion it elf The presence of an organic cardiac murmur of cardiac enlargement or of dyspnea or cyanosis and clubbing without bronchopulmonary disease or brain injury beginning in infancy or early childhood should suggest congenital heart disease Rheumatic heart disease is very uncommon before the age of five and rare before the age of three If the patient is first seen in late childhood or after puberty the congenital nature of the lesion may be suspected from the history of a cardiac murmur or other evidence of heart disease since birth or early childhood A harsh systolic murmur and thrill denote congenital heart disease if they are discovered before the age of 20 The absence of a history of rheumatic fever is confirmatory evidence

An analysis of the signs and symptoms usually permits a clinical diagnosis of the common forms of congenital heart disease Certain characteristic manifestations reveal the congenital origin of specific cardiac anomalies even when there is no history of a lesion since birth

Congestive heart failure occurring in an acyanotic infant should suggest patent ductus arteriosus coarctation of the aorta an ectopic tachycardia or one of the causes of so called idiopathic hypertrophy of the heart The occurrence of dyspnea on feeding associated with stridor suggests the possibility of a vascular ' ring especially a double or right aortic arch

Cyanosis and Cardiac Enlargement in Infancy and Later

Cardiac enlargement and cyanosis in infancy without an associated murmur suggest the diagnosis of complete transposition of the great vessels But cyanosis at or shortly after birth completely relieved by oxygen and diminished by crying suggests pulmonary atelectasis rather than congenital heart disease Methemoglobinemia from drinking well water rich in nitrates from wax crayons acetophenetidin acetanilid sulfonamides or dyes may simulate cyanosis But there are no cardiac enlargement no murmurs and no limitation of exercise Atresia of the aortic isthmus may produce a cyanosis which is limited to the lower extremities if there is no transposition while cyanosis is more intense in the upper half of the body if transposition and isthmus atresia are associated Tricuspid atresia and nonfunctioning right ventricle are distinguished by left axis deviation and left ventricular enlargement

If cardiac enlargement cyano is and a murmur are pre ent in infancy the diagnostic pos ibilities are very numerous and require systematic study of the location of the murmurs roentgenoscopy angiocardiography etc

After the first three years of life, cardiac enlargement murmur and cyanosis are usually due to tetralogy of Fallot, somewhat less commonly to pulmonary stenosis with interatrial septal defect, or the Eisenmenger complex and occasionally to transposed great vessels or tricuspid atresia, persistent truncus arteriosus, levocardia Taussig Bing heart and anomalous pulmonary venous drainage and others The cyanosis is usually less intense and starts later in childhood or only after puberty in cases of Eisenmenger complex or pulmonic stenosis with atrial septal defect as compared with that in tetralogy of Fallot

Murmurs

In early infancy there may be a generalized systolic murmur which only later assumes its characteristic quality and site of maximum intensity A rough loud murmur with maximum intensity in the second left interspace near the sternum may be due to a patent ductus arteriosus pulmonic stenosis or the tetralogy of Fallot Occasionally its maximum intensity is one interspace lower The murmur of a patent ductus arteriosus is usually a pathognomonic machinery like murmur extending through systole and diastole, but it may be absent in infancy or occur only during systole Then however there is usually electrocardiographic evidence of left axis deviation or hypertrophy When there is a patent ductus with reversal of flow, there may be only a systolic murmur or none but the distribution of cyanosis is diagnostic (p 770) The second pulmonic sound is accentuated In aortic septal defect the machinery murmur is heard maximally over the lower sternum or in the fourth left interspace

A venous hum gives a continuous murmur which however is loudest in diastole is heard also to the right of the sternum and changes in intensity with changes in position of the head and neck

A roaring systolic and sometimes diastolic murmur occurs in rupture of a congenital aneurysm of the sinus of Valsalva into the pulmonary artery or right chambers, but there is a history of sudden onset of the murmur in adult life

The murmur of pulmonary stenosis is purely systolic and the second pulmonic sound is often weak or absent A loud systolic murmur with maximum intensity in the third or fourth interspace to the left of the sternum, should suggest an interventricular septal defect The murmur becomes distinctly weaker toward the clavicle or apex but is often transmitted to the left scapular region The atrial septal defect is associated with a variable murmur which may also be located in the third left interspace near the sternum Systolic murmurs in the interscapular regions axilla or along the sternum may be found in cases of adult coarctation of the aorta with well developed collateral circulation A harsh systolic murmur and thrill loudest in the second right interspace, suggests subaortic or aortic stenosis An apical diastolic murmur may occur with an atrial septal defect, interventricular septal defect or a patent ductus arteriosus

In practice, the murmur and history suggest the presence of congenital heart disease, but, except in the case of a patent ductus arteriosus or aortic septal defect, the murmur is not characteristic of a specific lesion However, if one considers the murmur in connection with the absence or presence of cyanosis the possibilities are usually narrowed to (a) atrial or ventricular septal defect or isolated pulmonic stenosis in cases without cyanosis or (b) tetralogy of Fallot, Eisenmenger's syndrome, pulmonic stenosis with interatrial septal defect, patent ductus with pulmonary hypertension and reversed shunt, tricuspid atresia or cases of single ventricle or single outflow tract when there is cyanosis The individual conditions in each group can then be differentiated as a rule by the site of the murmur and the nature of the second pulmonic sound by the time of onset of cyanosis when present, but chiefly by the fluoroscopic and roentgenographic appearance, especially by increased or decreased vascularity of the lung fields

Thrills are not diagnostic They do help to confirm the organic nature of a systolic murmur Furthermore in acquired heart disease they occur, as a rule, in systole over the aorta (aortic stenosis) or in diastole over the apex (mitral stenosis) Thrills in the second, *third* or fourth left interspace near the sternum almost invariably indicate the presence of congenital heart disease, except when there *is a* sudden perforation or tear of a cardiac structure

Roentgenologic Signs

Roentgen ray examination of the chest *is* invaluable in the diagnosis of many of the common congenital cardiac lesions, but only a

few of these are associated with a pathognomonic cardiac contour With some lesions the roentgen ray configuration of the heart is either fairly characteristic or is of great diagnostic help when interpreted in association with the clinical history and physical signs Fluoroscopy oblique views and examination after a barium swallow are essential in addition to a conventional roentgenogram of the chest

The diagnosis of *dextrocardia* can be made from the roentgen ray examination alone The bulk of the cardiac shadow is to the right of the midline The right leaf of the diaphragm is lower than the left In cases of true dextrocardia the electrocardiogram will prove the diagnosis

Adult coarctation of the aorta is often associated with smooth notching of the lower borders of the posterior ribs and occasionally with a localized defect in the descending arch of the aorta when viewed in the left anterior oblique position and with other distinctive signs (p 777) Hypertension weak or absent femoral pulsation and evidence of collateral circulation in the chest wall are also present in most cases

Persistent *double aortic arch and right sided aortic arch* presents distinctive features a pulsating shadow of the right aortic arch to the right of the sternum small or absent left aortic knob displacement of trachea and especially of the barium filled esophagus to the left and forward

Anomalous entrance of the pulmonary veins into the right atrium superior vena cava etc *persistent left superior vena cava aberrant right subclavian artery* and *pulmonary arteriovenous fistula* all have distinctive roentgen ray appearances which have been described

Even in the absence of a distinctive abnormality the roentgenologic examination of the chest usually helps to differentiate the various lesions if attention is paid to (1) the presence of cardiac enlargement and the chamber involved (2) the prominence of the pulmonary artery and prominence and pulsation of the main hilar arteries (3) the caliber of the pulmonary vessels and consequent clarity or engorgement of the lung fields

Among the acyanotic lesions *atrial septal defect* is likely to be associated with enlargement of the heart involving the right atrium and ventricle but especially with a large pulmonary artery pulsating hilar vessels and engorged pulmonary vessels In contrast in *isolated pulmonic stenosis* there may be pulmonary artery enlargement due to post-stenotic dilatation but the peripheral vessels are diminished in caliber and the lung fields clear *Ventricular septal defect* may be associated with a normal sized heart pulmonary artery and branches But with a high (large) septal defect there may be a large pulmonary artery and vessels and differentiation from atrial septal defect depends on cardiac catheterization studies *Patent ductus and aortico pulmonic septal defect* may resemble interatrial septal defect but the murmur is pathognomonic there is a large pulse pressure and there is usually left axis deviation in the electrocardiogram *Persistent truncus arteriosus* is usually unaccompanied by cyanosis and can be distinguished by the prominent aortic knob enlargement of the heart especially the left ventricle and the absence (indentation) of the pulmonary artery salient

Among the lesions associated with cyanosis a diminished caliber of the pulmonary arteries with clear lung fields and usually an indentation of the pulmonary artery salient is observed in tetralogy of Fallot tricuspid atresia (without transposition) and Ebstein s anomaly In pulmonic stenosis with right to-left shunt through an atrial septal communication the pulmonary vessels are small but the main artery is prominent owing to post-stenotic dilatation In some cases of tetralogy of Fallot in which the pulmonic stenosis is valvular the appearance may be similar and differential diagnosis depends on catheterization and angiocardiographic studies Tricuspid atresia is distinguished by the frequent absence of the right ventricular shadow and by left ventricular hypertrophy in the electrocardiogram Ebstein s anomaly is differentiated by the very large right atrium and the usual right bundle branch block in the electrocardiogram

The other relatively common cyanotic cases are associated with *increased caliber* of the *pulmonary* vessels and include Eisenmenger s syndrome (or large ventricular septal defect with right-to-left shunt) transposition of the great vessels patent ductus or aortic septal defect with reversal of flow (marked pulmonary hypertension) and pulmonary atresia or single ventricle or single outflow tract (including pseudo-truncus arteriosus) in which the lungs are supplied by

enlarged bronchial arteries Eisenmenger s complex is distinguished in this group by late and mild cyanosis transposition of the great vessels by deep cyanosis from birth, rapid progressive cardiac enlargement and often a narrow vascular pedicle The conditions with large bronchial arteries are characterized by coarse stippling of the hilar vascular markings

Other abnormal cardiac silhouettes are not characteristic but aid in confirming a diagnosis made on other grounds or in suggesting the presence of cardiac disease Generalized cardiac enlargement without murmurs may be due to a bilocular or trilocular heart, origin of a coronary artery from the pulmonary artery glycogen storage disease of the heart or cases of so called idiopathic hypertrophy (p 784)

Electrocardiogram[404 107 431 373]

The electrocardiogram is characteristic in cases of true dextrocardia with situs inversus Distinctive electrocardiograms have been described in infants with idiopathic cardiac hypertrophy without murmurs due to anomalous origin of the left coronary artery from the pulmonary artery (p 791) and to glycogen disease of the heart (p 786) Otherwise the electrocardiogram does not generally afford specific diagnostic aid to individual congenital cardiac diseases But the presence of right or left or combined ventricular hypertrophy when considered with the presence or absence of cyanosis and the roentgenologic findings in the heart and lung fields, may aid considerably in the differential diagnosis

Left axis deviation and left ventricular hypertrophy in a noncyanotic infant with a systolic murmur would suggest patent ductus arteriosus, subaortic or aortic stenosis or coarctation of the aorta In older children the typical murmur in patent ductus and other findings in coarctation and aortic stenosis would be more diagnostic *Left ventricular* hypertrophy in a non cyanotic infant with cardiac enlargement and no murmur suggests idiopathic cardiac hypertrophy (fibroelastosis) Electrocardiographic evidence of left *ventricular hypertrophy in a cyanotic infant* with a cardiac murmur would suggest tricuspid atresia Left axis deviation is common in cases of Eisenmenger s complex with combined ventricular hypertrophy

Most of the common congenital cardiac lesions other than patent ductus arteriosus coarctation of the aorta aortic stenosis and tricuspid atresia, are associated with right ventricular hypertrophy Attempts have been made to correlate different distinctive patterns with individual diseases associated with right ventricular hypertrophy, based on differences in hemodynamic disturbance [70 127 ...] However, due regard must be maintained for electrocardiographic changes that occur with age, and for differences due to degree of right ventricular hypertrophy rather than to specific etiologic disease or hemodynamic disturbance But differences in patterns may be related to the site of ventricular hypertrophy, since hypertrophy does not occur uniformly throughout the right ventricle, e g, certain lesions such as pulmonic stenosis involve predominantly the outflow tract whereas others, such as interatrial septal defect, involve primarily the inflow tract Thus, incomplete right bundle branch block ("diastolic overloading"[70] or "surcharge" pattern of right ventricular hypertrophy) is characteristic of interatrial septal defect but also occurs commonly in Ebstein's disease and sometimes in ventricular septal defects and other congenital cardiac lesions The "systolic overloading" or "barrage" pattern of right ventricular hypertrophy is observed in cases of isolated pulmonic stenosis and is characterized by a tall R wave in V_1 and other right precordial leads, in association with S-T depressions and T wave inversions in these leads This pattern is rarely if ever seen in tetralogy of Fallot and helps to distinguish this complex from pulmonic stenosis with intact ventricular septum but with atrial septal defect On the other hand incomplete bundle branch block has been observed in 19 of a series of 50 cases of isolated pulmonic stenosis[365] Electrocardiographic evidence of combined ventricular hypertrophy is common in ventricular septal defects and in some cases of patent ductus arteriosus with moderate pulmonary hypertension and in the Eisenmenger and Taussig Bing complexes Right axis deviation in association with the characteristic machinery murmur of patent ductus *denotes an additional lesion* usually pulmonic stenosis or an interventricular septal defect as well

Angiocardiography[152 170] (p 11)

Angiocardiography has become one of the most valuable techniques in the diagnosis of congenital heart disease It reveals with more certainty than the conventional roentgeno-

gram the specific chambers or vessels affected by enlargement or malposition It discloses the sequence of the circulation It differentiates between aneurysms and thoracic tumors unrelated to the cardiovascular system When surgical correction of a cardiac anomaly is contemplated angiocardiography serves to confirm the preoperative diagnosis discloses or excludes associated anomalies and reveals the size position and configuration of structures important to the surgeon

The technique has been described (p 11) For more precise diagnosis selective angiocardiography may be employed (p 15)[34]

Angiocardiography permits a precise diagnosis of dextrocardia persistent left superior vena cava right aortic arch and coarctation of the aorta but retrograde aortography yields a more distinct picture in the latter Dextroposition of the aorta and right to-left shunts in the tetralogy of Fallot and Eisenmenger are usually clearly disclosed by premature visualization of the aorta and right ventricular enlargement in both diminutive pulmonary arteries in the former and normal or enlarged pulmonary arteries in the latter Similarly a right to left interatrial shunt is disclosed by premature opacification of the left atrium ventricle and aorta and the interatrial defect may be visualized A patent ductus may be indicated by persistent visualization of the pulmonary artery and occasionally by a dilatation of the aorta at the site of the ductus The course of the blood stream and the nature and position of the various chambers and great vessels are often disclosed by angiocardiography in conditions with transposition of the great vessels tricuspid atresia pulmonary atresia Ebstein's anomaly of the tricuspid valve and conditions with a single outflow tract

Retrograde Aortography (p 16)

This technique is often superior to intravenous angiocardiography in demonstrating or excluding lesions of the thoracic aorta or aortic arch especially in infants Retrograde aortography is particularly valuable for accurate delineation of the character and extent of the constriction in coarctation of the aorta and the concomitant presence of a patent ductus arteriosus or other associated lesions Retrograde aortography has been successfully employed to differentiate patent ductus arteriosus aortic septal defect coarctation of the aorta and truncus arteriosus from lesions such as a high interventricular septal defect and congenital aortic stenosis[105]

Hypertension in a young person should always suggest the possibility of adult coarctation of the aorta A blood pressure which is significantly less in the lower than in the upper extremities weakness or absence of the femoral pulse evidence of a collateral circulation in the chest wall and notching of the lower borders of the ribs observed roentgenoscopically prove the diagnosis The possibility of congenital heart disease should also be considered in cases of young persons with cerebrovascular accidents in subjects with congenital anomalies such as mongolism and in patients with subacute bacterial endocarditis

Circulation Time Studies

The presence of a venous arterial (right-to-left) shunt may be demonstrated by the administration of ether as in the tests for determining the circulation time (p 214) When such a shunt exists the ether reaches the systemic capillaries and causes distinct unpleasant paresthesias of the skin of the face and subsequently of the extremities[9] This has been observed particularly in cases of the tetralogy of Fallot but it probably also occurs occasionally in cases of atrial or ventricular septal defects or patent ductus arteriosus when the usual left-to right shunt is reversed It also occurs in trilocular or bilocular hearts or in cases with extensive septal defects which are practically tantamount to bilocular hearts in which there is a fairly free mixing of arterial and venous blood even when the major current is in one direction In children as little as 1 or 2 minims of ether may produce the effect (See also intracardiac Evans blue right ventricle-to-ear time p 759)

Cardiac Catheterization (see also p 74)

In cases of interatrial septal defect the right atrial blood oxygen content significantly exceeds (by 2 volumes per 100 cc or more) that of the superior vena cava or the average of both venae cavae The catheter may pass through the septal defect When the pulmonary veins empty into the right atrium the right atrial blood oxygen is high and when all the veins drain into it the oxygen content equals that of a peripheral artery

In cases of interventricular septal defect the right ventricular blood oxygen content significantly exceeds (by 1 vol per 100 cc or

more) that of the right atrium Similar findings are noted in cases of tetralogy of Fallot and Eisenmenger, but with tetralogy of Fallot the pulmonary arterial pressure is lower than that of the right ventricle The catheter may enter the septal defect or the overriding aorta

In cases of patent ductus arteriosus the pulmonary arterial oxygen exceeds that of the right ventricle by at least 0 5 volume per 100 cc The catheter may enter the ductus

In patent ductus with reversal of flow the right ventricular and pulmonary arterial systolic pressures are greatly increased and equal or exceed systemic blood pressure

In uncomplicated pulmonic stenosis the pulmonary artery pressure is low or normal, that of the right ventricle increased

Inhalation of Oxygen

A marked rise in arterial oxygen saturation on breathing oxygen suggests intrinsic pulmonary rather than congenital cardiac disease as the cause of cyanosis

Indicator Dilution Curves

Distinctive dilution curves have been observed following the rapid injection of 0 5 mg per kilogram body weight of the Evans blue dye T 1824 into an antecubital vein[300] or catheter The varying concentration of the dye in arterial blood is measured continuously at the ear by a double scale ear oximeter or at the radial artery by a cuvette oximeter for whole blood Dye curves associated with left to right shunts are similar and characterized by a relative reduction in peak concentration of the dye and a prolongation in the disappearance time of the curve [64] These abnormalities can be related quantitatively to the magnitude of the shunt, but do not disclose the site of the shunt Dye dilution curves have also been obtained in cases of anomalous entrance of the pulmonary veins into the right atrium[300] and various forms of cyanotic congenital heart disease [391 90]

Chapter 31

RHEUMATIC FEVER

Etiology Pathogenesis and Pathology

GENERAL CONSIDERATIONS

In the following discussion rheumatic fever is used to denote the general disease and rheumatic heart disease its cardiac manifestations Cardiac disease is the most serious manifestation of rheumatic fever It is erroneous to consider cardiac involvement merely a complication of this disease, because it occurs almost as often as any other symptom The heart rarely escapes damage in the chronic life history of rheumatic fever Since there is no specific reliable test for this disease only a complete understanding of all the manifestations of rheumatic fever will lead to a thorough recognition of the presence of rheumatic heart disease Even when cardiac involvement is absent in the early stages the physician s diagnosis of rheumatic fever is a warning of potential cardiac disease, since the victim of rheumatic fever is a favored candidate for acute recurrences which may spare the heart at first but rarely later Of 100 consecutive cases of rheumatic fever seen by Coombs [25] predominantly in children 59 presented signs of carditis at their first visit and many of the others developed such signs later so that at least 75 per cent eventually manifested some cardiac lesion In a series of 1000 patients with rheumatic fever followed at least twenty years by Bland and Jones [7] about 800 developed cardiac disease *Practically the importance of rheumatic fever lies in the frequency and seriousness of its cardiac lesions*

Incidence and Importance of Rheumatic Fever and Rheumatic Heart Disease

A host of statistical surveys attest to the relative frequency and importance of rheumatic fever and its cardiac disturbances The data vary according to studies made in urban or rural communities temperate, subtropical or tropical regions seasons of the year among school children or general population civilians and military personnel as well as with differences in diagnostic criteria and acumen

Patients with rheumatic fever form 3 to 7 per cent of the total sick admitted to the large general hospitals of Europe and the United States [101] Accurate determinations of the incidence of rheumatic fever and heart disease are impossible since the disease is not generally reportable and its diagnosis is frequently indefinite In the Scandinavian countries where rheumatic fever is reportable the incidence is between 1 and 3 per thousand Estimates based on various statistical analyses indicate that there are about one million cases of rheumatic heart disease in the United States [101] Reports from the British Ministry of Health[48] indicate that there were 25 000 fatal cases of rheumatic heart disease annually in England and Wales that these formed 40 per cent of all cardiac deaths and that in two thirds of these cases heart disease developed between the ages of 5 and 15

The highest incidence of rheumatic fever and rheumatic heart disease is among children and adolescents According to studies in the schools of several large cities rheumatic heart disease was encountered in 2 to 4 per thousand children between the ages of 6 and 19 [62] In New England and in London the incidence is closer to 2 per cent Keith[71] estimated that rheumatic heart disease occurs in [illegible] [illegible] to 1 36 per cent of American 0 1 to 2 08 per cent of British and 0 36 to [illegible] 92 per cent of Canadian school children Maresh et al [85] found the incidence of rheumatic heart disease to be [illegible] to 7 per 1000 among sixth grade school children in Colorado The seriousness of rheumatic heart disease among young people is

indicated by mortality statistics In the age groups between 5 to 9, 10 to 14 and 15 to 19 rheumatic fever and heart disease rank first as the cause of death, exceeding such diseases as tuberculosis and appendicitis as well as the combined mortality from all of the common contagious diseases Between 20 and 24 rheumatic fever ranks second only to tuberculosis as a cause of death Recent statistics indicate that there has been a reduction in the mortality rate among young people aged 5 to 24 from rheumatic fever (1 6 per 100 000 in 1943) and from rheumatic heart disease (about [illegible] per 100,000 in 1943) [9-6, 46, 141] By 1952 the mortality in this age range was 1 4 from rheumatic fever and only 1 9 per 100 000 from rheumatic heart disease [139] The incidence of new cases of rheumatic fever in the United States appears to have diminished strikingly in the past ten years [148] This may be related to the widespread use of the sulfonamides and antibiotics in nasopharyngeal and tonsillar infections but the progressively downward trend in children's mortality from rheumatic fever and rheumatic heart disease had been strikingly apparent even before the introduction of these drugs

Studies of the incidence of rheumatic heart disease and rheumatic fever among selective service applicants drafted troops and military personnel also attest to the importance of this disease [86] Among the first two million American selectees between the ages of 21 to 36 in the second World War, about 100 000 were found to be unfit because of cardiovascular disease [114] Reexamination by expert cardiologists of these disqualified individuals disclosed that at least 50 per cent suffered from rheumatic valvular defects [11]

The incidence of rheumatic heart disease relative to other etiologic types of heart disease varies in different localities according to the relative frequency of rheumatic fever In large cities of temperate zones such as New York Boston and London rheumatic heart disease represents between 25 and 30 per cent of all cardiac ailments In these places it ranks below coronary (atherosclerotic) and hypertensive heart disease Below the age of 50 it is the commonest type of organic cardiac ailment However, in many southern regions of the United States and in other localities with a high incidence of syphilis rheumatic heart disease is said to follow coronary (atherosclerotic), hypertensive and syphilitic heart disease in that order

Public Health Aspects

The frequency and importance of rheumatic fever and heart disease among school children drafted troops, applicants for life insurance and industrial workers emphasize the need for a public health program With due allowance for statistical inadequacies the available data teach the tragic lesson that in contrast with other major forms of heart disease rheumatic heart disease maims its victim before adolescence, impairs his efficiency and earning power throughout adult life and usually destroys him in his prime Many analogies with tuberculosis including the chronicity of rheumatic fever, social and economic predisposing factors, evidence of infectious etiology, as well as the greater mortality from rheumatic heart disease among young subjects, suggest the need for a public health program and the hope that such a program with respect to rheumatic fever, as with tuberculosis, will yield gratifying accomplishments However it is important to stress that any contemplated public health program for rheumatic fever is handicapped by our ignorance of its exact cause, and by the lack of some exact diagnostic test or specific treatment However, the prophylactic and therapeutic use of antibiotics against the hemolytic streptococcus may prove to be an effective means of attack against rheumatic fever and its recurrences

The need for a public health program and suggestions for such a program have been repeatedly presented [71, 101, 116] London has developed a scheme for the treatment and supervision of juvenile rheumatism[4] making rheumatic fever a reportable disease and providing beds for the treatment of rheumatic fever patients at public expense Special hospital units devoted exclusively to rheumatic fever have been built Emphasis has been placed on the chronic, relapsing nature of the disease Similar programs have been initiated in individual states in this country and a more concerted national effort in this direction has begun since the end of the war The Children's Bureau of the Department of Labor, the Rheumatic Fever Council of the American Heart Association and the Helen Hay Whitney Foundation have been most active

It is important to have a central integrating agency which keeps a registry of rheu

matic fever patients and which coordinates the work of various interested public and private agencies Rheumatic fever should be a reportable disease Expert clinical and laboratory facilities should be made available for aid to the physician in the diagnosis treatment and follow up of patients Case-finding methods should be improved and used more widely especially in schools and among siblings of known rheumatic fever patients Nursing hospital and social service facilities need to be enhanced Hospital facilities should take cognizance of rheumatic fever as a chronic disease as well as of its acute and subacute manifestations Rehabilitation programs should be developed and vocational guidance should be made available to rheumatic patients after convalescence Cooperation of employers should be obtained to aid in the placement of rheumatic patients in industry Research facilities need to be fostered and augmented with respect to epidemiology etiology clinical and laboratory features Educational programs should be designed for physicians nurses welfare workers and the lay public

DEFINITION AND CRITERIA

Rheumatic fever is a chronic inflammatory disease generally punctuated by recurrent acute episodes Its exact cause is unknown The strongest evidence for specificity as presented by pathologists, is the Aschoff body a granulomatous lesion analogous to the tubercle of tuberculosis or the gumma of syphilis There are additional pathologic lesions in rheumatic fever whose structure and distribution are almost specific for the disease Certain clinical features (e g mitral stenosis) are likewise of an almost specific nature

There is no special diagnostic laboratory test for rheumatic fever Fairly rigid criteria are available for diagnosis post mortem especially when Aschoff bodies are present But as will be indicated in the section on Pathology the diagnosis can generally be made even in the absence of these bodies The clinical diagnosis is dependent on less rigid criteria and requires a general consideration of the presence of numerous often seemingly unrelated clinical features including chorea cutaneous lesions hemorrhagic and pleuropulmonary as well as cardiac and arthritic symptoms Some of these, like erythema annulare subcutaneous nodules chorea or mitral stenosis occurring in children or young individuals are practically pathognomonic of rheumatic heart disease (See also p 840)

ETIOLOGY AND PATHOGENESIS

INFECTIOUS NATURE OF RHEUMATIC FEVER

Belief in the infectious nature of rheumatic fever is based on (1) the outbreak of epidemics (2) its occurrence with or after infectious diseases (3) a purportedly high familial association (4) the similarity of its climatic distribution and seasonal occurrence to that of other well known infections and (5) various clinical pathologic bacteriologic and immunologic considerations (infra)

1 On the basis of numerous hospital statistics Newsholme[97] pointed out that in certain years the incidence of rheumatic fever reached epidemic proportions Various epidemics of the disease were observed in army navy and air force barracks[3, 44, 19, 30, 66] Grenet[59] reported an epidemic in a regiment located in a certain sector When this regiment was removed to a distant area additional cases broke out among them On the other hand a new regiment which occupied the original affected area was unaffected These observations tended to indicate that the disease was spread from man to man independent of environment Epidemics of rheumatic fever have also been reported in various schools and in connection with the establishment of hospitals or convalescent homes for rheumatic cardiacs

2 A remarkable feature noted in these and other reports was the occurrence of the epidemics following outbreaks of acute tonsillitis pharyngitis or other respiratory infections and after scarlet fever (p 808) Of course it is generally impossible to be certain that these rheumatic outbreaks are truly epidemics and not merely simultaneous reactivations of the rheumatic process in rheumatic individuals by incidental respiratory infections

3 A number of writers have noted a relatively high incidence of rheumatic fever occurring in more than one member of a family[69] Paul and Salinger's[103] observations on the spread of rheumatic fever through families could be interpreted to indicate the infectious nature of the disease, for both the

initiation of the disease and periods of recurrent activity occurred simultaneously in different members of a given family

4 Rheumatic fever like several other infectious diseases, occurs rarely or infrequently in subtropical or tropical regions and in the warm and dry seasons of the year (p 813) In this respect it particularly resembles the streptococcal infections Years in which the incidence of rheumatic fever is high are associated also with a high incidence of these infections

5 Clinically rheumatic fever resembles other infectious diseases in the occurrence of fever sweats leukocytosis, increased rate of sedimentation of erythrocytes, skin lesions inflammatory pulmonary complications, etc Pathologists generally have accepted an infectious etiology of rheumatic fever because of the analogy of the specific Aschoff body with the specific granuloma in other infectious diseases because of the exudative and productive inflammatory lesions and because of the contiguous spread of the disease in the involved organs The bacteriologic and immunologic evidence for the infectious nature of rheumatic fever is that which will be shortly presented favoring the specific etiology of various bacterial agents

SPECIFIC CAUSE

No specific microorganism has been established as the cause of rheumatic fever Most of the evidence concerning a causative agent has related to streptococci But several other organisms have been invoked as the specific cause including the tubercle bacillus spirochetes and filterable viruses The theories as to causation of rheumatic fever can be considered as (1) hemolytic streptococcal, (2) allergic or hypersensitivity theory (3) non streptococcal

I The Hemolytic Streptococcus and Rheumatic Fever

The etiologic importance of the hemolytic streptococcus is based on clinical epidemiologic bacteriologic and immunologic observations

Preceding Pharyngitis or Tonsillitis The occurrence of sore throat or tonsillitis just prior to an attack of rheumatic fever is a common clinical observation The frequency with which reported epidemics of rheumatic fever were preceded by epidemics of pharyngitis or tonsillitis, occurring one to three weeks earlier, has been mentioned Schlesinger[111] in England and Coburn[20] in this country disclosed that the preceding pharyngeal infections were almost exclusively due to the hemolytic streptococcus Family outbreaks of hemolytic streptococcal infections (Lancefield's type A) are followed in some members of the family by suppurative lesions such as otitis, in others by rheumatic fever[101] A community outbreak of a milk borne epidemic of streptococcus sore throat was followed two weeks later by many cases of rheumatic fever[84] Epidemics of pharyngitis and tonsillitis in crowded populations of boarding schools have similarly been followed by rheumatic fever[44] Among naval recruits, crowded together in various stations during the last war cases of rheumatic fever appeared within a few weeks after hemolytic streptococcal infections hit their peak[44]

Preceding Scarlet Fever The association of rheumatic fever with scarlet fever was particularly noted by Cheadle[18] and others Since scarlet fever is due to an erythrogenic strain of hemolytic streptococcus and since typical clinical features[143] and pathologic evidence[41] of rheumatic fever and rheumatic heart disease are not infrequently observed one to three weeks after scarlet fever, this association may be interpreted to support the etiologic relationship of hemolytic streptococci to rheumatic fever

Hemolytic Streptococcus Infection Before Rheumatic Recurrences Recurrences of rheumatic fever and carditis commonly appear a few weeks after a hemolytic streptococcal pharyngeal infection In most of the reported epidemics of rheumatic fever, not only the initial attacks but also recrudescences followed infections with streptococcus *A* In a high percentage of cases of rheumatic fever among naval recruits in the last war a careful history and examination disclosed that the patient had previously experienced rheumatic fever and that the present attack represented a recrudescence following a hemolytic streptococcal infection Among carefully studied small rheumatic populations in rheumatic cardiac convalescent homes recurrences of rheumatic fever almost never appear except after a hemolytic streptococcal infection

These observations do not signify that all cases of tonsillitis scarlet fever or other hemolytic streptococcal infections are followed by an attack of rheumatic fever, even

if the patient has already suffered a previous attack. Such streptococcal infections in normal children, adolescents or young adults are probably followed by rheumatic fever in [illegible] per cent of cases. Among subjects with previous rheumatic fever a recurrence may be activated by streptococcus A infection in as many as 25 per cent or more. However many of the forty or more strains composing Group A hemolytic streptococci may differ fundamentally in virulence and particularly in their ability to precipitate or activate rheumatic fever. Thus in the same group of rheumatic children one epidemic of streptococcus A infection induced a recurrence of rheumatic fever in 50 per cent of the children, whereas two subsequent streptococcus A epidemic infections caused very few or no cases.[76] In some instances in which attacks of rheumatic fever are not preceded by overt respiratory infections, careful clinical observation may disclose mild pharyngitis or tonsillitis while nasal and pharyngeal cultures disclose the presence of hemolytic streptococci.

Similar Incidence of Streptococcus Hemolytic Infections and Rheumatic Fever. Hemolytic streptococcal infections and rheumatic fever are similar in their geographic, climatic and seasonal incidence. Seegal et al.[1] pointed out that scarlet fever, like rheumatic fever, becomes less frequent as one travels from northern to southern United States and that hemolytic streptococci are found in throat flora less commonly in the subtropical and tropical islands of the West Indies than in the northern half of the United States. Farquhar and Paul[38] noted a similarity in the seasonal incidence of hospital admissions in New Haven between that of rheumatic fever and that of scarlet fever, acute tonsillitis and erysipelas. Coburn[17] noted that patients with active rheumatic fever in New York had hemolytic streptococci in their throats. When the patients were removed to Puerto Rico, the hemolytic streptococci disappeared from their throats and the disease became inactive.

Streptococcus Hemolyticus Antibodies.[85] *Antistreptolysin.*[147, 208] Todd[131] reported the presence of an antigen termed *streptolysin* or *streptohemolysin* in the broth of hemolytic streptococcus cultures, which is hemolytic for the erythrocytes of rabbits. Two varieties have been described: streptolysin O (oxygen labile) and streptolysin S (oxygen stable).[62] The sera from horses which had been immunized with Streptococcus hemolyticus and the sera of humans convalescing from Streptococcus hemolyticus respiratory infections, including scarlet fever, were found to contain an antibody termed *antistreptolysin* (or antihemostreptolysin) which neutralized streptohemolysin and prevented its hemolytic action. It has also been found that about 70 to 90 per cent of patients suffering from acute rheumatic fever have abnormal quantities of antistreptolysin O in their serum.[130, 22] The finding has been interpreted to indicate a [illegible] relation between hemolytic streptococc[illegible] infections and rheumatic fever. The [illegible] ment of non suppurative complic[illegible], especially rheumatic fever, has been [illegible] excessive antibody formation of [illegible] elevated antistreptolysin found in the [illegible] globulin fraction is one example. T[illegible] of antistreptolysin in some cases of [illegible] streptococcal infection or of rhe[illegible] may be due to the failure of [illegible] streptococcal A strains to el[illegible] tolysin O.

The titer of antistrepto[illegible] significantly in the secon[illegible] set of the hemolytic strep[illegible] or tonsillitis, and reaches [illegible] the fourth to sixth week [illegible] minishes.[113] The titer is e[illegible] the highest dilution of [illegible] pletely inhibits the lysis [illegible] blood cells by one unit [illegible] Streptolysin O is now av[illegible] (Difco Laborato[illegible] inhibiting diluti[illegible] to contain 300 u[illegible] normal antistre[illegible] units, the seru[illegible] rheumatic feve[illegible] 250 to 1000 uni[illegible]

Antifibrinolysi[illegible] molytic streptoc[illegible] clot of human p[illegible] tion by these b[illegible] (plasminogen) [illegible] (or streptokina[illegible] vates plasmino[illegible] proteinase whi[illegible] the serum of p[illegible] streptococcal [illegible] with rheumati[illegible] amounts of [illegible] which neutra[illegible] it [illegible]

that patients with rheumatic fever have recently suffered from a hemolytic streptococcal infection

Hyaluronidase and 'Antihyaluronidase' (Hyaluronidase Inhibitor) The collagenous ground substance which is primarily affected in rheumatic fever contains hyaluronic acid as a principal substrate Many strains of hemolytic streptococci have been found to produce hyaluronidase, an enzyme capable of hydrolyzing hyaluronic acid and decreasing its viscosity, thereby favoring the passage of pathogenic microorganisms into collagen tissue Thus Guerra[58] demonstrated that a suitable dye when injected intradermally with hyaluronidase spread to a much greater extent than when the dye was injected with saline In patients with rheumatic fever, there was much more diffusion of the dye than in normal controls Hyaluronidase was interpreted as a 'spreading factor" produced by hemolytic streptococci and accounting for its invasiveness of collagen tissue in rheumatic fever Salicylates were found to inhibit this spreading effect [illegible] but these findings were not confirmed [60]

It is of interest that types 4 and 22 of the streptococcus A are the ones which produce large amounts of hyaluronidase but do not cause rheumatic fever The hyaluronidase effect appears to be antagonized by adrenocorticotrophic hormone The antistreptococcal hyaluronidase "antibody" or hyaluronidase inhibitor titer was found to be elevated in the sera of patients with rheumatic fever or other diseases which have been related to the hemolytic streptococcus [illegible] There is uncertainty whether antihyaluronidase is actually an antibody, hence some prefer to use the term hyaluronidase inhibitor The latter has been found to contain heparin

A mucin clot prevention test has been based on the ability of hyaluronidase to destroy the capacity of protein hyaluronic acid complex to form a typical mucin clot on addition of acetic acid Human serum contains a substance (hyaluronidase inhibitor) which inhibits the action of hyaluronidase on mucin clot prevention The mean titer of hyaluronidase inhibitor in the sera of patients with early active rheumatic fever was found to be higher than that of sera from patients with subsiding or inactive rheumatic fever, hemolytic streptococcal disease or non streptococcal infectious diseases [61]

Although the incidence of elevated serum hyaluronidase inhibitor and elevated antifibrinolysin and antistreptolysin titers is equally high in patients with rheumatic fever, there are many individual patients in whom only one or the other is elevated [106, 83] Stollerman et al [illegible] found a high initial titer of either antistreptolysin O antistreptokinase or antihyaluronidase in the sera of 95 per cent of patients who could be studied within the first two months of onset of an attack of rheumatic fever

Bacteriostatic Antibodies Streptococcus A type-specific bacteriostatic antibodies have been found to develop in the blood of patients following group A streptococcal infections [77] The presence of these antibodies is demonstrated by the phagocytosis of virulent strains of A streptococcus which produce large amounts of type specific M (protein) antigen Similar bacteriostatic antibodies have been demonstrated in the blood of patients with acute rheumatic fever [illegible]

Concomitant with the rise in individual antibodies in cases of rheumatic fever there is an increase in serum gamma globulin fibrinogen alpha globulins, mucopolysaccharides and mucoprotein

The *C reactive protein* is not specifically related to rheumatic fever or streptococcus A infections, and is discussed on page 836

Sulfonamide and Penicillin Prophylaxis and Treatment of Hemolytic Streptococcal Infections The incidence of rheumatic fever has been diminished significantly by active treatment of hemolytic streptococcal infections or by prophylactic use of sulfonamides[78] or penicillin[14] [illegible] to prevent such infections Rapid control of epidemics of hemolytic streptococcal infection in military barracks by chemotherapy or antibiotics was followed by a sharp diminution in new cases of rheumatic fever [illegible] These observations on the prophylaxis and treatment of hemolytic streptococcal infections add support for the theory of a causal relationship between such infections and rheumatic fever

Critique of the Hemolytic Streptococcal Theory In brief, the hemolytic streptococcal theory maintains that rheumatic fever is a phase in the life history of pharyngeal infection with streptococci of Group A *Phase I* is the primary hemolytic streptococcal infection Phase II is a subsequent quiescent period of one to three weeks during which a series of

events occur involving the action of streptococcal products and the complex reaction of the host to the streptococcus and its products (antigen antibody mechanisms) Phase III is the period of the active rheumatic inflammation and phase IV an inactive rheumatic stage which may become activated again by a hemolytic streptococcus infection Variations in the strain type and virulence of the infecting streptococcus and differences in susceptibility of the host account for the failure of many hemolytic streptococcal infections to be followed by active rheumatic disease Furthermore the continued presence of the hemolytic streptococcus or multiple hemolytic streptococcal infections may be necessary

It appears improbable that the hemolytic streptococcus per se is the causative organism directly responsible for rheumatic fever

(1) Blood cultures during active rheumatic fever are almost always negative Hemolytic streptococci have not been isolated with any regularity from rheumatic tissues

(2) Rheumatic fever or rheumatic heart disease has never been reproduced convincingly by hemolytic streptococci or indeed by any other means The spontaneous occurrence in rabbits and guinea pigs of myocardial inflammatory foci resembling Aschoff bodies is a source of misinterpretation of experimental results in these animals Neither could the claims of the experimental production of rheumatic fever in guinea pigs by the combination of vitamin C deficiency and the injection of hemolytic streptococci be accepted or substantiated[1 0] Kellner and Robertson[73] injected intravenously into experimental animals a proteolytic enzyme streptococcal proteinase obtained from hemolytic streptococci and produced selective necrosis of heart muscle However the lesions do not resemble those of rheumatic fever and no Aschoff bodies were produced

(3) The above mentioned findings of hemolytic streptococci in throat cultures in relation to subsequent attacks of rheumatic fever and the findings of hemolytic streptococcal antibodies have been contraindicated especially by Wilson and her associates[146] The frequent disappearance of hemolytic streptococci from the throats of rheumatic patients during the quiescent interval (phase II) and during rheumatic activity (III) is another objection leveled at the hemolytic streptococcal theory

The purported absence of throat infections prior to some attacks of rheumatic fever and the frequent failure of rheumatic subjects to suffer a recurrence despite a streptococcal throat infection are additional criticisms of the theory

However the seeming occurrence of rheumatic fever without previous throat infection and the isolation of group A streptococcus in only 50 to 60 per cent of patients during the acute phase of rheumatic fever[55] might be controverted if bacteriologic studies could be made with more regularity and by special bacteriologic techniques Moreover the frequent absence of rheumatic activity after a hemolytic streptococcal infection and the occasional absence of significant levels of antistreptolysins during rheumatic activity may be dependent on the particular type of hemolytic streptococcus responsible for the throat infection or special susceptibility of the host However there is still uncertainty as to whether rheumatic fever follows only specific types or strains of streptococcus A pharyngitis[107] At present the weight of evidence strongly supports the hypothesis that the hemolytic streptococcus (Group A) or specific types of this streptococcus are important in initiating or precipitating the first or subsequent attacks of rheumatic fever in susceptible individuals However the mechanism by which the hemolytic streptococcus actually produces the pathologic and clinical manifestations of the disease and the manner in which rheumatic fever activity persists for many months in the absence of demonstrable streptococci are among the important gaps in the streptococcal theory of rheumatic fever

2 Hypersensitivity Theory of Rheumatic Fever

The hypersensitivity or allergic theory has been proposed to account for some of the gaps in the streptococcal theory and for the failure to isolate a specific causative organism from the blood joint effusions or the affected tissues in cases of acute rheumatic fever and rheumatic heart disease

Theory of Hypersensitivity to Streptococcus A (Hemolyticus) At the present time the most widely accepted theory of the pathogenesis of rheumatic fever proposes that this disease results from infection with the hemolytic streptococcus but only in those subjects who exhibit an exaggerated immunologic response (hypersensitivity) to that organism or its

products[129] The evidence for the role of the hemolytic streptococcus has been presented The evidence for hypersensitivity to this organism is less direct

The general idea that rheumatic fever might represent some type of immunologic reaction was suggested by the analogy to serum sickness in which a latent period of 10 to 21 days elapses between foreign serum injection (sensitization) and the serum sickness reaction In rheumatic fever there is a similar interval between the hemolytic streptococcal pharyngitis and the subsequent appearance of active rheumatic fever[118] Furthermore, this interval appears to correspond to the interval required for the development of large quantities of circulating antibodies In both diseases fever non suppurative arthritis and cutaneous lesions are characteristic manifestations This concept appeared to be supported by a variety of studies in which lesions resembling those of rheumatic fever were induced in rabbits following the repeated injection of horse serum[74, [illegible], 110] However, discordant observations[18] have been made by others and despite some resemblance of the experimental lesions to those of rheumatic fever the latter disease as it occurs in humans has not been produced experimentally The belief that periarteritis is an allergic disease, the association in some patients of rheumatic fever and periarteritis nodosa,[41] and the claim that both periarteritis nodosa and rheumatic fever may be produced experimentally by the same technique of foreign protein sensitization[110] are also cited in support of the hypersensitivity theory of rheumatic fever But there are many differences between rheumatic fever and periarteritis nodosa[82]

That rheumatic fever is a hypersensitivity response to the hemolytic streptococcus is indicated by the exceptionally high concentration of antistreptolysin and other antibodies to hemolytic streptococcal antigens in patients with active rheumatic fever,[21, 61] as compared with subjects who do not develop rheumatic fever after hemolytic streptococcus pharyngitis However there are exceptions to this general observation Furthermore there is no universal relationship between the development of such streptococcal antibodies and rheumatic fever, thus high antistreptolysin O titers may be observed in only 70 to 90 per cent of cases of active rheumatic fever

Another example of the possible relationship of rheumatic fever to circulating streptococcal A antibodies is the observation that when penicillin is administered early in the course of a hemolytic streptococcal infection it both suppresses the development of antibodies and prevents rheumatic fever But Catanzaro et al,[11] by withholding penicillin until the ninth day after the onset of a streptococcus A infection, were able to prevent rheumatic fever without suppressing the antistreptolysin response These observations were interpreted to suggest that the development of rheumatic fever requires the presence of *living streptococci* throughout convalescence that some antigenic product of the streptococcus is produced continuously during the acute and convalescent phase and that rheumatic fever is the pathologic result of a hypersensitivity of the tuberculin or "delayed" type

In evaluating studies concerning streptococcal A antigens and antibodies it should be borne in mind that streptolysin antistreptolysin represents only one of a host of possible antigen antibody combinations and that the particular antigen antibody complex which may be responsible for rheumatic fever is as yet unknown Neither is it clear how the hypothesized antigen antibody reaction causes tissue damage or how its localization to specific tissues is determined It is also well to mention that there is no significant evidence relating the specific clinical manifestation of rheumatic fever with individual antibodies or their antigens

Autoantibody Theory Still another variant proposes that rheumatic fever is caused by autoantibodies[13] in response to damaged tissue of the host, and such antibodies result in further tissue damage and antigen formation Cavelti[12] produced antibodies to the heart and connective tissue as well as kidney of rats and rabbits, by repeated injections of emulsions of the homologous tissues in conjunction with killed streptococci On the basis of his experimental observations and the finding of autoantibodies to human heart in the blood of 75 per cent of patients with acute rheumatic fever Cavelti suggested the following hypothesis of rheumatic fever Streptococcal substances in combination with connective tissue, including that of the heart, produced an autogenous antigen (streptococcus heart) which incited the development

of specific antibodies The latter were thought to precipitate the rheumatic lesion by reacting with the streptococcal tissue antigen The observations of Cavelti have not been confirmed [37]

Shwartzman Reaction as a Possible Mechanism in Rheumatic Fever Another suggested mechanism by which the hemolytic streptococcus host relationship may precipitate rheumatic fever involves the generalized Shwartzman reaction Cardiac tissue necrosis with giant cells and other inflammatory cells fibrinoid change in the coronary arteries pericarditis and mild valvulitis were induced when animals were prepared by injection of hemolytic streptococci and the lesions induced by subsequent injection of endotoxins from gram negative bacteria [123] [131] Furthermore leukocyte platelet thrombosis of capillaries and small veins similar to the lesions occurring in the Arthus and Shwartzman phenomena were found in the hearts of patients dying in the course of rheumatic fever [1 2]

Whereas Group A streptococci are unable to cause rheumatic fever directly it is possible that repeated streptococcal infections by their effect on the host create new substances which are then capable of producing rheumatic fever Thus although cell free streptococcal culture filtrates or heated streptococci are inactive in the preparation of rabbits for the generalized Shwartzman reaction soluble extracts of rabbit s skin which has been subjected to multiple infection by hemolytic streptococci are effective in preparing rabbits for this reaction [121] Furthermore cardiac lesions closely resembling those of rheumatic fever were induced in rabbits following repeated skin infections with Group A streptococci [91] These studies on the concept of the hemolytic streptococcus host combination have at present only an indirect speculative bearing on the pathogenesis of rheumatic fever Rheumatic heart disease as seen in the human has not been produced in animals on the basis of this or other concepts

3 Non streptococcal Theories of Rheumatic Fever

Besides the streptococci, a variety of organisms have at times been implicated as the specific causative agent of rheumatic fever In particular the failure to isolate with regularity a specific bacterial agent has suggested that the responsible cause may be an unidentified virus Schlesinger Signy and Amies[119] observed particles resembling virus elementary bodies obtained by high speed centrifugation of pericardial or pleural fluid from persons with acute rheumatic pericarditis Saline suspensions of these bodies were agglutinated by sera of patients with active rheumatic fever Virus bodies were observed by Coles[24] in Giemsa stained spreads of pericardial fluid from cases of acute rheumatic fever but similar bodies were seen in the pericardial fluid of 25 of 50 nonrheumatic cases Eagles and Bradley[29] also demonstrated the nonspecific character of these agglutination reactions

Claims for the tubercle bacilli[81] and for pleuropneumonia organisms have not been substantiated [117]

PREDISPOSING CAUSES OF RHEUMATIC FEVER

Geography and Climate

It has long been recognized that rheumatic fever is essentially a disease of temperate climates and is relatively rare in the tropics The disease is common in Great Britain and France but rare in the tropical possessions of these nations [3] In Canada and the United States the incidence of rheumatic fever diminishes progressively as one proceeds southward [4] Paul and Dixon[107] found the incidence of rheumatic heart disease ten times as frequent in a group of Indian school children living close to the Canadian border (Wyoming and Montana) as among a similar group near the Mexican border (Arizona) An analysis of numerous Army Air Force posts in the United States in the last World War revealed a very high incidence of rheumatic fever in the northern Rocky Mountain regions and Great Lakes as compared to those near the Mexican border and Gulf of Mexico [64] Coburn[19] *emphasized the* rarity of rheumatic fever in Puerto Rico and noted the subsidence of symptoms and absence of recurrences in rheumatic patients transported there from New York On the other hand I have frequently observed active rheumatic fever in Puerto Ricans who have come to live in New York City

The significance of a possible relationship between geography and climate and the incidence of rheumatic fever must be evaluated with caution In the first place there is much less certainty than formerly as to the relative rarity of rheumatic fever and heart disease in southern and tropical countries Chavez[16] reported a surprisingly high inci

dence of rheumatic heart disease in Mexico, and other observers have discovered rheumatic fever or heart disease in subtropical or tropical places in which the disease was considered almost non existent, such as Ceylon India China Costa Rica Hawaii and Panama In the second place, admitting differences in incidence depending on geography and climate it is uncertain whether such correlation depends on meteorologic conditions (temperature rainfall, barometric pressure etc), racial differences economic and dietary differences bacteriologic flora and immunity, or especially crowding with its predisposition to the spread of infection

Season

The greatest incidence of rheumatic fever is in the colder and wetter months of the year, and most commonly in January February, March and April [101] In Great Britain a high incidence has been reported as beginning somewhat earlier, e g , October or November and continuing through the spring [45] In India Kutumbiah[79] observed no seasonal variation in the occurrence of rheumatic fever The seasonal relation to streptococcal or other respiratory infections has been repeatedly noted and this may account for the seasonal incidence of rheumatic fever [107] The seasonal incidence is probably not related to cold or dampness as such for in World War I rheumatic fever occurred much less commonly among troops in action in cold damp trenches than among those in warmer and drier but overcrowded barracks

Urbanization

Rheumatic fever occurs much more frequently in industrialized, well populated cities than in rural areas [6] The correlation is not linear for the mortality rate from rheumatic heart disease is higher in Denver, Colorado than in many much more populous and industrialized cities To the extent that urbanization predisposes to rheumatic fever, it appears that crowding and the consequent spread of infection are the important factors

Economic Status and Housing The Factor of Crowding

British investigators have emphasized the greater frequency of rheumatic fever among the lower economic groups [2 4 45 4 67] In one series there was an incidence of 13 1 per cent rheumatic patients in the outpatient department and only 0 7 per cent in private practice Nevertheless there is some evidence that rheumatic fever, unlike tuberculosis, does not strike the very destitute but rather those above this level In this country poverty has not appeared to be a significant predisposing factor

The question of housing is closely related to economic status Rheumatic fever has often been associated with dampness in general and damp housing in particular Geographic studies of the incidence of rheumatic fever in London show a close correlation with proximity to the course of old streams [13] In New York, Ingermann and Wilson[69] found the smallest percentage of cases in districts farthest from the river fronts A high incidence of rheumatic fever has been reported in houses judged to be damp by British sanitation inspectors[137] and particularly among individuals residing in basements or ground floors without cellars beneath them Other reports minimize the importance of dampness in housing [81]

It is probable that economic status and housing are predisposing factors in rheumatic fever, chiefly in so far as they lead to crowded living conditions An analysis of rheumatic heart disease in Bristol England, revealed that its incidence was closely related to crowding in the home [105] The factor of crowding and consequent predisposition to the spread of hemolytic streptococcal infection was also considered significant in explaining the greater frequency of rheumatic fever in northern as compared with southern United States,[102] and in accounting for the occurrence of epidemics in boarding schools, hospital wards and barracks [144]

Family Incidence, Heredity and Constitution

A number of investigators have called attention to a significantly high family incidence of rheumatic fever [15 69 103] Cohn[2] stated that 8 to 10 per cent of members of rheumatic families experienced rheumatic fever but only 2 9 per cent of the families of nonrheumatic controls Similar observations have been made by Massell and Jones[85] and others A significant familial tendency to rheumatic fever is however, by no means universally accepted as fact In my own experience dealing chiefly with inactive rheumatic heart disease it is very exceptional to encounter more than one member of a family with rheumatic mitral stenosis or rheumatic aortic insufficiency It should be pointed out that the diagnosis of mitral stenosis or aortic insuf

ficiency is subject to less inaccuracy than the diagnosis of rheumatic fever

A high family incidence has been variously attributed to infectious communicability of rheumatic fever to similar environmental factors in members of the same family to hereditary or constitutional susceptibility or to a combination of these Evidence for frequency of rheumatic fever among certain anthropologic types or in individuals with certain pigmentation of skin eyes hair (e g, red hair) is unconvincing Wilson and her associates,[145] after many years of careful observation of families with rheumatic fever have concluded that the susceptibility to this disease is an inheritable characteristic, dependent on a single autosomal recessive gene

Age

About 90 per cent of first attacks of rheumatic fever occur between the ages of 5 and 15 More occur between 5 and 10 than between 10 and 15 Less frequently rheumatic fever begins between the ages of 15 and 20 between 1 and 5 or between 20 and 25 or older, in the given order[6] Reports of clinically active rheumatic fever in old individuals[51] are diagnostically unconvincing Thus in its primary stages rheumatic fever is essentially a disease of elementary school children The probability of a first attack and the tendency to recurrence diminish significantly after puberty is established Rheumatic fever among military personnel in the last war occurred chiefly in the youngest recruits, in many of these a careful clinical history and examination usually disclosed a previous attack As a rule, an upper respiratory infection precedes the episode of acute rheumatic fever by two weeks in the young adult as it does in the child[65] The age incidence of rheumatic fever has been related to the incidence of Group A beta hemolytic streptococci in the throat at various age levels[1 6] In young children (ages 6 to 9) Group A organisms were recovered from throat cultures twice as frequently as in older children (ages 12 to 15) and six times as frequently as in adults

Rheumatic fever is very uncommon in the first two or three years of life In infancy it is extremely rare Denenholz and Rambar[8] reported a case in a 10 day old infant Most of the reported cases in infancy are instances of placental infection from rheumatic mothers or infection in the sucklings of such infected mothers The youngest case I have seen concerned a seventeen months old child who, two days after a fall suffered pain in an ankle associated with fever and pulmonary symptoms Postmortem examination shortly afterward revealed myocardial Aschoff bodies and other evidence of active rheumatic heart disease

Sex

There is a slightly greater incidence among females chiefly because of the preponderance of females affected by chorea[3 101] Excluding the latter the incidence is essentially the same in both sexes

Race

The data are inconsistent regarding racial differences in the incidence of rheumatic fever Some statistics appear to indicate a greater frequency of the disease among the Irish the Anglo Saxons and the Jewish races The incidence among Negroes has been found to be higher equal to or lower than that among white subjects in different locations At present, there is a generally prevailing higher mortality among non white than among white children most probably due to adverse socio-economic environment rather than to constitutional differences in susceptibility

Nutrition Endocrine Factors

Undernutrition and improper nutrition have been considered as factors predisposing to rheumatic fever Epidemiologic and experimental evidence that a deficiency of ascorbic acid may be an etiologic factor was presented by Rinehart Connor and Mettier[111] The diet of patients with rheumatic fever has been reported to be deficient in vitamins A and D and in calcium and phosphorus[104] However rheumatic fever has occurred with great frequency in naval and other military installations among young recruits who were well nourished and properly fed It is improbable that nutrition is either an essential or important factor in the development of rheumatic fever However it may be a nonspecific factor in determining resistance to infection

Rheumatic fever has been related to relative adrenal cortical insufficiency Kelley et al[7] observed an elevation of cortical steroids early in the acute phase presumably in response to stress with subnormal levels later in the attack and even during the inactive period Animal experiments suggested that the adrenal cortical insufficiency preceded

rather than resulted from the rheumatic fever

Physical Factors Trauma

Frequently the localization of rheumatic arthritis is determined by physical strain Thus the joints of the lower extremities are more apt to be affected when the patient s occupation demands excessive walking or standing the joints of the hands may be involved among typists or seamstresses

The French school of physicians repeatedly emphasized the importance of trauma in determining the onset or recurrence of rheumatic fever The most striking instances are those in which within a few days after a fall or other injury acute rheumatic fever develops first in the joint nearest to the injured region [43] The factor of coincidence is difficult to exclude

PATHOLOGY

GENERAL FEATURES

Pathologically rheumatic fever is characterized by *proliferative* and *exudative inflammation* involving primarily collagen tissue or its ground substance There is a pronounced tendency to affect tissues lined by endothelium including blood vessels endocardium pericardium and synovia

The *primary rheumatic lesion* is characterized by swelling and occasional necrosis of collagen or of the ground substance between the collagen fibrils This undergoes a hyaline or eosinophilic alteration termed fibrinoid degeneration Klinge[74] refers to this early change as the rheumatic fruh infiltrat ' in analogy with tuberculosis but the use of this expression in rheumatic fever may be confusing The swelling of collagen is associated with an exudative reaction consisting of edema lymphocytes and other round cells, and less characteristically of polymorphonuclear and plasma cells Recent studies indicate that the early fibrinoid change which was thought to represent degeneration of collagen, is actually material deposited in the ground substance between the collagen fibers [1] Chemical studies have indicated that the fibrinoid is resistant to collagenase, whereas it is susceptible to tryptic digestion suggesting its protein nature The fact that fibrinoid stains with Schiff s reagent after periodic acid oxidation suggests that it contains mucopolysaccharides The precipitated fibrinoid may result from the interaction of acid mucopolysaccharides and alkaline protein material from plasma or necrotic tissue or both The possible relation of the mucopolysaccharide, hyaluronic acid, to rheumatic fever has been mentioned

The *proliferative reaction* is characterized by granulomatous formations which in their most characteristic form are called Aschoff bodies (infra) This proliferative phase is often so dominant that Fahr[14] refers to rheumatic fever as rheumatic granulomatosis The proliferative reaction consists of focal (Aschoff bodies) or diffuse cellular collections including numerous round cells macrophages fibroblasts and peculiar large cells which may be multinucleated The exudative and proliferative reactions are not sharply demarcated both occurring simultaneously in varying intensity

The *final stage of rheumatic inflammation* is characterized by healing and scar formation In the valves such scarring results in serious deformities The above-mentioned exudative and proliferative inflammatory lesions represent the *active stage* of rheumatic fever In the *inactive stage*, the inflammatory reaction is absent and only the healed scars are observed

CARDIAC LESIONS

Localization of Rheumatic Lesions

Rheumatic cardiac lesions are characterized by their widespread distribution in the endocardium, myocardium, pericardium and conduction system This is the basis for the term *rheumatic pancarditis* The detailed studies of Gross and his associates on rheumatic lesions in their numerous sites of localization have provided an extensive anatomic armamentarium with which to establish the essential rheumatic nature of cardiac disease even in the absence of Aschoff bodies or a typical clinical history of rheumatic fever

Specific and Non specific Lesions

The *specific lesions* are the Aschoff bodies which are described in the next section It is generally agreed that the presence of myocardial Aschoff bodies is definite evidence of rheumatic heart disease " " The granulomatous lesions described as occurring in animals following various experimental efforts to produce rheumatic fever do not show the specific characteristics of the Aschoff bodies

The *non specific but rather characteristic*

lesions include the macroscopic and microscopic alterations in the left atrium, the vascularization and inflammation of the valves (including the valve rings), the valvular verrucae the valvular deformities the pericardial lesions, myocardial scars and certain lesions at the root of the aorta and pulmonary artery

Some lesions are very characteristic if not specific Among these may be mentioned the banded appearance and palisade formation of the cellular exudate in the left atrial endocardium the subendocardial reduplications in the left atrium and valve and the vascular lesion termed the intimomusculoelastic variety

The Myocardial Aschoff Body

Aschoff bodies are rounded or spindle shaped submiliary nodules of microscopic size Rarely conglomerations of Aschoff bodies form grossly visible nodules which appear as pearly white streaks They occur in any portion of the heart, but most often in the subendocardial regions of the left ventricle and frequently in close proximity to small blood vessels They primarily involve the interstitial tissue

The structure of the Aschoff body undergoes a life cycle corresponding with the clinical course of the disease [64] The earliest development representing a pre Aschoff body stage is characterized by swelling and fibrinoid degeneration of the interstitial ground substance and local accumulations of small round cells apparently lymphocytes At this stage argentophilic fibers can be demonstrated by Pap s stain between the swollen collagen fibers and close to the round cells At this stage also the lesion is not specific for rheumatic fever and this must be kept in mind in the evaluation of similar experimental lesions

The typical specific Aschoff body presents certain definite features

(1) There are characteristic cells with abundant somewhat basophilic cytoplasm and irregular boundaries (ragged edges) The cytoplasm may appear as irregular broken syncytial masses of indefinite outline

(2) Many of these cellular nuclei have an owl eye or ' target appearance The nuclei are of circular shape with deeply staining nuclear membrane and a dark sometimes stellate (wheel spokes) nucleolus

(3) There are multinucleated giant cells with usually two or three and occasionally seven or more round or oval nuclei situated in the center of the cell There has been disagreement as to whether these multinucleated cells of the Aschoff body are derived from non myogenic mesenchymal cells or from injured myofibrils [88] According to the recent studies of Wagner and Tedeschi [140] giant cells may arise from either source but the mesenchymal giant cell is specific for rheumatic fever whereas the myogenic giant cell is non specific and may be found also in a variety of other diseases such as giant cell myocarditis, lupus erythematosus and polyarteritis

(4) Other cells within the Aschoff body proper resemble the fibroblast or fibrocyte while still others are small cells with large solidly staining polymorphous nuclei (pyknotic cells)

(5) Among the characteristic owl-eyed giant fibrocytoid and pyknotic cells is swollen collagen or ground substance which has become disintegrated and granular Silver impregnation reveals argentophilic fibers

(6) The Aschoff body proper composed of the above elements is usually surrounded by a mantle of polymorphonuclear cells lymphocytes plasma cells fibroblasts or occasional eosinophils

While the above elements are always present their relative proportions and their figurative arrangement undergo variations according to the acuity or chronicity of the disease the looseness or compactness of the affected tissues and perhaps also according to the immunologic state of these tissues Eventually the Aschoff body is converted into a characteristic spindle shaped flame-shaped or triangular scar lying between the muscle bundles and surrounding blood vessel [4]

Aschoff Bodies in Resected Left Atrial Appendages

Aschoff bodies have been found in 16 to 74 per cent (average 33 per cent) of the atrial appendages which were removed in the course of operations for mitral stenosis Among the larger series of case Decker et al [27] reported the presence of Aschoff bodies in 83 of 183 appendages (45 per cent) and Tedeschi et al [139] in 75 of 400 appendages (18 8 per cent) It is a striking fact that although the Aschoff body has always been regarded as denoting *active* rheumatic fever it has not been possible to correlate the finding of Aschoff bodies in the atrial appendages with

clinical or laboratory evidence of active rheumatic fever [90] In fact, patients with any manifestations suggesting the possibility of rheumatic activity were not subjected to operation Studies of autopsy material disclosed that the findings in the removed appendages were representative of the findings elsewhere in the heart The patients with Aschoff bodies in their atrial appendages disclosed no greater tendency to postoperative rheumatic recrudescence or to an increase in operative mortality or morbidity than those whose atrial appendage showed no Aschoff bodies [17]

It is apparent that the Aschoff body cannot be regarded as an invariable sign of clinically active rheumatic fever This apparent change in concept can probably be explained by attention to the life cycle of the Aschoff body, as stressed by Gross and Ehrlich [84] Accordingly one should distinguish between active and healed Aschoff bodies [130] By careful histologic (and histochemical) studies of 400 consecutive left atrial appendages removed at mitral commissurotomy in patients with clinically inactive rheumatic fever, in 75 of which Aschoff bodies were found, Tedeschi et al [130] determined that evidence of active rheumatic carditis was present in only 8 In the remaining 392 cases (98 per cent) only healed or healing lesions were noted In 67 of the 75 cases with Aschoff bodies, the Aschoff bodies were senescent, i e healed Thus the Aschoff body, pathologically, may be active or healed It is not always invariably indicative of clinical rheumatic activity It may denote such activity only when careful study of its life cycle reveals that the Aschoff body is in its 'active' or "juvenile stage

Pericardial Lesions

Pericarditis is one of the most frequent and most characteristic of rheumatic lesions The occurrence of acute pericarditis and of adherent pericardium was described by Baillie[5] and other early writers The typical reticulated, curdled appearance of fibrinous pericarditis was described by Corvisart and Laennec the latter noting its similarity to "bread and butter" an expression retained by Hope and all textbook writers after him Gross lesions are almost invariably present either diffusely or as localized patches of fibrous thickening

In the *active cases* there may be a universal fibrinous exudate with thickening glazing and adhesions There is a variable amount of straw colored, turbid fluid containing many shreds of fibrin Occasionally the effusion is fibrinopurulent With recurrent attacks the pericardium is converted into a thick shaggy membrane with numerous tenuous adhesions In the *inactive cases* the pericardial layers are thick and adherent to each other and to neighboring extracardiac structures Frequently there is complete obliteration of the pericardial sac but in the early stages there may still be serofibrinous or serohemorrhagic exudate sacculated between adhesions Calcification may occur Occasionally, there are peculiar polypoid and cystlike formations

Microscopically, pericardial lesions are found in almost 100 per cent of the *active cases* [4] The earliest lesions are represented by swelling and degeneration of collagen and ground substance in the lamina propria inflammation and vascularization of the same layer and of nearby portions of the subjacent adipose layer Soon there is an exudation of fibrin which together with the subjacent inflammation, represents the non-specific reaction of a serous membrane to an injury The mesothelial cells may become completely desquamated and may form pseudo-gland structures or polyps With recurrent infections and in later stages of the active cases there is marked thickening of the pericardial membranes with layers of fibrin inflammatory exudate and granulation tissue The pericardial layers become adherent and the pericardial cavity is obliterated

In the *inactive cases* the pericardial layers are thickened and adherent owing to the formation of considerable fibrous tissue There may be inflammatory residua consisting of infiltrations of small round cells in the deeper layers of the lamina propria and adjacent layers and an increased number of vessels showing structural changes

Rheumatic Lesions in the Left Atrium

Detailed descriptions have been reported by MacCallum[83] and by Gross[57] (see p 817)

Macroscopic Appearance The characteristic lesions are usually situated on the posterior wall of the left atrium just above the posterior cusp of the mitral valve They consist of an irregularly raised series of ridges and mounds forming tawny gray patches, or occasionally flat yellow plaques In the *inactive* stage the lesions become grayer and more translucent and the endocardium may appear

wrinkled There may be hyaline plaques occasionally with lime Macroscopic lesions in the left atrium are reported to occur in 29 to 80 per cent of rheumatic hearts the higher percentage in the active cases Massive calcification of the left atrium may be observed in cases of rheumatic heart disease with a long history of atrial fibrillation and congestive heart failure [113]

Microscopic Appearance The atrial endocardium becomes widened by edema and cellular infiltration The collagen and interstitial ground substance undergo swelling and degeneration and assume a banded appearance The various inflammatory cells are often oriented characteristically at right angles to the atrial lumen and may be palisaded in layers along the bands of swollen collagen The normal avascular endocardium becomes highly vascularized by the penetration of capillaries at right angles from the subendocardial layer

The *inactive or healed lesion* consists of pronounced widening of the atrial endocardium by fibrous tissue A considerable portion of the thickening is due to characteristic endocardial reduplications [14] composed of newly formed layers of tissue arising from the normally inconspicuous subendothelial mesenchyme These wide reduplications are demarcated by condensations of elastic tissue each one representing an individual attack of rheumatic fever

Lesions of the Valves

Rheumatic valvular lesions have been described in detail by Coombs [8] Swift [17] Gross and Friedberg [46] and others

Active Stage The most frequent lesion is the thickening of the valve cusp and its loss of transparency The most characteristic lesion is the vegetation or verruca ' The verrucae appear as rows of fine glistening grayish or yellow wartlike vegetations on the closure line of the mitral and aortic and much less commonly on the tricuspid or pulmonic valves in the given order of frequency Not infrequently the tricuspid leaflets and occasionally the pulmonic leaflets disclose distinct microscopic lesions when they appear normal on gross examination The normally concave scalloped margins of the atrioventricular valves are thickened and straightened The atrial surface may show gross vascularization

Microscopically the earliest valvular lesions occur at the ring ' or attachment of the cusp to the fibrous annulus [17, 46] The close anatomic relationship of the four fibrous annuli to each other accounts for the ease of extension of the inflammatory process from one ring to the others The ring becomes vascularized and swollen with edema and inflammatory cells The inflammatory process extends throughout the cusp and produces a valvulitis before there are verrucae [50] The typical rheumatic proliferative and exudative lesions occur The cusp becomes thickened by edema capillary vascularization and cellular infiltration (lymphocytes predominantly and occasionally polymorphonuclear leukocytes but Aschoff bodies fibroblasts macrophages and plasma cells also occur)

The verrucae in active cases consist of hyaline eosinophilic material resulting from swollen degenerated collagen and disintegrated cells near the surface of the valve The verruca arises chiefly from swollen degenerated valvular substance which is extruded beyond the surface of the cusp However platelet thrombus and a small amount of fibrin arising from the blood stream may be deposited as a cap on the valvular component of the verruca According to Tweedy [126a] the high incidence of these thrombotic deposits rather than the valvulitis or degenerated collagen is responsible for valvular thickening and fusion of chordae tendineae

Inactive or Healed Stage (see chapters on individual valvular lesions)

Lesions of the Coronary Arteries and Their Branches

Lesions of the vascular apparatus including the coronary arteries represent a fundamental feature of the pathology of rheumatic fever [121, 55] but it is doubtful whether they are of sufficient importance to account for clinical phenomena The usual evolutionary degenerative changes in the coronary vessels are accelerated and intensified in cases of rheumatic fever therefore coronary atherosclerosis may occur much earlier in such cases This is exemplified by a seventeen months old child whom I observed with acute rheumatic fever whose heart at postmortem examination disclosed a complete thrombosis of a major coronary artery

There may also be non specific degenerative or inflammatory lesions which are occasionally grossly visible in the small myocardial arteries but which are more often of micro

scopic size. The gross lesions may be those of polyarteritis nodosa[41] while the microscopic lesions consist of intimal proliferation and necrosis, endarteritis verrucosa or polyposa, or fibrin like occlusions which become organized and recanalized.[139] Gross, Kugel and Epstein[57] described intimo musculo elastic lesions of the small coronary arteries characterized by intimal proliferation of smooth muscle and elastic tissue and considered almost specific for rheumatic fever.

Lesions in the Aorta and Pulmonary Artery

Klotz[7] gave the first detailed descriptions of rheumatic vascular lesions including those of the aorta. Pappenheimer and von Glahn,[93] Gross[53] and others also contributed studies of rheumatic aortic lesions. Occasionally there are macroscopic brownish ridges or plaques on the inner surface. The usual lesions at the root of the aorta are microscopic and situated chiefly in the outer portion of the media and in the adventitia following the course of the vasa vasorum. There are collections of lymphocytes, polys and Aschoff bodies, edema, pronounced capillarization and scarring and disruption of the elastica. Similar lesions are also found occasionally in the pulmonary artery and have been described by Paul,[99] Chiari,[16] and others.

Lesions in the Atrioventricular Conduction System

The frequent occurrence in rheumatic fever of arrhythmias and especially of partial heart block may be due in many instances to anatomic lesions in the conduction system. Gross and Fried[5] found exudative or vascular lesions within the bundle of His or surrounding tissue in 66 per cent of active cases.

EXTRACARDIAC LESIONS IN RHEUMATIC FEVER

Subcutaneous Nodules

Pathologically these are proliferative lesions consisting of collagen swelling and degeneration, inflammatory cells, edema and vascularization similar to that in other rheumatic lesions.[89] Often there is a necrotic center containing fibrinoid material. Structures resembling Aschoff bodies have been reported. The nodules may show scarring, calcification and rarely deposition of cartilage or bone. Allowing for the difference in milieu, the subcutaneous nodule corresponds in structure and specificity to the Aschoff body. Some investigators have reported histologic resemblances to the nodules found in rheumatoid arthritis,[26] but I believe there are essential pathologic differences.[70]

Pulmonary and Pleural Lesions

Pulmonary and pleural lesions occur frequently in rheumatic fever, but there is disagreement as to the specificity of a rheumatic pneumonia.[100, [illegible], 8]

The lungs have been described as characteristically large, purplish red, beefy and of india rubber consistency.[illegible] The involved areas are non friable and homogeneous and present atelectasis and splenization rather than hepatization. *Microscopically*, the affected parts show edema and hyperemia, *local* atelectasis and widespread focal hemorrhagic lesions involving lobules or groups of lobules.

The alveolar walls are thickened by proliferating capillary endothelial cells and fibroblasts, and the interstitial tissue is thickened by edema and inflammatory and mononuclear cells.

The alveolar lumina are filled with edema fluid and frequently by a hemorrhagic and fibrinous exudate. Mononuclear cells predominate and include desquamated epithelial cells and phagocytic cells.

Vascular lesions of the capillaries and small arteries consist of intimal thickening, hyaline thrombi, occasional scarring or necrosis of the media and adventitial and periadventitial cellular infiltrations.

A hyaline membrane lining the bronchioles and alveolar ducts is a characteristic feature, and possibly represents a *transformed* fibrinous exudate.[illegible]

A fibrinous or serofibrinous pleural exudate may be present. Proliferative and exudative "rheumatic like" lesions have been described, but no definite Aschoff bodies have been demonstrated.

Other Lesions in Rheumatic Fever[illegible]

Abdominal pain may be related to necrotizing arteritis of visceral arteries[41] *or other* vascular lesions. Serous peritonitis with vascular lesions and inflammatory exudate in the subperitoneal tissue has been described by Rhea[109] in fatal cases of rheumatic fever. Specific rheumatic lesions have been reported in the peritonsillar tissue[47] and in the regional lymph nodes draining rheumatic tissues.[40]

Cerebral lesions associated with chorea include a disseminated meningoencephalitis affecting chiefly the corpus striatum.[49] A meningoencephalitis has also been reported in rheumatic heart disease without *chorea*.[44]

Bruetsch[9] has repeatedly reported and emphasized the occurrence of cerebral lesions and cerebral sequelae of rheumatic fever In particular, he observed a "rheumatic obliterating arteritis involving the small meningeal and cortical vessels with consequent infarction and softening of cerebral tissue Certain cases of mental illness and epilepsy were attributed to such rheumatic cerebral lesions

RELATION OF RHEUMATIC FEVER TO RHEUMATOID ARTHRITIS

There are many differences between the clinical manifestations and course of rheumatic fever and of rheumatoid arthritis chief of which is the frequency of cardiac involvement in the former In recent years necropsy findings have been reported which suggest that cardiac lesions of rheumatic fever are encountered with significant frequency in cases of rheumatoid arthritis [6 10] although there are also contrary reports[31] Rosenberg and associates[11] recorded the finding of rheumatic heart disease in 16 (53 per cent) of 30 autopsied cases of rheumatoid arthritis and Young and Schwedel[149] in 25 (66 per cent) of 38 such cases In evaluating these reports it is important to know the exact criteria employed for the diagnosis of rheumatic heart disease and the incidence of such ' rheumatic lesions in control groups Thus according to criteria used by Hall and Anderson[44] rheumatic stigmata in presumably normal hearts were found microscopically in 90 per cent of 112 hearts and Aschoff bodies in 30 per cent of the hearts If such criteria are employed the finding of rheumatic lesions in cases of rheumatoid arthritis loses significance In general there appears to be a definite distinction between the pathologic lesions usually associated with rheumatic fever and those of rheumatoid arthritis[6] The clinical course and electrocardiographic findings in rheumatic fever are not observed with rheumatoid arthritis In the course of observing several hundred patients with rheumatoid arthritis over many years I have only once observed the appearance of rheumatic cardiovalvular disease (aortic insufficiency) in later adult life

Chapter 32

RHEUMATIC FEVER

Clinical Picture

INTRODUCTION

The clinical picture of rheumatic fever may be dominated by cardiac or extracardiac symptoms. But even when the obvious symptoms are extracardiac one can almost always assume the probability of cardiac involvement. The most characteristic clinical picture of rheumatic fever is that of an acute migrating polyarthritis with fever and other evidences of toxemia. But especially in children, the clinical picture may be dominated by extra-articular manifestations including chorea, abdominal pain, cutaneous and subcutaneous lesions and cardiac disease. Atypical, mild and subclinical forms of rheumatic fever are not uncommon among both children and young adults.

Rheumatic fever is characterized by its chronicity and tendency to recurrent exacerbations. The recurrences, like the original attack, consist of any one of the variety of clinical forms which rheumatic fever may assume. Thus the first attack may be one of chorea, the second polyarthritis and the third pancarditis. Or cardiac disease may be present from the beginning, each new attack leading to further myocardial and valvular damage. The acute attacks generally last one to three months but occasionally there are fulminating cases ending fatally in several days or weeks. Usually the disease enters a chronic afebrile stage in which there may be no symptoms unless an acute exacerbation occurs.

Rheumatic heart disease is considered as being *active* or *inactive* depending on the persistence or subsidence of acute rheumatic inflammation. This distinction is important in the management of the patient and the evaluation of his prognosis. As in tuberculosis inactive rheumatic heart disease is not synonymous with cure, for there is a great tendency to recurrence of the active disease. The symptoms of active rheumatic heart disease are due to the inflammatory lesions in the heart and the associated toxemia. The symptoms of inactive heart disease are due to the scars and deformities produced by healing of the inflammatory lesions and to the associated chemical changes in the myocardium. These alterations may be insufficient to produce clinical symptoms during long intervals of the inactive stage.

MODES OF ONSET

The onset may be insidious or acute. Vague prodromata may precede the acute outbreak. Characteristically a hemolytic streptococcal sore throat, tonsillitis or scarlet fever is followed by a latent period of one to four weeks after which symptoms of rheumatic fever appear. Following are some of the more common ways in which rheumatic fever and rheumatic heart disease begin.

1. *Arthritis and fever* are the commonest symptoms of onset. Occasionally there is no definite arthritis, but only fleeting multiple joint pains without noticeable inflammation or pain and disability involving a single joint.

2. *Cardiac symptoms* may first attract attention to the patient's illness. The chief complaint may be precordial pain due to a fibrinous pericarditis or a pericardial effusion, or else there is palpitation resulting from tachycardia and extrasystoles. Occasionally dyspnea, edema, abdominal distress and other symptoms of myocardial failure appear to be present from the beginning.

3. *Chorea* may be the first and sole evidence of the initial attack of rheumatic fever. Occasionally this follows a physical or psychic trauma. Cardiac lesions and other rheumatic

symptoms may develop concomitantly with this initial attack or more often in subsequent rheumatic episodes

4 *Abdominal and gastrointestinal symptoms* Vague fleeting abdominal pains are uncommon prodromal symptoms of rheumatic fever Occasionally the abdominal pain is severe and simulates an acute surgical complication

5 *Fever of obscure origin* associated with malaise headache or anorexia may be present for some weeks before other evidences of rheumatic fever appear

6 Rheumatic heart disease may be *latent* its recognition depending on discovery of a valvular lesion at routine physical examination Or cardiac failure may develop in an individual who gives no history of rheumatic fever The rheumatic etiology of the failure is suggested by the finding of evidence of valvular disease

7 Rarely the first symptoms of rheumatic fever are subcutaneous nodules, cutaneous lesions such as erythema marginatum or profuse epistaxis

Non specific prodromata have been mentioned as preceding the well defined symptoms particularly in children The symptoms in the prodromal stages of rheumatic fever include pallor fatigability anorexia, digestive disturbances abdominal pain loss of weight nervous irritability so-called growing pains in the joints and adjacent muscles and tendons respiratory infections adenopathy and low grade febrile attacks

CLINICAL FORMS OF RHEUMATIC FEVER

The lesions of rheumatic fever may affect almost every organ Correspondingly the clinical symptoms and combinations of symptoms are remarkably protean However certain common clinical forms of the disease may be distinguished according to the predominant symptoms As the disease becomes prolonged or acute exacerbations ensue these clinical forms tend to intermingle

1 The *articular form* is the most distinctive and the most easily recognized Fever and arthritis may occur after a free interval of one to three weeks following an upper respiratory infection The onset of fever and polyarthritis may be more gradual the temperature rising as the inflammation spreads from joint to joint until many of them have been successively involved When fully developed the clinical picture is that of a general infection with toxemia chilliness (or occasionally rigors) and severe sweats but the acute migrating polyarthritis is the dominant feature

2 The *cardiac form* is the most serious clinical variety of rheumatic fever It is especially frequent in children The illness may present any one of the modes of onset listed above but evidences of cardiac disease rapidly dominate the clinical picture Fever and other signs of infection are present Frequently there are symptoms of fresh pericarditis or pericardial effusion The heart becomes enlarged Evidences of left and right heart failure may become prominent Valvular disease may develop under observation or may represent residua of a previous attack Joint symptoms cutaneous lesions pulmonary disease are overshadowed by the pancarditis Cardiac failure may subside and recur with renewal of the infection Death may result occasionally If the patient recovers he is left with an enlarged heart badly functioning valves an injured myocardium and pericardial adhesions

3 The *typhoidal* or *influenzal form* embraces the cases in which fever and toxemia are the dominant features The patient may be mistakenly treated for grippe pneumonia or typhoid fever Fever of obscure origin may be the only evidence of a recurrent bout of rheumatic fever and particularly of a reactivation of rheumatic carditis

4 The *pulmonary form* refers to cases with predominant pleural and pulmonary symptoms Fever generally of high degree is invariably present Pericarditis and other cardiac symptoms are usually and extra cardiac symptoms are sometimes associated

5 The *abdominal form* Occasionally abdominal and gastrointestinal symptoms not only initiate the rheumatic attack, but continue as its essential features

6 *Chorea* may be classified as a *neurologic form* of the disease Its rheumatic nature is denoted by the later development of other classic features of rheumatic fever in one half to three quarters of the cases of chorea

Atypical Forms in Young Adults

Observations during World War II and subsequently disclosed the relative frequency of rheumatic fever among young adults in the military forces[78, 89, 102] Usually the clinical picture was characterized by fever and an

acute polyarthritis Not infrequently, however, there was only mild pain and stiffness in a single joint, without systemic symptoms, or there were only chills and fever, or vague muscular pains backache and urinary symptoms or abdominal and gastrointestinal symptoms In some of these reported cases, one may question the diagnosis of rheumatic fever despite electrocardiographic abnormalities (See also p 843)

GENERAL COURSE OF RHEUMATIC FEVER

In general the course of rheumatic fever may be classified under four general types

1 The *recurring type* is characterized by an acute attack which subsides in one to six weeks in mild cases or in six weeks to four months in severe cases Subsequently there is complete inactivity for one or more years *After two to five such attacks, the disease remains inactive* This is the most common form

2 The *chronic active type* in which there are troughs of relatively little clinical activity but in which there is never complete subsidence From time to time there are clinical exacerbations Progressive cardiac failure leads to fatality after many months or after several years

3 The *chronic inactive type* in which carditis is part of the initial attack but there is no recurrence of activity thereafter

4 The *acute fulminating type* is uncommon and is characterized by high fever and toxemia with severe carditis and heart failure and a fatal issue after several weeks or months

THE INDIVIDUAL FEATURES OF RHEUMATIC FEVER

These are classified as (1) general, non specific evidences of infection and (2) local manifestations which are more characteristic and depend on the involvement of numerous individual organ systems

GENERAL SYMPTOMS

The general symptoms may be very vague particularly in the prodromal period and in children The affected child tires easily, appears pale and listless eats little, loses weight and seems to be wasting He may be brought to the doctor because of "nervousness" pallor and undernutrition, poor schoolwork, or because it is feared he is suffering from pulmonary tuberculosis When the disease is well defined, there are distinct symptoms of a general infection

Fever

This is an almost constant symptom except in chorea It is the most practical and reliable guide to persistence of infection when the local symptoms have disappeared The temperature curve is rather variable but four general types may be mentioned (1) an irregular well marked febrile course lasting from a week to three or four months, (2) a continuous low grade febrile or subfebrile course, (3) a continuous low grade curve accentuated by more definite bouts of fever lasting several days, (4) an infrequent hyperpyrexia which has been virtually eliminated since the introduction of salicylates

The temperature usually ranges up to 103° F, occasionally higher, with daily variations of 1° to 3° F Before the use of salicylates characteristic types of the fever curve were described Friedlander[7] described monocyclic, polycyclic and continuous varieties In the "monocyclic" variety which composes about 60 per cent of cases, there is a progressive steplike rise in temperature lasting about a week each elevation corresponding to the involvement of new joints As the inflammation involves new joints it subsides in the original sites which are not implicated again *The* temperature falls gradually when no *further* joints are affected In the "polycyclic" variety, cycles such as that described come and go with relapses, the same or new joints being involved *The course is more severe and more* prolonged than in the monocyclic variety, pericarditis, pneumonitis and *heart failure* are common In the "continuous" *temperature* curve there is a prolonged irregular elevated temperature

The duration of the fever is quite variable Gull and Sutton[85] using only mint water to treat their cases concluded that the average duration of uncomplicated rheumatic fever was nineteen days Pribram[70] reported that of 457 cases treated with and without salicylates 27 per cent had fever for two to three weeks 16 per cent for three weeks or more and 3 per cent for more than thirty days *In the remaining,* 54 per cent the duration of fever in a single acute attack was less than two weeks The entire illness generally lasted one and one half to two times as long as the fever The ad

ministration of salicylates reduced the temperature but not the duration of the attack, which ranged between 14 7 and 47 5 days Similarly, Miller[60] found an average duration of 33 days in 3500 cases of rheumatic polyarthritis the period being the same whether or not salicylates were administered

Persistence of Activity without Fever Fever is an almost invariable accompaniment of active rheumatic disease However occasionally the temperature is normal despite the presence of active infection In chorea, which is generally accepted as a manifestation of active rheumatic fever the temperature may remain normal throughout the attack In the prearthritic or precardiac stages of rheumatic fever there is often no fever although progressive anemia fatigability loss of weight, etc, indicate active disease Similarly there may be no fever toward the end of a rheumatic attack when all symptoms have disappeared yet there may be persistent rheumatic inflammation as indicated by tachycardia leukocytosis and increased rate of sedimentation of red blood cells There may be little or no fever with subcutaneous nodules although these represent active rheumatic disease Thus while fever is a valuable guide to rheumatic inflammation its absence is not conclusive that activity has subsided

Pulse

A regular tachycardia of 100 to 140 is a common sign of rheumatic activity The tachycardia is often out of proportion to the degree of fever The pulse is full, bounding easily compressible and often dicrotic In convalescence there may be bradycardia When the temperature has reverted to normal either spontaneously or with salicylates a persistent tachycardia usually indicates continued rheumatic activity probably within the heart

Sweating

Profuse sweating has been described as a characteristic feature, particularly of the articular form of the disease In recent years this manifestation has appeared to be less prominent

Loss of Weight and Undernutrition

These are frequently present in the prodromal stages of the initial and subsequent attacks Weight curves especially in children are valuable guides to the progress of the rheumatic patient and to the persistence of active inflammation

LOCAL SYMPTOMS

The numerous symptoms of rheumatic fever are evidence of widespread involvement of many organs The most characteristic symptoms are due to lesions of the heart (pancarditis), the joints (arthritis) the skin (subcutaneous nodules) and the nervous system (chorea) But almost every organ may be affected, as shown by the widespread vascular lesions described Many of the lesions, however, fail to cause obvious symptoms

Of 1108 rheumatic patients under the age of 12 seen in a first attack carditis was present in 61 per cent arthritis in 57 per cent, chorea in 56 per cent and subcutaneous nodules in [illegible] per cent [illegible] In a similar series observed by Coombs[20] in an outpatient department, 72 5 per cent showed cardiac disease 61 [illegible] per cent arthritis, 47 2 per cent chorea, and 4 per cent subcutaneous nodules Coburn[16] listed the frequency of various symptoms in 162 patients presenting the "rheumatic state as follows

	Per cent
Polyarthritis	85
Pancarditis	65
Recurrent epistaxis	48
Muscle (growing) pains	47
Attacks of pallor	36
Severe headaches	33
Cardiac pain	3[illegible]
Chorea	[illegible]
Abdominal pains nausea vomiting	20
Erythema marginatum	17
Subcutaneous nodules	13 6

These and other statistical analyses indicate the great frequency of cardiac disease in rheumatic fever Because of its frequency and seriousness as compared with other symptoms cardiac disease is the central feature of any consideration of that disease Our presentation of individual symptoms is therefore concerned essentially with cardiac manifestations Extracardiac symptoms are presented primarily from the point of view that they may be the earliest or most prominent clues leading to the diagnosis of rheumatic heart disease or to the detection of a reactivation of rheumatic cardiac infection

Cardiac Symptoms

Rheumatic cardiac symptoms are classified according to their occurrence in the (a) *active* or (b) *inactive* stage of the infection They are further classified according to the anatomic site of the lesions into (1) *endocardial* and *valvular,* (2) *myocardial* and (3) *pericardial* manifestations

It should be noted that in both the active and inactive stages cardiac lesions may be present without producing overt symptoms The latter depend on the extensiveness of the anatomic lesions and their situation in critical cardiac sites In the absence of symptoms or a history of rheumatic fever, rheumatic heart disease is discovered accidentally on physical examination or sometimes for the first time at postmortem examination [] Occasionally the presence of rheumatic heart disease is first disclosed when the patient is observed because of the development of atrial fibrillation, congestive heart failure or bacterial endocarditis

Active Stage of Rheumatic Heart Disease

1 *Endocarditis and valvulitis* The development of endocarditis may be documented by (1) an alteration in cardiac sounds, (2) the occurrence of new cardiac murmurs and (3) a change in the character of murmurs previously present [, 101] But there may be no specific evidence of valvular involvement during the acute attack

Very early there is a loss of the distinctive muscular quality of the first sound at the apex It may become prolonged and diminished in intensity It has been described as "impure" "murmurish" or "mushy" Sometimes there is a splitting or reduplication of the second sound at the apex an occurrence emphasized by Sansom[8] and Cheadle[] A loud third sound is common during the acute attack [90] In fact a triple rhythm usually due to a loud third heart sound occasionally to gallop rhythm, is a frequent finding in acute rheumatic fever

Blowing systolic murmurs occur early and frequently They are located at the apex to the left of the sternum at the level of the fourth rib, over the pulmonic or aortic area or over an extensive precordial area They are best heard when the patient is supine These systolic murmurs may indicate early organic involvement of the valvular endocardium, but must be distinguished on the one hand from functional murmurs due to the associated fever or anemia, or cardiorespiratory factors, and on the other hand from the organic murmurs of chronic valvular deformity which evolve later in the course of the disease [68] The early systolic murmur may completely disappear with subsidence of the active stage of the disease

Occasionally a mid-diastolic apical murmur has been reported as occurring in the early stages of rheumatic fever and disappearing after the rheumatic attack abates [] This should not be confused with the diastolic murmur of mitral stenosis [55] The apical mid diastolic or presystolic murmur of acute rheumatic fever has been explained as due to relative mitral or tricuspid stenosis secondary to dilatation of the left or right ventricle [101] This explanation is unclear, but relative mitral stenosis may be due to increased speed of blood flow Phonocardiography may be necessary to distinguish a crescendo-type of first sound, a loud third sound or gallop rhythm, which may simulate an apical presystolic or mid-diastolic murmur [1, 57, 8] Subsequently, organic murmurs of chronic valvular disease may or may not develop Sometimes signs of organic valvular disease develop early in the course of what appears to be the first active stage of the disease In such instances one is at a loss to determine whether these signs are the result of a previous unnoticed attack or whether they can develop with unusual rapidity in the course of the first one

2 *Pericarditis* In the active stage two clinical varieties of pericarditis may be distinguished[93] (1) *acute fibrinous pericarditis* and (2) *pericarditis with effusion*

Postmortem studies disclose that organization of the inflammatory exudate and the development of adhesions occur even in the active stage but these give no clinical symptom in the active disease (p 818) The incidence of clinical pericarditis in rheumatic fever is variously reported as 3 per cent [76] 5 per cent [] and 13 per cent [20] and 5 to 10 per cent in the *recent cooperative study* of cases in the United Kingdom and the United States [] Pericarditis is often overlooked clinically unless frequent and careful examinations are made Recent pathologic studies indicate microscopic pericardial lesions in almost 100 per cent of patients dying of active rheumatic heart disease but clinical evidence were reported only when the lesions were severe and extensive [5]

When there is clinical evidence of pericarditis, the patient is usually suffering from a serious form of rheumatic heart disease The recognition of pericarditis should call attention to the underlying myocardial infection Pericarditis is also associated with other serious visceral rheumatic infections, particularly pleurisy and pneumonia Subcutaneous

nodules are said to be associated frequently when there is pericarditis

(1) ACUTE FIBRINOUS PERICARDITIS The essential symptom is substernal, precordial or abdominal pain and the essential sign a pericardial friction rub The rub is usually heard for four days or less but occasionally for longer periods A detailed discussion of the symptoms and signs of acute fibrinous pericarditis is presented in Chapter 22

The occurrence of acute pericarditis is often marked by a rise sometimes considerable in the fever curve In young adults in the army signs of pericarditis usually developed within a few days after the onset of acute rheumatic fever Evidence of pneumonia, pleurisy pulmonary infarction or heart failure often accompanies pericarditis

(2) PERICARDIAL EFFUSION of slight degree is generally associated with acute pericarditis

The precordial pain and pericardial rub of the acute fibrinous pericarditis may or may not disappear with the formation of a considerable effusion The patient may suffer precordial oppression and a characteristic sense of anxiety Restlessness insomnia delirium and other mental symptoms occasionally occur With large effusions the patient is exceedingly dyspneic and orthopneic so that he must sit upright in bed Tachypnea is a frequent and prominent symptom The patient may become cyanotic or flushed but often he presents an intense pallor The picture of an intensely pale and dyspneic child sitting up anxiously in bed and complaining of precordial pressure and pain is very suggestive of rheumatic pericarditis with considerable effusion Dysphagia aphonia and an irritative cough may result from pressure on the esophagus or recurrent laryngeal nerve The diagnosis may be confirmed radiologically[7] and by pericardial paracenteses A detailed account of the symptoms and signs of pericarditis with effusion is given in Chapter 22

3 *Myocarditis* Lesions of the myocardium proper are the most important cardiac evidences of active rheumatic fever Recognition of these lesions requires frequent regular examinations In the presence of a rheumatic pericarditis or valvular disease one can virtually assume myocardial involvement An unexplained rise in temperature in the course of rheumatic fever is a significant clue suggesting the necessity of careful examination of the heart An increased pulse rate is merely evidence of the general infection But a disproportionate rise in pulse rate or a persistent tachycardia despite a spontaneous or salicylate induced fall in temperature suggests the presence of carditis

The patient s *symptoms* may be few or they may be numerous and severe Precordial pain of variable severity is frequent

The *signs* of active rheumatic myocarditis are visible tumultuous cardiac action changes in heart sounds rapid cardiac enlargement evidences of heart failure disturbances in cardiac rate and rhythm Electrocardiographic changes also denote myocardial involvement

The earliest signs of myocarditis are changes in the quality intensity and pitch of the first sound[48] This becomes dulled muffled or almost obscured It may appear to have the same pitch and quality as the second sound, producing a tic tac or dup dup effect (embryocardia) instead of the normal lub-dup or lub dupt A blowing systolic murmur may be due to myocardial disease inflammation of the valve rings and cusps or to other factors (such as fever and anemia) associated with the rheumatic affection The cardiac impulse is generally diffuse and feeble But when the acute myocarditis is superimposed on a previously damaged heart with chronic valvular disease and hypertrophy the cardiac [illegible] pulse is more apt to be strong and tumultuous

Evidences of right and left heart fail[illegible] are commonly observed in [illegible] forms of rheumatic myocard[illegible] pericardial or pleural [illegible] tribute to the severity of the dyspnea and orthopnea Diastolic gallop [illegible] portant sign of left ventr[illegible] myocarditis during [illegible] fever However a presystolic [illegible] in the absence of heart fa[illegible] duction time is prolo[illegible] is audible It may also [illegible] gush a physiologic [illegible] tachycardia from a [illegible] rhythm When [illegible] failure [illegible] there may be a sub[illegible] children right-sided [illegible] may be predomi[illegible] the [illegible] The patient s extre[illegible] edema the liver [illegible] Hydrothorax develops and [illegible]

may be ascites The patient complains of abdominal distress and nausea and he may vomit Some children present a puffy face as in glomerulonephritis Unexpected weight gain may precede visible edema There may be cyanosis of the lips and fingertips if anemia is not too severe The cervical veins and those of the extremities become distended, and the venous pressure is elevated

Cardiac enlargement may occur rapidly with active rheumatic heart disease if there is severe myocardial involvement and failure The enlargement may be the result of a previous attack It can be interpreted as a sign of activity only if it develops or progresses under observation and if there are other evidences of active rheumatic fever There may be a diminution in cardiac size with subsidence of rheumatic activity and restoration of cardiac compensation [9]

Disturbances of cardiac rhythm are both frequent and valuable signs of rheumatic myocarditis, but usually are discovered only by electrocardiography (p 837)

Inactive Stage of Rheumatic Heart Disease The clinical picture of inactive rheumatic heart disease is essentially that of valvular disease of the heart Proof that the disease is inactive consists of negative observations For practical purposes rheumatic heart disease is considered as being inactive when in addition to the absence of fever tachycardia and other symptoms of active rheumatic infection, the white blood count, rate of sedimentation of red blood cells and repeated electrocardiograms are normal and the serum has no C reactive protein

Subjective symptoms may be entirely absent in the inactive stage of rheumatic heart disease Physical signs, however, are generally well defined Both the physical signs and the subjective symptoms when present are those of chronic valvular heart disease with or without heart failure These are discussed in detail in the chapters on the individual valvular lesions (Chapters 26 to 29) In a series of 2476 persons with rheumatic heart disease rejected by draft boards in five large American cities there were signs of mitral insufficiency alone in 750, of mitral stenosis alone in 750 of aortic insufficiency alone in 208, of aortic stenosis in 72 and of combined mitral and aortic valvular disease in 628 [84]

Complications of Rheumatic Heart Disease The chief complications of rheumatic heart disease are (1) cardiac failure, (2) atrial fibrillation and other arrhythmias, (3) subacute and acute bacterial endocarditis, (4) embolization More rarely there are anginal syndrome with or without coronary sclerosis or occlusion, essential hypertension hyperthyroidism (Graves' disease), Adams Stokes syndrome Many other so-called complications are really essential elements of the rheumatic affection or represent unrelated intercurrent infections (See also individual valvular diseases, Chapters 26–29)

Extracardiac Manifestations

Arthritis Arthritis is the most constant and most conspicuous local manifestation of the disease Characteristically, there is a symmetrical polyarthritis, primarily affecting large joints, with rapid development and subsidence of inflammatory phenomena and successive involvement of new joints as inflammation in the others regresses But in many cases reported among military forces only a single joint was affected [illegible] The joints most frequently involved are the knees ankles shoulders and wrists However, almost any joint may be implicated, including the small joints of the hands and feet the elbows, hips, vertebrae the sternoclavicular and temperomandibular and crico-arytenoid joints, and even the symphysis pubis Trauma and strain sometimes appear to play a role in determining the affected joints

The symptoms vary considerably in severity and consist of pain redness swelling increased warmth of the skin overlying the joint, and disability The acute symptoms, including swelling and effusion *generally respond* remarkably to the administration of adequate doses of salicylates, but there may be a slight persistent residual pain and swelling Inflammation in a given joint may develop fully in a few hours Its subsidence is more gradual requiring between one day and one week and occasionally longer

The synovial fluid is a pale yellow fluid which may be clear or slightly cloudy and may contain some flakes There is an early predominance of polymorphonuclear leukocytes with a few mononuclear cells and undifferentiated young connective tissue cell Later there are numerous clasmatocytes containing degenerated cells and debris [11] Sup-

puration does not occur except by secondary infection with pyogenic organisms

Tendinitis Myositis Tenosynovitis Bursitis. Pain in the juxta articular region may be due to inflammation of neighboring tendons and muscles They are responsible for the growing pains in children which should not be confused with the more significant rheumatic arthritis [16] As I have pointed out with Gross [5] *polymyositis* may occur when periarteritis nodosa is associated with rheumatic fever In *tenosynovitis* of the hand, considerable effusions may occur

Subcutaneous Nodules These nodules represent one of the pathognomonic features of rheumatic fever and have been reported to occur in 5 to 20 per cent of cases [47] In the recent cooperative study [1] of 500 cases of acute rheumatic fever they were observed in 21 7 per cent of the cases in the United Kingdom and in 7 4 per cent of the cases in North America While they may appear in connection with any other rheumatic symptoms their seriousness lies in their association with severe cardiac lesions which arise sooner or later in most cases Cheadle[15] assigned them an ominous prognosis because he observed that there was frequently a fatal pericarditis However I have repeatedly seen children with rheumatic fever and nodules recover and experience a favorable clinical course It is important to recognize these nodules because in some of the attacks they may represent the only local manifestation of rheumatic involvement as in the following case I observed

> A three year old child had a temperature between 99 5 and 100 5 F and was found to have subcutaneous nodules A diagnosis of rheumatic fever was made from this alone The diagnosis was confirmed six months later when while the patient was suffering from pallor loss of appetite and loss of weight the nodules reappeared but without fever or leukocytosis Examination revealed a large heart and signs of mitral stenosis pleural and pericardial effusions Four years later the nodules recurred in association with polyarthritis erythema annulare and urticaria Post mortem there was active rheumatic heart disease mitral stenosis cardiac hypertrophy and adherent pericardium

The nodules are grayish translucent conical or rounded elevations of circular or oval outline varying in size from that of a pinhead to about 2 cm in diameter They are situated subcutaneously unattached to skin so that the skin can be moved freely over the nodule They tend to occur over bony prominences and may be attached to fascia aponeuroses (especially the galea aponeurotica) tendons and periosteum (skull) The back of the elbow the bony prominences on the dorsum of the hand or foot the malleoli patella skull spines of scapula and of vertebrae are favorite sites of localization but the clavicles, ribs crests of the ilia sternum acromium and rarely the flexor tendons of the hand may also be involved They tend to assume a symmetrical distribution They vary in number from a few to over one hundred at a time As with other rheumatic symptoms there is frequently a characteristically rapid evolution and disappearance of nodules followed by recurrence in new locations Because of their occasional evanescence they may be overlooked Usually however, because of recurrences nodules may be observed for weeks or months There is no redness and usually no pain or tenderness (The pathology of subcutaneous nodules is discussed on p 820)

Cutaneous Lesions. The most significant cutaneous lesion is the lesion variously termed *erythema annulare* e marginatum e circinatum or e gyratum according to its configuration [42 47 46] I believe that this lesion is specific for rheumatic fever and is similar in importance to the subcutaneous nodule as a clue to the presence of the disease, the probability of cardiac involvement and the persistence of rheumatic activity A characteristic histologic picture has been described [14] As Cheadle[15] pointed out erythema annulare and subcutaneous nodules are often present simultaneously Coburn[16] found the former in 17 per cent of his series of cases a frequency which was slightly higher than that of the subcutaneous nodules In the recent cooperative study [1] of acute rheumatic fever, *erythema marginatum was observed in about* 4 per cent of the American cases and about 8 per cent of those in the United Kingdom

Characteristically the erythematous lesions occur on the trunk but may appear on the extremities They begin as reddish or violaceous macules or papules 1 to 5 mm in diameter (erythema papulosum) at which stage they are non specific They develop rapidly, literally under one s eyes into much larger lesions which by clearing in the center, form circles or segments of circles which join or intersect to trace various types of scalloped serpentine or crescentic patterns At their margins the lesions are pale pink or dull red

sharply circumscribed and slightly elevated, the centers are flat and colored by a faint brown pigmentation The lesions disappear almost as rapidly as they develop, only to reappear in new crops

The rheumatic significance of various other cutaneous lesions encountered is questionable *Urticaria* is of course not specific, but I have observed it developing in definite relation to attacks of rheumatic fever Various other erythemas reported in association with arthritis are not examples of rheumatic fever but belong to the group described by Osler[62] as erythema with visceral lesions *Erythema multiforme* except in so far as it may include erythema annulare is not related specifically to rheumatic fever and its appearance is coincidental Diffuse *petechiae* (very rarely white centered) are occasionally observed, but widespread purpura is not a feature of the disease[4] Most cases of purpura with arthritis or arthralgias are instances of Schonlein's disease (peliosis rheumatica) and are mistakenly called rheumatic fever *Erythema nodosum* sometimes reported as appearing in rheumatic fever is I believe a non specific toxic or allergic manifestation The painful *ephemeral nodules* described in the French literature probably represent the so-called Osler nodes in subacute bacterial endocarditis (p 872)

Chorea and Other Neurologic Symptoms The essentially rheumatic nature of chorea minor (Sydenham) is no longer questionable Hughes and Brown[42] who early emphasized its relationship to polyarthritis and endocarditis found evidence of rheumatic affection in 85 per cent of their cases of chorea Like the subcutaneous nodules with which it is frequently associated, chorea is essentially a manifestation of rheumatic fever in childhood In young male adults in the army in World War II, chorea was observed very rarely in association with rheumatic fever

It may be the first symptom and is frequently complicated or followed by carditis Among 1181 rheumatic children studied by Kaiser[45] chorea was the original expression of the disease in 326 or 28 per cent Carditis was associated or developed subsequently in 58 per cent Coombs[20] observed carditis in 76 per cent of cases and Osler[63] reported the cardiac valves intact in only 8 per cent of 125 fatal cases of chorea Chorea occurs preponderantly among females In pregnancy it is occasionally observed in a severe form (chorea gravidarum)[64], artificial abortion or premature induction of labor may be required

There has been some question as to the occurrence of a non rheumatic, possibly psychogenic chorea According to Coburn[17] and Kagan and Mirman,[43] at least one half of their observed cases of chorea in children were unaccompanied by other symptoms of rheumatic fever or by the development of cardiac disease These non rheumatic cases were characterized by absence of family history of rheumatic fever, absence of preceding respiratory infection and by normal leukocyte count and sedimentation rate during the attack of chorea

Clinically, chorea is characterized by constant, uncoordinated purposeless muscular movements Its onset is usually insidious but occasionally it develops immediately after a fall a trauma sudden fright or emotional upset In those cases commencing gradually the child begins to drop things, spill food and find it impossible to button her clothes She develops nervous symptoms including irritability, restlessness, sleeplessness night shrieks and bed wetting The child may be scolded at school for writing badly or slopping ink Exaggerated uncoordinated and explosive movements occur spontaneously as well as with muscular effort and are beyond voluntary control Facial grimaces rolling of the eyes, tossing of the head and wrinkling of the forehead combine to sketch a distorted picture The imbecilic appearance which results is belied by the school record of these children who are often unusually bright and even precocious Because of the disease however they slur their words phonate badly or may be unable even to speak They walk improperly, trip themselves move about irregularly and too rapidly in a manner which the title St Vitus' dance, well characterizes

In severe cases the children must often be kept in a bed with side bars in order to avoid self harm In such cases also they may be unable to swallow, requiring tube feeding as well as special nursing care because of loss of control of bladder and bowels Severe cases are easily recognized In mild ones there may be only a muscular restlessness The nature of the disease can be verified by requesting the child to hold her hands steadily outstretched for several minutes or by holding her hands enclosed in those of the examiner, whereupon the exaggerated twitchings are observed or

felt Chorea may occasionally affect a single extremity or half the body producing a picture simulating a monoplegia or a hemiplegia

A moderate leukocytosis and mild fever may be present but in the absence of other rheumatic manifestations the course is entirely afebrile Eosinophilia may be present The attack of chorea may last six to eight weeks or be even more protracted Recurrences are encountered sometimes with additional cardiac damage Death in an acute attack occurs in about 3 per cent of the cases, or in as many as 7 to 20 per cent when chorea occurs during pregnancy

Pathologically chorea is a meningoencephalitis involving particularly the basal ganglia especially the caudate nucleus and putamen in the corpus striatum and also the internal capsule and cortex[31] However the pathologic changes are usually surprisingly mild The almost invariable complete clinical recovery suggests that the alterations are essentially reversible and therefore are probably predominantly exudative Vascular lesions minute areas of softening degeneration of nerve cells and inflammatory foci have been described

Cerebral rheumatism was a term formerly applied to psychic disturbances including personality changes headache insomnia delirium and eventual coma associated with hyperpyrexia These manifestations are rare since the use of salicylates although toxic doses of the latter may also produce delirium and other mental disturbances More recently the finding of a chronic obliterating endarteritis (p 820) in the brains of persons dying of rheumatic heart disease has led to the concept that various clinical forms of rheumatic brain disease are due to these underlying lesions[1, 96] Rheumatic endarteritis of the brain has been found in 5 per cent of patients in a mental hospital and in 9 per cent of patients with dementia praecox Convulsive seizures (rheumatic epilepsy) have also been attributed to rheumatic cerebral lesions These interesting concepts are still hypothetical

Respiratory Symptoms Pharyngitis tonsillitis sinusitis and laryngitis occur frequently before the onset of an acute episode of rheumatic fever A specific rheumatic nature has sometimes been ascribed to these upper respiratory infections The characteristic rheumatic inflammation including Aschoff bodies has been observed in the peritonsillar fibrous tissue and adjacent musculatures Hoarseness and respiratory distress may be due to pressure on the recurrent laryngeal nerve inflammation of the crico arytenoid joints or large lymph nodes

Pleurisy either fibrinous or with effusion is observed clinically in 5 to 15 per cent and post mortem in more than 50 per cent of cases[65] Pleurisy is generally associated with pulmonary and cardiac disease including pericarditis[76] Pleural effusion may be unilateral or bilateral and occurs more frequently on the left side probably due to the proximity of the left pleura to the pericardium Paul[65] however found it more often on the right side at postmortem examination and even in the absence of gross pericarditis Microscopic lesions may have been present in the pericardium in such cases As indicated by Bezançon and Weil[8] the pleural lesions may arise by extension from cortical pulmonary disease (cortico pleurite) as well as from the pericardium

The onset of pleurisy is associated with sharp pain over the chest and intensified by inspiration or motion of the chest wall Pain may radiate to the abdomen and produce a picture resembling an acute abdominal complication A pleural friction rub may be present or only diminished breath sounds and a few subcrepitant rales After a few days the pain usually disappears and there are evidences of fluid at the bases of the lungs posteriorly The physical signs are often confusing because of the frequent association of pulmonary lesions and pericardial effusion The pleural effusion is rarely of sufficient size to produce significant respiratory distress or require tapping If routine anteroposterior and oblique roentgenologic views of the chest are taken a rheumatic pleurisy may be demonstrated in a high percentage of cases[87] The interlobar fissures appear thickened

The specific rheumatic nature of the pleurisy was first mentioned by Stoll and accepted by numerous French and English observers[65] Clinically a resemblance to rheumatic arthritis has been seen in the rapid development and subsidence of the pleurisy

Pathologically the rheumatic nature of the pleurisy has been supported by the observation of inflammatory lesions in the subendothelial connective tissue consisting of collagen swelling and degeneration edema infiltration

with lymphocytes, leukocytes and giant cells and scar formation, but Aschoff bodies have not been described

The pleural exudate[7] is serofibrinous appears turbid and straw colored and on standing one hour separates out a clear serous fluid and a coagulum containing a variety of cells French authors lay special stress on the characteristic nature of the cellular exudate which is composed of a predominance of polymorphonuclear leukocytes over lymphocytes and especially of endothelial cells occurring in large numbers both singly and in sheets The effusion is an exudate It may be hemorrhagic In many of the cases with sanguineous effusion, it is probable that the pleural exudate appeared in connection with pulmonary infarction Rapid and complete resorption of the effusion is the rule, but occasionally resorption is delayed (pleurésie fixé) and adhesions may develop

Pneumonia in Rheumatic Fever The occurrence of a *specific rheumatic* pneumonia has been the subject of considerable confusion and disagreement (p 820) Latham[51] and Fuller[3] first emphasized the occurrence of a rheumatic pneumonia physical signs of which they observed clinically in about 15 per cent of their cases of rheumatic fever Griffith et al[3] reported the clinical observation of pneumonitis in 11 3 per cent of 1046 patients with prolonged rheumatic fever The pathologic findings in the lung have been described above (p 820)

The reported clinical features of "rheumatic pneumonia" are even less consistent than the pathologic findings Rabinowitz[71] emphasized the presence of atypical bilateral, migrating signs of consolidation without the usual symptoms of pneumonia, i e, cough was slight or absent sputum scanty and fever of low grade Seldin and his associates[85] on the other hand characterized rheumatic pneumonia by the abrupt onset of profound breathlessness and orthopnea, hacking cough, scanty sputum which is occasionally blood streaked pleuritic pain and frequent cyanosis These symptoms are associated with high fever, leukocytosis and bilateral multilobar, nonsegmental infiltrations similar to the shadows of pulmonary edema Physical signs are relatively few According to Griffith and associates[3] rheumatic pneumonia is characterized by dyspnea and tachycardia fever pleuritic pain cough and malaise, shifting areas of dullness, diminished breath sounds and fine râles and transient pleural effusions The roentgen ray appearance is similar to that of primary atypical pneumonia

Lustok and Kuzma[88] found that fever dyspnea and tachypnea were almost always present, cough chest pain and cyanosis were very frequent and hemoptysis occurred in one third of the cases They stated that a clinical diagnosis of rheumatic pneumonitis was warranted on the basis of (1) disproportionate respiratory distress with severe cough chest pain, cyanosis and hemoptysis not relieved by oxygen, (2) evidence of carditis not severe enough to explain the pulmonary findings, and (3) roentgenologic finding of "increased perivascular markings arising at the hilus and progressing to nodulation, confluence and massive consolidation with relatively clear apices and bases"

It is very probable that the reported symptoms, physical and roentgen ray signs associated with so-called rheumatic pneumonia do not have a unitary pathologic basis, but result from pulmonary infarction left sided heart failure with or without transient pulmonary edema, as well as an atypical pneumonia which may or may not be characteristic of rheumatic fever In particular the occurrence of pulmonary infarcts, due to emboli from thrombi in the leg veins or right atrium, is often overlooked They may be characterized by sudden dyspnea, tachycardia, fever and leukocytosis with or without pleural effusion while the better known chest pain and hemoptysis are absent or over shadowed Heart failure may be precipitated or intensified by such emboli and, in particular, transient pulmonary edema may ensue Persistent rheumatic activity or recrudescence is often diagnosed when unrecognized pulmonary infarction occurs

Corresponding to these mixed pathologic lesions roentgenologic examination of the lung may disclose a variety of pictures[84] including (1) pulmonary congestion with increased vascular markings due to early left heart failure, (2) acute pulmonary edema with central densities radiating from the hilar regions (3) pulmonary infarcts often indistinguishable from areas of consolidation or atelectasis (4) pleural effusion which may be due to rheumatic inflammation or to pulmonary infarction, (5) "rheumatic pneumonitis" characterized by large, small or

confluent densities indistinguishable from atypical pneumonia, atelectasis or infarction In cases of prolonged rheumatic fever and rheumatic heart disease there may be roentgen ray evidence of chronic pulmonary edema pulmonary fibrosis and pleural thickening

Gastrointestinal and Abdominal Symptoms Constipation diarrhea and abdominal distention have been noted as frequent complaints in children prior to development of definite rheumatic fever ('pre-rheumatic children')

Abdominal pain is a common and serious symptom There may be abdominal tenderness nausea and vomiting I have occasionally observed such patients mistakenly operated upon for acute appendicitis Abdominal pain may arise by several mechanisms Most commonly it is referred from the chest, where there is a pericarditis or pleurisy There may be a polyserositis including a perihepatitis as well as pleuropericarditis In right sided heart failure, pain abdominal tenderness and vomiting may be due to a congested liver I have reported two cases in which an appendectomy was performed because of abdominal pain and tenderness due to a diffuse necrotizing arteritis involving the appendiceal as well as other vessels[4] Pain may result from a serous peritonitis Rhea[73] recently observed such a case in which he reported finding a rheumatic inflammation but his microphotographs do not appear to show specific lesions

Renal Symptoms Intermittent slight *albuminuria is common in the presence of fever* According to Goldring and Wyckoff[29] there is often a mild focal nephritis as indicated by abnormal urinary protein casts leukocytes and erythrocytes determined by the Addis sediment count

Acute diffuse glomerulonephritis is uncommon, occurring in less than 1 per cent of cases of rheumatic fever[76] Baehr and Schiffrin[4] discovered only 2 cases of acute diffuse glomerulonephritis among 235 necropsied cases of rheumatic heart disease Glomerulonephritis and rheumatic fever were found by Hartman and Bland[38] to be associated in 2 5 per cent of 117 cases of clinically diagnosed acute nephritis

Diseases of Blood Vessels The diffuse vascular lesions described by Klotz[50] and by von Glahn and Pappenheimer[85] are clinically insignificant I have reported with Gross[24] four anatomically proven cases of active rheumatic heart disease with diffuse necrotizing arteritis In these cases the vascular lesions were sufficiently extensive to produce symptoms which dominated the clinical picture including orchitis and abdominal pain which induced surgical intervention

Epistaxis has been repeatedly noted as a manifestation of rheumatic children, especially during rheumatic activity or before a recurrence[illegible] I believe the frequency and significance of epistaxis as a specific rheumatic symptom has been exaggerated

Blood and Urine A *leukocytosis* is common in active rheumatic fever[89] and is a significant index of active infection The white blood count is generally between 10 000 and 16 000 per cubic millimeter Occasionally it may exceed 20 000 or it may lie within normal limits Salicylate and hormone therapy may lower the white blood count as well as the temperature A leukocytosis may persist into the afebrile stage It then becomes a more delicate index of rheumatic activity than the temperature An absolute and relative increase in polymorphonuclear leukocytes accounts for the leukocytosis There is a shift to the left in the number of non filamented polymorphs by the Schilling count The remaining white cells are normal but in chorea there may be an eosinophilia[5]

Anemia is a common feature of active rheumatic fever The hemoglobin may fall as low as 6 or 7 gm per 100 cc although it usually lies between [illegible] and 12 gm and *gradually rises as rheumatic activity subsides* The red blood cell count ranges between 3 and 4 million per cubic millimeter The anemia is of the microcytic type[illegible]

That the *rate of sedimentation of red blood cells is increased* in rheumatic fever was observed by *Kahlmeter*[44] In one hour the column of plasma by Westergren's method may reach 100 to 120 mm as compared with 1 to 7 mm for normal women and 1 to 11 mm for men With subsidence of rheumatic activity the rate of sedimentation reverts to normal Of great significance however is the observation that the sedimentation rate may remain rapid for some time after the temperature and white count become normal[illegible] Thus it appears to be an especially sensitive index of persistent rheumatic infection With congestive heart failure occasionally the sedimentation rate may fall to normal even in the presence of rheumatic activity[66] but see

p 156 In cases of chorea without associated manifestations of rheumatic fever or carditis, the sedimentation time is normal[17]

The *C reactive protein*[94] not present in normal blood, appears in the blood (probably in the beta globulin fraction[100]) in a variety of infections and other conditions including acute rheumatic fever[2, 74] It is absent in inactive rheumatic fever This protein reacts in vitro with the somatic "C" polysaccharide of pneumococci to give a precipitate A positive reaction is graded from 1 plus to 8 plus In general the presence of C reactive protein in the serum during rheumatic fever tends to parallel the erythrocyte sedimentation rate, but some observers regard it as a more sensitive index of rheumatic activity However, because of its non specificity it is not diagnostic of rheumatic fever Its value rather is to determine activity in a patient known to have rheumatic fever but no other disease associated with C-reactive protein It may also be helpful in excluding active rheumatic fever in a doubtful case, if no C reactive protein is present

The *fibrinogen* content of the blood plasma was reported as being elevated by Bezançon and Weil,[8] who use this as a sign of persistent activity It appears to parallel the sedimentation rate

An *abnormal (shortened) coagulation band in the Weltmann reaction* is associated with rheumatic activity and was considered by Scherlis and Levy[11] to be at least as significant in this respect as the rapid sedimentation rate

The *formol-gel* test may be positive, but this is only irregularly found with active rheumatic fever The positive formol gel test corresponds with the tendency to high serum globulin in rheumatic fever[22, 62]

Serum mucoprotein was found to be elevated during the active disease,[49] and the concentration returned to normal more slowly than the erythrocyte sedimentation rate Hence it was suggested that serum mucoprotein may be a more sensitive index of persistent rheumatic activity An elevated serum mucoprotein is also found in a variety of other conditions Similarly *serum hexosamines* which are constituents of serum mucoprotein, are also elevated in almost all patients with rheumatic fever at some time in the course of the disease[77, 45] But the elevation in serum hexosamine is not necessarily the cause of the increased serum mucoprotein in rheumatic fever The elevation in serum mucoprotein and serum polysaccharide has been related to the concept that rheumatic fever is a disease of mesenchymal tissue particularly of the interstitial ground substance The latter is rich in mucopolysaccharides, especially in hyaluronic acid Hexosamines (glucosamines) arise as a result of the depolymerization of hyaluronic acid by hyaluronidase

Hyaluronidase inhibitor (antihyaluronidase) is present in the serum in increased concentration during active rheumatic fever[30]

Diphenylamine Reactor[18] The blood contains an unidentified substance which reacts to diphenylamine and is increased in concentration during the peak or shortly after the height of acute rheumatic fever but occurs also in other conditions

Blood cultures are generally negative In about 5 per cent of cases an occasional positive *blood culture is obtained usually of the* Streptococcus viridans (alpha) or anhemolyticus (gamma)[55] But these organisms are almost invariably grown only in fluid media a point which indicates that the organisms are few in number On the other hand positive cultures of these organisms in subacute bacterial endocarditis are obtained as a rule both on solid and fluid media

The *urine* contains a trace of *albumin* in the febrile state and in the presence of congestive heart failure

ELECTROCARDIOGRAPHIC CHANGES

Electrocardiographic abnormalities are almost always present at some time during the course of active rheumatic fever[11, 40] These disturbances are only occasionally recognizable clinically Since the arrhythmias are characteristically evanescent, the frequency with which they are discovered is proportional to the frequency of cardiac and electrocardiographic examination

The importance of electrocardiographic changes in rheumatic fever lies in the facts that (1) they suggest the occurrence of cardiac damage in almost every case of that disease, (2) they may serve as an important sometimes as the only, sign of cardiac damage Shapiro[84] demonstrated the persistence of active disease in 65 per cent of children with supposedly quiescent rheumatic heart disease by taking successive electrocardiograms which revealed abnormal or changing curves There is a mistaken notion that these

electrocardiographic changes are themselves diagnostic of rheumatic carditis On the contrary, the changes are nonspecific and are confirmatory only if the diagnosis of rheumatic fever is justifiable on other clinical grounds Similar changes are found in a host of infections and other conditions in which chronic clinical heart disease does not develop

Three types of electrocardiographic abnormalities are encountered in rheumatic fever (1) impaired atrioventricular conduction (2) abnormalities in the QRST complex and more rarely in the P wave and (3) changes in cardiac rate and rhythm

1 Impaired Atrioventricular Conduction

(a) *Prolongation of the P R interval* is the most frequent significant electrocardiographic abnormality in rheumatic fever The P R interval exceeds 0 20 second occasionally lies between 0 3 and 0 4 and even longer P R intervals have been observed Prolonged P R interval has been noted in 25 to [illegible] per cent of active cases the higher incidence being obtained with frequent and numerous electrocardiographic examinations[illegible, 80, 61] A prolonged P R interval may be encountered in a great variety of infections and infectious diseases (Chapter 36) but not as regularly as in rheumatic fever As a rule the prolongation of the P R interval is a transient disturbance but occasionally it persists for weeks or months

The prolongation of the P R interval may be due directly to reversible rheumatic inflammation of the a v node and bundle[83] but it has also been attributed to vagal stimulation[illegible] Thus carotid sinus pressure and prostigmine may increase the prolongation of the P R interval[illegible] while atropine reduces the P R interval in rheumatic fever[75] These observations however, do not exclude the possibility that the effect of rheumatic fever is on the conduction system directly, while the augmenting or inhibitory effect of the drugs is by way of the vagus nerve Furthermore rheumatic lesions may render the a v conduction system abnormally sensitive to vagal stimulation

(b) More severe grades of *heart block* are occasionally observed with 2 1 3 1 or 3 2 block Dropped beats and Wenckebach periods have been noted Complete heart block is very uncommon but it may be the earliest manifestation of rheumatic heart disease and may occur in the absence of fever[93, 97] Rarely there is an Adams-Stokes syndrome[illegible] Almost always heart block disappears when the infection subsides but occasionally it persists permanently Bundle branch block is observed occasionally Interference dissociation (p 330) may be an early finding and occurred in 18 of 1000 cases of rheumatic fever studied by Rosenberg[78]

2 Abnormalities in QRST and in P Waves

The frequency of QRS ST and T wave changes in rheumatic fever was emphasized by Cohn and Swift[19] and by Rothschild et al[78] Blackman and Hamilton[9] reported finding ST and T wave changes in 61 per cent of their cases

(a) *Deviations in R T or S T interval* There may be an elevation or depression of RST transition Most often there is an R T elevation in two or more leads due to rheumatic pericarditis

(b) *T wave alterations* consist of inversion especially in leads I and II Similar T wave inversions and R T abnormalities are observed also or only in the precordial leads[3, 22] The T waves may also be diphasic or of low voltage Inverted T waves in some cases are due to pericarditis with effusion

(c) Changes in the QRS complex consist of lowering of the voltage of the major deflection or occasionally of notching slurring and widening due to delayed intraventricular conduction or bundle branch block

(d) A *prolongation of the Q T interval* relative to the cardiac cycle (corrected Q T interval or Q T) has been stressed as a universal finding in active rheumatic carditis by Taran and Szilagyi[81, 13] They found the Q T interval to be a measure of the severity of the carditis and valuable both for following progress and discovering persistent activity even when all other laboratory criteria are normal A confirmatory study was reported by Kornel and Braun[50] The value of measuring the Q T interval and its clinical significance are still moot questions Technical difficulties in measurement impair any practical value

(e) P wave inversion or flattening has been described as evidence of rheumatic activity[81]

3 Changes in Cardiac Rate or Rhythm

(a) *Sinus tachycardia* is almost always found in the presence of fever and often for a variable period after the fever is gone Occasionally there are attacks of paroxysmal tachycardia Bradycardia is rarely found in

Chapter 33

RHEUMATIC FEVER

Diagnosis, Differential Diagnosis, Prognosis and Treatment

DIAGNOSIS OF RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

The diagnosis of rheumatic fever and rheumatic heart disease[5, 41] involves the recognition of (1) active rheumatic fever with or without cardiac involvement and (2) rheumatic heart disease in patients without rheumatic activity.

THE PRESENCE OF ACTIVE RHEUMATIC DISEASE

It is important to reemphasize that there is no specific test for rheumatic fever and that diagnosis of this disease is often necessarily based on non specific clinical and laboratory abnormalities which are similar to those caused by other diseases. In order to establish relatively uniform statistical data and to avoid the serious implications, restrictions and psychologic disturbances that accompany a diagnosis of rheumatic fever, it seems desirable to satisfy strict criteria before this diagnosis is justified. The frequent discovery of rheumatic heart disease on physical or postmortem examination in subjects who presented no history of rheumatic fever suggests that the latter is often overlooked or that it often occurs in a subclinical unrecognizable form. However, this does not justify the overemphasis in recent years on minor and nonspecific abnormalities as an adequate basis for the diagnosis of rheumatic fever.

Rheumatic fever may be indicated by cardiac or extracardiac symptoms. Even when there are only extracardiac symptoms the probability of cardiac involvement in the first or subsequent attacks of rheumatic fever is so great that the patient must immediately be considered as having actual, possible or potential heart disease. The diagnosis of rheumatic fever is relatively simple when several of the more characteristic features develop simultaneously or in rapid sequence. Difficulty arises when there are only non specific *general* symptoms such as fever, tachycardia, etc., or when there is only a single localizing symptom such as joint pains.

Criteria for Diagnosis of Active Rheumatic Fever

The diagnosis of rheumatic fever is often based on certain "major" and "minor" criteria as set up by Jones.[55] With slight modification, the major criteria include (1) carditis, (2) arthritis or arthralgia, (3) chorea, (4) subcutaneous nodules and (5) erythema annulare (marginatum).[36, 76] Because of the relative infrequency of the last three the major diagnostic criteria are usually carditis and arthritis. According to Jones[55] a diagnosis of rheumatic fever is justified in a given case if two major manifestations are present. This is generally satisfactory since usually one of these is carditis. But it is essential that the evidence for carditis be acceptable (infra).

According to Jones also a diagnosis of rheumatic fever is generally justified if there are one major and two minor manifestations. This is satisfactory if the major manifestation is carditis, subcutaneous nodules or erythema annulare, and possibly chorea, and if one is certain of the accurate interpretation of these symptoms. But this combination of criteria is frequently inadequate for the diagnosis of rheumatic fever if the major manifestation is arthritis, since it is often impossible to differentiate rheumatic from other forms of arthritis. Thus the combination of arthritis or arthralgia, fever and a rapid sedimentation rate is commonly used as a basis for the diagnosis of rheumatic fever. Yet the joint symptoms may actually be due to rheumatoid arthritis, Still's disease, lupus erythematosus

osteomyelitis, leukemia, sickle cell anemia, undulant fever or other conditions and the fever and rapid sedimentation rate are common to all of these.

The *minor criteria* or manifestations of rheumatic fever may be classified into two groups. The first includes malnutrition, pallor, fatigability, recurrent sore throat, frequent epistaxis, abdominal pain, precordial pain and pulmonary findings. These serve at most to arouse suspicion when they occur in a child or adolescent and to stimulate careful observation for possible rheumatic fever. The second group includes fever, leukocytosis, increased rate of erythrocyte sedimentation, presence of C reactive protein or a high titer of antistreptolysin, antistreptokinase or hyaluronidase inhibitor. These are non specific findings which are not diagnostic of rheumatic fever but denote rheumatic activity, *provided a diagnosis of rheumatic fever can be otherwise supported on the basis of the major manifestations.* On the other hand, absence of fever, leukocytosis, rapid sedimentation rate, etc., except during treatment with large doses of salicylates or adrenal cortical drugs, would almost always exclude the diagnosis of rheumatic fever (but not chorea). In the child with definite evidence of rheumatic cardiovalvular disease, especially with a recent previous attack of rheumatic fever, the diagnosis of a rheumatic recurrence should be entertained on less rigid criteria than are required to diagnose the first attack. Similar latitude may be considered during epidemics of definite rheumatic fever, e.g., in boarding schools or barracks.

Arthritis and Arthralgias. In evaluating the presence of arthralgias or arthritis a distinction should be made between muscle and tendon "growing pains," which are non rheumatic, and definite joint pains, which may or may not denote rheumatic fever.[98] A striking, rapid amelioration of pain and fever should follow adequate doses of salicylates, but this response in itself cannot be accepted as sufficient evidence for the diagnosis of rheumatic fever. A streptococcal sore throat or scarlet fever one to three weeks preceding the arthritis enhances the probability of rheumatic fever but is likewise not an absolute diagnostic criterion.

Carditis. The most important feature of rheumatic fever and the most definitely diagnostic is cardiac involvement. *The combination of fever with congestive heart failure, rapidly progressive cardiac enlargement or pericarditis* in a child or young adult almost always denotes active rheumatic fever. Evidence of endocardial or valvular involvement, as indicated by cardiac murmurs, is sometimes difficult to evaluate in the presence of fever and anemia. In a child with previous rheumatic cardiovalvular disease, the occurrence of new murmurs, fever or arthritis is strongly indicative of another attack. In the adult over 25 years of age this is less certain (p. 843). In the child with fever, the recent appearance of apical and pulmonic systolic murmurs in combination with rapid, tumultuous cardiac action is indicative of rheumatic carditis. This is even more probable if there is an apical presystolic or mid diastolic murmur or a triple rhythm due to a loud third sound or gallop rhythm. In the young adult, benign non specific pericarditis (p. 603) is difficult to exclude if there is no evidence of valvular heart disease or heart failure. As a rule careful observation will disclose confirmatory findings such as arthritis, subcutaneous nodules or distinctive erythemas in the child with rheumatic fever and pericarditis.

Electrocardiographic abnormalities, especially a pronounced prolongation of the P R interval, are in themselves or in combination with fever insufficient to justify a diagnosis of rheumatic fever or rheumatic heart disease, since these abnormalities occur with many other infections and infectious diseases (Chapter 36). However, they may indicate cardiac involvement or continued activity in cases in which the diagnosis of rheumatic fever or rheumatic heart disease is justified on other grounds. Polyfocal extrasystoles, ectopic tachycardias including atrial fibrillation and sinoatrial, atrioventricular and bundle branch block are other electrocardiographic abnormalities which may indicate cardiac involvement in a patient with rheumatic fever.

Sydenham's chorea is suggestive of rheumatic fever even when it occurs as an isolated symptom. But when it occurs in association with fever, arthritis or other symptoms of rheumatic fever which in themselves are non specific, a definite diagnosis of rheumatic fever is justified.

Subcutaneous nodules and *erythema marginatum (annulare)* are in themselves diagnostic of rheumatic fever, but there are occasional errors in interpretation of these

subcutaneous and cutaneous lesions As a rule *the diagnosis can be made with certainty* because careful observation will disclose simultaneous fever, joint pains, carditis or other rheumatic phenomena

Laboratory Aids in the Diagnosis of Rheumatic Fever[71,172]

There is no specific laboratory test that is analogous to the Wassermann test for syphilis The presence of streptococcus A antibodies in high titer in the serum, especially antistreptolysin O is indicative of recent Streptococcus hemolyticus infection and indirectly of rheumatic fever if there are clinical manifestations of the latter The antistreptolysin O titer in rheumatic fever usually exceeds 250 units (p 809) but is more significant when it exceeds 400 or 500 units [86,14,92] Serial determinations are preferable since an increased antibody titer usually becomes detectable only the second week after the streptococcal infection and does not attain maximal levels for four to six weeks When rheumatic fever is doubtful clinically, a persistently normal antistreptolysin titer tends to exclude that diagnosis Occasionally the titer of antifibrinolysin (antistreptokinase) or hyaluronidase inhibitor is high in rheumatic fever when that of antistreptolysin is not Since either the antistreptolysin O, antistreptokinase or hyaluronidase inhibitor concentration is significantly elevated in 95 per cent of cases of acute rheumatic fever normal values for all three strongly oppose a diagnosis of rheumatic fever All other laboratory findings in rheumatic fever (p 835) are non specific and not diagnostic Many of them are useful however to determine the persistence of activity in a known case of rheumatic fever

Signs of Persistent Rheumatic Activity

When typical clinical signs of rheumatic fever disappear persistent rheumatic activity may be denoted by various clinical or laboratory findings These include

Fever A low grade fever may persist for many weeks or months This may be discovered only by rectal thermometry performed several times daily On the other hand good clinical judgment often justifies disregarding prolonged low grade elevations in temperature in the absence of other significant manifestations Some normal children have a temperature slightly beyond the usual normal range [110] Disappearance of fever *is suggestive of subsidence of activity provided* that salicylates or similar antirheumatic drugs have been discontinued On the other hand, it is generally well known that rheumatic activity often persists for weeks after the temperature has fallen to normal and that such rheumatic activity may be disclosed by other clinical or laboratory findings

Tachycardia A rapid cardiac and pulse rate persists as a rule, even after the temperature is normal It usually denotes rheumatic activity and often cardiac impairment However, occasionally a rapid pulse rate during convalescence slows if the patient is gradually permitted to resume activity In such instances the tachycardia is due to a generally poor physical fitness (lack of training) rather than to specific myocardial disease Not infrequently a persistent tachycardia is of "nervous" or psychic origin and the sleeping pulse rate is found to be normal [91]

Leukocytosis Although the white blood count may be normal, there is usually a leukocytosis in the presence of persistent rheumatic activity Special emphasis is placed on a polymorphonuclear shift to the left in the Schilling hemogram Often leukocytosis in acute rheumatic fever persists for days or weeks after the disappearance of fever

Increased Sedimentation Rate of Erythrocytes This is generally regarded as a sensitive test of persistent rheumatic inflammation Accuracy in performance of the test is essential if this is to be used as a decisive factor in determining the presence of persistent rheumatic activity Occasionally slight elevations in sedimentation rate (up to 40 mm in one hour) are found in individuals without apparent disease In rheumatic fever the sedimentation rate is usually between 60 and 130 mm in one hour but this may be depressed in the presence of heart failure

The presence of C reactive protein in the serum is a very sensitive index of rheumatic activity and has been used as a guide to therapy [2,101,87] The C-reactive protein may disappear and the sedimentation rate return to normal during adequate salicylate or adrenal cortical hormone therapy before the attack of rheumatic fever is over (p 853)

Persistent weight loss or failure to gain is associated with active rheumatic fever Subsidence of activity usually is followed by

restoration of appetite and progressive gain in weight. Increased weight due to edema of heart failure must be excluded.

Electrocardiographic Abnormalities. Distinct prolongation of the P-R interval and especially continued electrocardiographic changes in successive records are usually indicative of persistent rheumatic activity.

Clinical observations must be carefully evaluated in any determination of persistent rheumatic activity. There must be no evidence of carditis, arthritis or other manifestations of rheumatic fever and the general appearance and behavior of the patient should signify the absence of active disease. In children and young adults with rheumatic cardiovalvular disease, progressive cardiac enlargement or the development or persistence of heart failure usually denotes persistent rheumatic activity whether or not there are any of the above-mentioned clinical or laboratory signs. *The presence of minor rheumatic manifestations* should suggest persistence of activity, even though such minor phenomena would not be sufficient to diagnose the actual attack of rheumatic fever. In fact *it is important to emphasize that the clinical and laboratory phenomena which denote persistent rheumatic activity are to be distinguished from those manifestations which are originally diagnostic of the disease.*

In my experience many a child and young adult with unexplained low grade fever has been long invalided and unfairly tagged with the diagnosis of rheumatic *fever* when the sedimentation time was found to be rapid—as if the unexplained fever suggested and the rapid sedimentation rate confirmed the diagnosis. A functional systolic murmur added to these two features frequently completes the unfortunate triad which leads to the unwarranted sentence of rheumatic heart disease. Not infrequently, determination of the temperature after the child has been at complete rest for half an hour dissipates the "fever," determination of the sedimentation rate by an expert slows the rate of fall of the erythrocytes to normal, and listening to the heart in full inspiration eliminates the murmur.

Cardiac Involvement During Acute Rheumatic Fever

Every attack of rheumatic fever involves the concomitant diagnosis of potential or possible rheumatic heart disease. A definite diagnosis of rheumatic heart disease during the attack must be based on symptoms and signs of cardiac failure, pericarditis or definite cardiac enlargement under observation. Diastolic gallop rhythm, a diastolic murmur, distinct prolongation of the P-R interval in the electrocardiogram, disproportionate and protracted tachycardia are suggestive but not definite evidences of organic rheumatic cardiac disease. A *loud* systolic murmur with radiation to the axilla, which is constant despite exercise or changes in position or respiratory phase and which persists for more than six months after subsidence of the acute attack, also denotes organic heart disease. However, the variability and regression of physical signs in organic rheumatic heart disease in children have been stressed by several observers.[11, 127]

Rheumatic Fever in Adults

The entire problem of acute rheumatic fever in adults requires reevaluation. I have become more and more skeptical of the diagnosis of clinical active rheumatic fever in subjects beyond the age of 20, whether or not the patient has rheumatic cardiovalvular disease. The problem of active rheumatic fever in the adult arises chiefly under three sets of circumstances: (1) An adult with or without previous rheumatic valvular disease develops *polyarthritis* and usually fever and a rapid sedimentation rate. (2) An adult with rheumatic cardiovalvular disease develops *fever*. (3) An adult with rheumatic valvular disease who has been well compensated for years develops progressive *congestive heart failure* without apparent cause.

1. In the first circumstance, that of arthritis, the diagnosis almost always should be rheumatoid arthritis, infectious arthritis or some other disease associated with arthritis rather than rheumatic fever. Again we must emphasize that there is no specific diagnostic test for rheumatic fever. No matter what lists of diagnostic criteria we set up or what arithmetical value we give to each, the diagnosis of rheumatic fever is unproven clinically unless unequivocal rheumatic heart disease develops. Polyarthritis in adults may be attributed to rheumatic fever if it is associated with heart failure or pericarditis or if new organic murmurs develop and persist. Even then, exceptionally, the heart failure and pericarditis do not necessarily prove rheumatic fever. In my experience polyarthritis in adults is not followed by the development of mitral

stenosis or aortic insufficiency except in very rare instances Since rheumatic fever is important because of its eventual cardiac complications and since in children unequivocal rheumatic fever almost always causes rheumatic heart disease arthritis in adults which does not produce heart disease is best not termed rheumatic fever

This is closely related to the problem of rheumatic fever and rheumatoid arthritis Whatever the findings of pathologists, these *two are different clinical diseases* Rheumatic fever is important because of its almost invariable cardiovalvular damage It does not cause persistent or progressive deformity and disability of the extremities Rheumatoid arthritis is important because it frequently causes deformity and disability of the extremities, *clinically* it is extremely exceptional to observe the development of rheumatic heart disease with rheumatoid arthritis By these criteria the nonspecific forms of arthritis in adults are not instances of rheumatic fever but of rheumatoid arthritis

2 When a person with inactive rheumatic heart disease develops fever, there is a tendency to attribute it to rheumatic fever if there is no other apparent cause This is partly due to the established teaching that rheumatic fever is a continuing disease even throughout adult life as evidenced by the finding of Aschoff bodies in a high percentage of cases at autopsy[90] and more recently in biopsies of atrial appendages at operation (p 817) But it is becoming apparent that Aschoff bodies are not always evidence of active rheumatic fever in the clinical sense, since there is no good correlation between the presence or absence of Aschoff bodies and clinical evidence of rheumatic activity It may be that more detailed study of the life cycle of the Aschoff body and the histochemical attributes of different Aschoff bodies may distinguish those which are fresh or active from those which represent the healed stage (p 818)

In my experience the occurrence of unexplained persistent fever in the *adult* patient (beyond 25) with rheumatic heart disease is virtually never due to rheumatic fever but is usually due to bacterial endocarditis if there is no previously established heart failure In *adult* patients with rheumatic heart disease and previously established heart failure unexplained fever for more than a week or two is likewise not due to rheumatic activity, but to pulmonary emboli or patchy bronchopneumonia

3 Finally, the development of congestive heart failure without apparent precipitating cause in the previously compensated adult rheumatic cardiac, or the progression of congestive heart failure, is attributed to rheumatic activity in the heart although there are no other clinical manifestations of active rheumatic fever This likewise is based without systematic evidence of clinical pathologic correlation on the studies showing the frequency of Aschoff bodies in the hearts of adult rheumatic cardiac patients However, the more carefully the clinical history is taken or the more closely the patient is observed the more often the onset of heart failure will be found to be precipitated by a non rheumatic infection, by unusual physical activity, by excessive sodium intake, by pulmonary embolism by tachycardia, by the onset of atrial fibrillation or by associated hypertensive or coronary heart disease In many other cases the development or progression of heart failure is apparently due to the prolonged mechanical strain of a severe valvular lesion as indicated by localization of heart failure *retrograde to the chamber* under strain, and by the amelioration of heart failure by surgical relief of the valvular lesion That heart failure in the adult rheumatic cardiac, who has had a relatively long period of compensation after his childhood rheumatic fever, is frequently or to any large extent *due to recurrent* rheumatic activation is unproven *It is* even a harmful concept if used as a *basis of* treatment of the patient

THE PRESENCE OF RHEUMATIC HEART DISEASE *IN PATIENTS WITHOUT ACTIVE RHEUMATIC FEVER*

This is generally the problem encountered in adult patients who often appear *healthy* and are unaware of any cardiac disease The physician must determine whether or not there is organic heart disease, and if present whether such heart disease is of rheumatic etiology

The existence of cardiac disease is usually clear when there are definite symptoms of heart failure, or of pronounced cardiac enlargement In the absence of such symptoms and signs the diagnosis is dependent on physical and roentgen ray examination and

electrocardiography In rheumatic heart disease the diagnosis usually is based on recognition of the evidences of valvular heart disease (Chapters 26–29) These evidences include characteristic murmurs and distinctive forms of cardiac enlargement as visualized by roentgen ray

When the presence of organic heart disease has been determined its rheumatic etiology may be surmised if there is a definite history of rheumatic fever This assumption is especially probable if there is also a history of a cardiac murmur which persisted after the rheumatic attack However more than half of young adults with rheumatic heart disease present no history of rheumatic fever [64]

The character of the valvular lesion is often suggestive of the rheumatic etiology The combination of aortic insufficiency and mitral stenosis or mitral stenosis alone almost always denotes rheumatic cardiovalvular disease Aortic stenosis as a rule signifies rheumatic heart disease although occasionally it may represent a congenital aortic or subaortic stenosis or rarely it may be due to non rheumatic calcification Aortic insufficiency alone is usually rheumatic or syphilitic the differential diagnosis is discussed elsewhere (p 692) Organic systolic murmurs may represent rheumatic mitral valvular disease or aortic stenosis but must be differentiated from functional murmurs (p 647) and murmurs due to congenital cardiovascular lesions (p 794)

Sometimes a rheumatic mitral stenosis is first suggested by left atrial enlargement on fluoroscopic or roentgenographic examination by unexplained hemoptysis atrial fibrillation cerebral embolization or heart failure Similarly aortic insufficiency may be first suggested by the abnormal configuration of the heart or by abnormal circulatory dynamics associated with this lesion (p 690)

That the rheumatic heart disease which the physician has diagnosed is *inactive* depends on negative data particularly the exclusion of all of the symptoms presented under active rheumatic fever

DIFFERENTIAL DIAGNOSIS OF RHEUMATIC FEVER

Since the discovery of rheumatic heart disease often depends on the recognition of non cardiac evidences of rheumatic fever it is important to consider the differential diagnosis of the general disease as well as of the cardiac lesion Problems in the differential diagnosis of rheumatic fever arise when there are only general non specific symptoms of an obscure infection or when the local symptoms present are confined to a single organ system

1 *Subacute Bacterial Endocarditis* This offers one of the most frequent problems in differential diagnosis in adults with compensated rheumatic heart disease The patient is recognized as having rheumatic valvular heart disease, but the physician must decide whether the fever and other symptoms present are due to activation of a rheumatic infection or to a complicating subacute bacterial endocarditis or to both The differential diagnosis is discussed on pages 877–878

2 *Grippe ' nasopharyngitis or other infections of the respiratory tract* may be erroneously diagnosed as rheumatic fever or vice versa Following a mild upper respiratory infection in a child there may be persistent low grade fever and indefinite muscle or juxta articular pain These are insufficient to diagnose rheumatic fever even when the sedimentation rate is rapid However awareness of the possibility of rheumatic fever may lead to careful observation and eventual discovery of cardiac involvement, arthritis nodules or characteristic rheumatic dermatoses A so called grippe or pneumonia ' followed several months later by definite cardiovalvular disease may have to be reinterpreted as an attack of rheumatic fever

3 *Pulmonary tuberculosis* may be considered when the rheumatic child presents fever anorexia pallor and malnutrition Roentgenographic examination of the chest tuberculin tests and sputum examinations decide the problem I have several times observed a tuberculous arthritis in a child treated as rheumatic fever until expert roentgenologic examination of the joint suggested the correct diagnosis

4 *Rheumatoid Arthritis in Adults and Still s Disease in Children* Rheumatoid arthritis is distinguished essentially by the absence of cardiac involvement Electrocardiographic abnormalities which are the rule in rheumatic fever, are absent in rheumatoid arthritis In rheumatoid arthritis the small joints are more frequently and more severely affected They may assume a persistent fusiform or

spindle shaped appearance Deformity and ankylosis are common but may develop only in advanced stages The rapidly migrating character of the rheumatic polyarthritis is rarely observed in rheumatoid arthritis and salicylates do not produce as dramatic a relief of pain disappearance of swelling and effusion and restoration of normal temperature

Still s disease in children is differentiated by the presence of rheumatoid arthritis and by the association of diffuse adenopathy and splenomegaly

5 *Osteomyelitis* may simulate rheumatic fever because of pain near the end of an extremity and the presence of fever Careful localization of the pain and tenderness and later roentgenologic examination suggest the proper diagnosis

6 *Leukemia and Cooley s Anemia* I have seen cases of these diseases erroneously diagnosed as rheumatic fever because of the combination of joint pains, pallor and anemia, and a cardiac murmur Fever may also be present Roentgen ray examination discloses characteristic bony lesions and abnormal cells are found in the blood

7 *Sickle cell anemia* may likewise be characterized by joint pains, anemia abdominal pain and a cardiac murmur which may be diastolic Its differential diagnosis is discussed on page 1052

8 *Poliomyelitis* may be confused with rheumatic fever but meningeal signs spinal fluid abnormalities and paralyses characterize the former Pains in the muscles should be distinguished from the joint pains of rheumatic fever

9 *Schonlein's disease* (peliosis rheumatica) is characterized by joint pains but can be distinguished by extensive purpuric lesions near the joints and by the absence of cardiac or other features of rheumatic fever

10 *Scurvy* Pain and swelling may seem to be localized to the joints and may suggest rheumatic fever The disease occurs mostly during infancy at which time rheumatic fever is rare A history of dietary deficiency ecchymoses (especially at the lower end of the femur), swelling and sponginess of the gums, characteristic roentgen ray appearance of the bones and therapeutic response to vitamin C are features of scurvy

11 *Hemophilia* is associated with hemorrhage into the joints with consequent pain and swelling Blood clotting studies are necessary for diagnosis

12 *Congenital syphilis* may simulate rheumatic fever when there is pain and swelling near the joints due to epiphysitis A positive Wassermann test and distinctive roentgenologic findings in the bones are diagnostic By similar means it is possible to distinguish the rapidly developing usually painless joint swellings occurring in late congenital or acquired syphilis (Charcot joints)

13 *Disseminated lupus erythematosus* is often diagnosed as rheumatic fever because of the frequent combination of fever and arthralgias or arthritis at the onset and the occasional presence of a pericardial rub It is distinguished by the appearance of the characteristic butterfly rash on the face and bridge of the nose, by lesions on fingers and palms, by leukopenia and by L E cells in blood or marrow

14 *Gonococcemia and Gonorrheal Arthritis* The history of urethral discharge, the tendency to monarticular involvement and the absence of striking response to salicylates aid in distinguishing gonorrheal from rheumatic arthritis When gonococcemia occurs there may be chills and papulovesicular skin lesions Bacteriologic study of urethral and cervical smears and of the blood is usually diagnostic

15 *Chronic meningococcemia* (without meningitis) is characterized by arthralgias without inflammation, continued fever and by characteristic slightly tender, papulo-urticarial cutaneous lesions Several cases which I observed were confused with rheumatic fever because of the presence of arthralgias and a systolic murmur, and in one case a prolonged P-R interval (0 22 second) The meningococcus may be isolated from cutaneous lesions or from the blood stream but cultures should be observed for at least two weeks before they are discarded

16 *Undulant fever*, like the two preceding may be characterized by arthralgias and continued fever Positive blood culture or agglutination reaction and the history of contact with infected animals or the ingestion of unpasteurized milk or its products are diagnostic features

17 *Rat bite Fever (Haverhill Fever)* The rat-bite fever due to the Streptobacillus moniliformis is characterized by fever, polyarthritis and a morbilliform or petechial rash

(Haverhill fever) The diagnosis is made by culture of the causative organism from the blood stream

18 *Ileitis and ulcerative colitis* may simulate rheumatic fever since they are not infrequently characterized by arthralgias or arthritis fever and erythema nodosum while the diarrhea may be minimal and overlooked A careful history and sigmoidoscopic and roentgenologic examination of the intestinal tract disclose the true diagnosis

19 *Acute appendicitis* is occasionally diagnosed when abdominal symptoms are prominent in cases of rheumatic fever The difficulty of differentiation is avoided if a careful history and examination are undertaken

20 *Non rheumatic Forms of Cardiac Disease* The differential diagnosis is discussed in the chapters on valvular heart disease pericarditis and endocarditis

Among other conditions which occasionally simulate rheumatic fever are coccidioidomycosis and rarely actinomycosis [6]

PROGNOSIS OF RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

The prognosis of rheumatic fever will be considered under three headings (1) The acute attack of rheumatic fever (2) The probability and significance of recurrent rheumatic attacks and further cardiac damage (3) The course of chronic rheumatic heart disease

THE ACUTE ATTACK OF RHEUMATIC FEVER

Recovery [illegible] the rule in the first acute attack of rheumatic fever In a series of 20 000 reported cases Atwater[4] found a mortality of 1 7 per cent in the acute attack In the recent cooperative study there were [illegible] deaths among 500 children with acute rheumatic fever (1 2 per cent) [illegible] Death in acute rheumatic fever results from cardiac failure pericarditis pneumonia pulmonary embolization bacterial endocarditis and toxemia In more than 75 per cent of the cases active rheumatic disease is the basic cause of these fatal complications Hyperpyrexia has become a rare cause of death since the use of salicylates

Higher mortality rates occur in patients with *recurrent* acute attacks usually associated with carditis and cardiac failure than in those with their first attack The distinction between mortality in the initial acute attack and subsequent attacks [illegible] seen in the statistics of Hassler and Moller[44] Of 110 patients suffering their first attack of rheumatic disease is the basic cause of these fatal episode, whereas of the 35 in a recurrent acute attack 32 per cent died The latter group is small and the mortality rate unusually high but undoubtedly the seriousness of the disease and the fatality rate increase with new attacks

The *duration* of the initial or subsequent acute attacks is variable Mild cases may hardly reach the clinical horizon or may appear as a simple febrile respiratory infection with or without arthralgias disappearing in a week or two The more fully developed attack lasts three to twelve weeks This however merely represents the average period of obvious clinical manifestations A subclinical period of activity indicated by subfebrile temperature leukocytosis increased rate of sedimentation of red blood cells etc or recurrent exacerbations after brief quiescence may prolong the attack In a series of 54 cases studied by Bland[8] the average duration of active disease was eight months Persistent rheumatic activity or cardiac failure for longer than six months denotes a serious prognosis

Aside from those children who die in the acute attack an additional 10 to 20 per cent never really recover but are left with badly functioning hearts or run a subacute course with persistent rheumatic activity or frequent recurrences of activity at short intervals Such children remain invalids who spend the greater part of time in bed require repeated or constant hospitalization and die within two to six years usually before reaching adult life

Finally about 80 per cent of patients with rheumatic fever reach adult life Many of these have experienced mild attacks or the attack of rheumatic fever is overlooked and surmised later when rheumatic cardiovalvular disease is accidentally discovered About 65 per cent of children who have had rheumatic fever not only attain adult life but can lead relatively normal lives [illegible] either because they have no apparent cardiac disease or because the cardiac lesions are well compensated The remaining 15 per cent who reach adult life have limited cardiac reserve or definite congestive heart failure and form the bulk of cardiac patients seen in clinics and hospitals The exaggerated pessimism of statistical data on the prognosis of adult rheumatic heart dis

ease is largely due to excessive weighting by these unfavorable cases

THE PROBABILITY AND SIGNIFICANCE OF RECURRENT RHEUMATIC FEVER AND CARDIAC DAMAGE

Following recovery from the acute attack, the prognosis is dependent on (a) the probability of recurrences of rheumatic fever and (b) the cardiac damage caused by the first or subsequent attacks Both of these are closely related to the age at which the initial attack occurs When the initial attack appears before the age of 10, a recurrence is to be anticipated in 75 to 90 per cent of cases [9, 120] Thereafter the probability and number of recurrences diminish [11] and they become infrequent after the age of 20

According to Cohn and Lingg [22] *and this* has also been my experience recurrence is the rule before puberty and becomes strikingly less frequent thereafter Wilson and Lubschez,[120] as well as Ehlertsen,[33] stressed not only the age of onset as a determinant of subsequent rheumatic recurrence but also the interval of freedom following an acute attack Thus in children below the age of 14 there was an incidence of about 40 per cent of recurrence within one year after an attack of rheumatic fever as contrasted with a risk of recurrence of 11 per cent following one year of freedom Practically one may assume that recurrence is improbable when the first attack occurs after the age of 20 or if five or more years have elapsed since the last attack and the patient is past the age of 16 However, under the stress of military training, crowding and constant reexposure to new recruits rheumatic recur*rence was not uncommon in young adults who* had long been free of rheumatic activity The incidence of rheumatic recurrences is being sharply reduced by the prophylactic use of sulfonamides or antibiotics and the vigorous treatment of streptococcus A infections in rheumatic children (p 856)

The incidence of significant *cardiac damage* in the initial attack of rheumatic fever varies between 30 per cent and 80 per cent of cases according to the age at the initial infection Cardiac involvement is most probable when the first rheumatic attack occurs between the ages of 5 and 10 The probability of cardiac involvement diminishes as the age of initial infection increases and becomes particularly infrequent when the first attack of rheumatic fever occurs in adult life [28, 60] This may be due to error in the diagnosis of rheumatic fever in the adult (p 843)

The occurrence of *subcutaneous nodules* has usually been associated with concomitant carditis and therefore with an ominous prognosis [15] but Bland and Jones[10] observed a 37 per cent mortality among rheumatic children with subcutaneous nodules followed for twenty years as compared with a 63 per cent mortality among those who had had pericarditis *Rheumatic pericarditis* is serious both because of relatively high acute mortality and the probability of permanent cardiac damage In 135 cases of acute rheumatic pericarditis studied by Massie and Levine [70] there was an acute mortality of 16 per cent in an average period of 5 weeks, a further mortality of 30 per cent among *82 of these patients who were* followed for a subsequent average period of 6 4 years On the encouraging side was the remarkable finding that 36 per cent of those followed had no clinical evidence of organic heart disease Thomas et al [109] reported no mortality in 8 cases of dry pericarditis and 50 per cent mortality in 30 cases of rheumatic pericarditis with effusion A more serious outlook is indicated by the observations of Ash [4] who found that 75 per cent of 553 children with rheumatic pericarditis were dead after a follow up period of 9 6 years Other evidences of *carditis,* such as cardiac enlargement and diastolic gallop rhythm, but especially congestive heart failure are also associated with a very high acute mortality, or with a high incidence of severe and permanent organic heart disease

Chorea in itself does not denote an unfavor*able prognosis with respect to* the probability of cardiac involvement However, other rheumatic manifestations eventually develop in the majority of cases of chorea and the incidence of cardiac disease is determined by these other rheumatic features *Jones and* Bland,[66] in an analysis of 482 cases of chorea observed an incidence of only 3 per cent of heart disease among 134 patients with chorea alone while among 184 patients with chorea and other evidences of rheumatic fever, heart disease was discovered in 80 per cent *In a* subsequent twenty year follow up *of* 1000 cases of rheumatic fever there was only a 1[illegible] per cent mortality in that period[10] *among* patients who had had chorea with or without cardiac involvement

Considering the entire course of the disease, it is probable that 65 to 75 per cent of children who suffer from rheumatic fever develop clinical heart disease with their first or subsequent attacks [illegible] [illegible] [10] If electrocardiographic changes or slight cardiac enlargement associated with systolic murmurs are accepted as evidence of organic heart disease then at least 90 per cent of patients with rheumatic fever may be considered as developing rheumatic heart disease [113] The stricter the criteria for the initial diagnosis of rheumatic rever, the higher is the incidence of subsequent fheumatic heart disease

Of 1000 children and adolescents hospitalized for rheumatic fever and followed by Bland and Jones [10] 653 had had signs of rheumatic heart disease on recovery from the initial illness but after 20 years the signs of heart disease had disappeared in 103 (16 per cent) On the other hand of the remaining 347 patients who recovered from their initial illness without detectable heart disease at the time, 154 or 44 per cent had acquired signs of valvular heart disease in the period of follow up

THE COURSE OF CHRONIC RHEUMATIC HEART DISEASE

The outlook for the child with rheumatic heart disease is now regarded as less unfavorable than formerly In a study of 717 cases of rheumatic fever and heart disease Wilson[114] noted that 18 per cent had died within an average period of eight years after the onset of rheumatic fever Stroud, Bromer and associates,[105] in a similar study of 458 rheumatic children, found that more than 20 per cent were dead within ten years after the initial rheumatic attack and another 20 per cent were totally disabled, in a more recent ten year study from the same institution the mortality rate had fallen to 15 per cent [106] Martin[46] studied some 1400 children with inactive rheumatic heart disease over a twenty year period About 30 per cent were dead at the end of that period, 10 per cent having died after two years and 26 per cent after twelve years In a twenty year follow up of 1000 children and adolescents who were hospitalized for rheumatic fever between 1921 and 1931 Bland and Jones[10] found that 202 (20 2 per cent) had died after the first ten years and a cumulative total of 301 had died after twenty years Rheumatic fever and congestive heart failure accounted for 80 per cent of the fatalities and bacterial endocarditis for an additional 10 per cent All these studies disclose that the great majority of fatalities occur below the age of 20 and that 70 per cent of children contracting acute rheumatic fever survive to an average age of 35 to 40

The chief danger lies in the probability of acute recurrences with a concomitant increase in cardiac damage Each new attack brings with it its percentage of acute mortality of cardiac failure or of progressive cardiac damage Thus the difficulty of prognosis in childhood lies not only in evaluating the effect of existing cardiac damage on life expectancy but in predicting what further injury will be wrought by subsequent attacks

If the child shows evidence of *right heart failure* the prognosis is very poor, it is doubtful whether he will survive puberty The existence of persistent *atrial fibrillation* also warrants a serious prognosis in that it denotes extensive myocardial damage Atrial fibrillation in rheumatic cardiac children occurs in fatal cases and is usually a late development However, this must be distinguished from the adult cases of rheumatic heart disease in which atrial fibrillation may persist for fifteen years or longer

Signs of *persistent active rheumatic disease* in a child with rheumatic heart disease always call for a guarded prognosis This applies particularly to the cases in which there is prolonged active carditis On the other hand if there is no cardiac failure if the cardiac rhythm is normal and if all signs of active disease subside the prognosis as to the organic cardiac lesion is temporarily improved Practically it may be considered that the early prognosis is greatly improved when puberty is passed when there are no longer signs of active rheumatic disease and when five years or more have elapsed since the preceding attack When this period is continued into maturity and the cardiac lesions remain well compensated the prognosis becomes increasingly favorable Conscientious uninterrupted use of antibiotics to prevent and eradicate streptococcus A infections may greatly and favorably change the outlook

If rheumatic patients dying in childhood or up to the age of 20 are segregated in statistical studies from those who survive the age of 20, the much more favorable outlook for duration

of life in the latter is no longer obscured by the unfavorable statistics in the former

The problem confronting the pediatrician or cardiologist who must give a prognosis regarding a *child* with rheumatic heart disease is quite different from that confronting the physician who attends an *adult* rheumatic cardiac patient For the latter has already overcome the serious dangers which are associated with recurrent attacks or persistent rheumatic activity of childhood, and which are the very elements that make prognosis unfavorable in earlier life The very fact that these adult individual have come to maturity despite recurrent rheumatic attacks indicates that the functional and anatomic damage in these individuals was least serious If they come to maturity with well compensated rheumatic heart disease the outlook is quite favorable for many years

Of about 800 children and adolescents who survived at least ten years after their initial attack of rheumatic fever, approximately 700 (87 5 per cent) were still alive after an additional ten years [10] Of 644 patients studied by de Graff and Lingg[27] 46 lived for more than 30 years and some more than 40 years Longevity was also noted by Wilson and Lubschez[100] during thirty years of observation of 1042 children with rheumatic fever In a study of autopsies from a city home for the aged I found the average age of death from rheumatic heart disease to be 65 years [27] This is not an average figure for longevity in rheumatic heart disease, but indicates the possible outlook for some patients In a more recent clinical pathological study of 253 autopsies in cases of rheumatic heart disease,[69] there were 50 (19%) between the ages of 40 and 81 (average, 57 3)

CAUSES OF DEATH IN RHEUMATIC HEART DISEASE

In children with rheumatic heart disease death in the great majority of cases is due to active rheumatic disease with resulting pancarditis heart failure pneumonitis pulmonary infarction and toxemia

Among adults congestive heart failure is the commonest cause of death Bacterial endocarditis embolization pulmonary infarction and bronchopneumonia and atherosclerotic coronary occlusion with myocardial infarction are among the other causes of death

Sudden death is much less common than in cases of atherosclerotic coronary disease or cardiovascular syphilis Its most frequent occurrence is in patients with aortic stenosis Its advent in aortic insufficiency has been exaggerated owing to inadequate segregation of cases due to syphilis

THE TREATMENT OF RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

THE ACUTE ATTACK OF RHEUMATIC FEVER

1 Bed Rest

Absolute confinement to bed is a vital element of the treatment of the active stage of the disease This includes pleasant surroundings and facilities for diversion if possible A choice must be made between hospitalization and home care of the child [14] The actual facilities at home, the availability of nursing care, the ability of the mother to administer medication and other measures if a nurse is not available, and general economic and social factors contribute to this decision [38] Removal from home and parental attention may present psychic trauma On the other hand home care when there are siblings who are well and active has its disadvantages There is considerable disagreement as to the proper duration of bed rest It may be accepted as a general principle that this period should be at least as long as there is rheumatic activity (For signs and tests of rheumatic activity see p 842 See also discussion of steroid hormone therapy p 852)

2 Diet and Regimen

The principle of the *diet* is to maintain nutrition When there is moderate or high fever the diet must be limited to fluids only and these must be rich in calories Vitamins and minerals may have to be supplied in concentrated form

Because of evidence that the serum vitamin A and carotene levels are reduced in rheumatic fever, the administration of vitamin *A* has been recommended[112] during the acute and subacute stages Similarly vitamin *C* supplements have been suggested as desirable[14] Since most of the patients are growing children an adequate protein intake is essential As with other febrile diseases fluids should be forced (at least 2500 to 3000 cc daily) *It is* especially important in rheumatic fever when there is a large fluid loss through excessive perspiration In the presence of congestive heart failure an extremely low *sodium* diet should be given (p 239)

Cathartics or enemata may be necessary while the patient is in bed. Mild cathartics such as aromatic extract of cascara or milk of magnesia are usually satisfactory.

3 Drug Therapy

Salicylates. Stricker,[104] who first recognized the therapeutic value of salicylates in rheumatic fever, considered them to be a specific cure for the disease. Although their specificity is no longer accepted, prolonged usage has established their antipyretic and analgesic effects, their striking relief of joint pain and swelling, and their beneficial influence on the general well being of the rheumatic patient. These rapid and impressive therapeutic effects of salicylates are so characteristic that they have been considered diagnostically important. However, a similar response may occur in other febrile states and occasionally such improvement is lacking in definite cases of rheumatic fever.

Since Pribram's[83] observations it has been taught that salicylates do not reduce the duration of the active disease. More recent studies have also indicated that the duration of rheumatic activity and the hospital stay of salicylate treated and untreated patients did not differ significantly.[74] On the other hand, Illingworth et al[51] gained the impression that in a group of patients with rheumatic fever treated with salicylates, fewer children developed additional rheumatic manifestations such as subcutaneous nodules, fewer suffered recurrences of arthritis, apical diastolic murmurs or evidence of persistent cardiac involvement than the children in a control group of cases of rheumatic fever not treated with salicylates. The question is far from settled because of the varied duration of individual cases and because the statistics available are not uniform in their criteria for subsidence of activity.

It has long been taught that salicylates do not prevent cardiac complications and that pericarditis, heart failure, pleuropulmonary symptoms and subcutaneous nodules have frequently developed in rheumatic children under full salicylate dosage.[illegible] On the other hand, Coburn[72] has claimed that intensive therapy sufficient to maintain a continuous salicylate plasma level of at least 35 mg per 100 cc, instituted early in the acute phase of rheumatic fever, not only rapidly suppressed the disease but also reduced the incidence of polycyclic recurrences and residual chronic activity and prevented cardiac residua. These claims have been supported by Peters and by others[59, 87] and disclaimed by still others who have used Coburn's therapeutic regime.[3, 115]

Some recent experimental observations suggested that the therapeutic effect of salicylates depends on their stimulation of the adrenal cortex,[47] but this has been refuted on the basis of other studies.[99, 6]

Indication for Salicylates in Rheumatic Fever. In view of the effectiveness and in my opinion the superiority of prednisone and other adrenocortical hormones, the role of salicylates in the therapy of rheumatic fever is now uncertain. McEwen[73] advocated the administration of salicylates in rheumatic fever without evidence of carditis, but this policy runs the risk of delay in the use of the hormones, of which the chief advantage may lie in their ability to prevent permanent cardiac damage when administered early. Salicylates may be of benefit in preventing the "rebound" phenomenon if administered when the dose of cortisone-like hormones is being finally reduced and for two or three weeks after the hormones are discontinued. Finally, there may prove to be some advantage in the simultaneous use of salicylates and cortisone-like drugs throughout the treatment of acute rheumatic fever.[40]

Administration and Dosage of Salicylates. *Acetylsalicylic acid* is given in a dosage of 0.06 gm (1 grain) per pound of body weight daily in divided doses up to a maximum of 10 gm daily. I often start by administering 0.65 gm (10 grains) every four hours throughout the 24 hour period and increase the dose or frequency until the desired effect is obtained. If toxic symptoms appear, the dose is reduced. The dose which is effective and non-toxic is continued until there are no signs of clinical activity, the blood count and sedimentation rate are normal and (if this determination is available) the C-reactive protein is no longer present. Thereafter salicylates are gradually reduced and discontinued.

Sodium salicylate may be administered in slightly higher dosage.

Sodium bicarbonate is administered with salicylates either as half the dose of sodium salicylate or in equal doses with acetylsalicylic acid. The alkali serves to diminish gastric irritation caused by the salicylates. According to Peters,[3] the toxic effects of very large oral doses of salicylates can be prevented by the simultaneous administration of

twice the dosage of sodium bicarbonate in solution In patients with rheumatic carditis and congestive heart failure the possible danger of administering significant quantities of sodium must be taken into account

The *toxic manifestations* of salicylates[39] include tinnitus, deafness vertigo headache, nausea and vomiting, and occasionally diarrhea Although there is some direct gastric irritation the toxic gastrointestinal symptoms are due to salicylate action on cerebral centers More serious evidences of salicylate intoxication are dermatoses, excessive vomiting Kussmaul respiration due to acidosis, tetany due to hyperventilation, delirium, mania, hallucinations, coma and death[93, 43] Hyperventilation appears to be due to increased sensitivity of the respiratory center to carbon dioxide and hydrogen ion produced by salicylates[1] This results usually in *respiratory alkalosis*[108] *But respiratory acidosis* may develop when respiration is inadequate[105]

Severe dyspnea from excessive doses of salicylates has been attributed either to fixed acid acidosis or medullary respiratory stimulation[49]

Hypoprothrombinemia may occur temporarily after a few days of intensive salicylate therapy[81] but with possible rare exception, it is insufficient to produce hemorrhagic phenomena

Corticotropin (ACTH) and Adrenal Cortical Hormones *Effect in Rheumatic Fever* The early dramatic report of Hench et al[46] on the beneficial effects of cortisone in acute rheumatic fever has been confirmed by numerous observers[63, 73] similar results have been observed with corticotropin, hydrocortisone and prednisone (Meticorten)[82] Within 12 to 48 hours following adequate doses of these hormones the fever subsides, joint pains and swellings diminish markedly or are completely alleviated and general toxicity abates Favorable but inconstant influence of these steroids has been noted with respect to the clinical evolution and subsidence of erythema marginatum[65, 73] and rheumatic subcutaneous nodules[17, 11, 119, 91]

There is a general impression that subcutaneous nodules resolve more rapidly on cortisone therapy than they would otherwise Histologic studies of nodules studied before and after the administration of such hormone therapy have indicated a striking diminution in inflammatory cellular elements following the hormone,[81, 77] although there are similar discordant studies by others[15, 8] Considerable interest is attached to the effect of these hormones on the subcutaneous nodules because of the similarity of the proliferative as well as exudative inflammatory lesions in the nodules to the more important lesions in the heart

Relative Effectiveness of ACTH Cortisone and Salicylates Six centers in the United Kingdom, five in the United States and one in Canada collaborated in a well controlled trial of the relative merits of ACTH cortisone and aspirin in the treatment of 497 patients with acute rheumatic fever and in the prevention of rheumatic heart disease in children under the age of 16 One year after the completion of treatment they reported that with minor differences there was no essential superiority of *any one of these agents over the others* None of the three agents resulted in uniform termination of the disease and, with all three agents, some patients developed fresh manifestations during treatment Treatment with the hormones resulted in more prompt control of certain acute manifestations, such as subcutaneous nodules, but this was balanced by a greater tendency for acute manifestations to reappear for a limited period when the six weeks course of treatment was discontinued At the end of one year there was no significant difference in the three treatment groups with respect to the cardiac status

Despite these findings ACTH cortisone and related hormones appear to be definitely superior to salicylates in the treatment of rheumatic fever None of the agents was found superior to the others in the restricted dosage employed in the cooperative study, in the control of the acute manifestations of the *average case* of rheumatic fever The superiority of the hormones becomes readily apparent only in the severely ill patient with rheumatic pericarditis high fever and frequent concomitant carditis and heart failure *provided adequate doses are employed* Pericarditis was present in 10 per cent of the cases in the United States 5 per cent of those in the United Kingdom The dosage of hormones in the United States cases was distinctly below optimal for pericarditis and even lower in the United Kingdom where more of the cases of pericarditis were treated

Similarly, heart failure occurred in about 10 per cent of the cases presumably essentially the same as with pericarditis Furthermore by chance there were about half as many cases with heart failure and pericarditis treated by aspirin as by ACTH and cortisone These data are mentioned to indicate that there were relatively few very severe cases which would test the advantage of hormones over salicylates and the minority of these were subjected to salicylate therapy In summary the comparative study could not demonstrate superiority of the hormones over salicylates because (1) suboptimal doses of the hormones were used especially for severe cases (2) therapy was discontinued too soon, (3) too few very severe cases of pericarditis and heart failure were treated

Effect of ACTH and Cortisone in Preventing Cardiac Damage Whereas the therapeutic efficacy of cortisone and corticotropin with respect to the acute inflammatory manifestations of rheumatic fever appears established, there is still uncertainty as to their possible benefit in preventing permanent cardiac damage as denoted by chronic valvular disease and cardiac enlargement Obviously patients suffering from their first attack of rheumatic fever, i e without previous cardiac disease are most suitable for evaluating such possible benefit of cortisone and corticotropin In the series of cases of Roy et al only 2 (6 5 per cent) of 31 patients treated within 7 days of their initial attack of rheumatic fever were left with significant murmurs whereas there were persistent murmurs in 17 (49 per cent) of 35 patients first treated between the eighth and fourteenth days in 22 (66 per cent) of 33 patients first treated between 2 and 4 weeks after onset in 15 (75 per cent) of 20 patients first treated between the fourth and sixth week, and in 36 (90 per cent) of 40 patients first treated after the sixth week In the same review of reported cases there is evidence that a reduction or disappearance of cardiac enlargement is most apt to occur the earlier hormone treatment is begun Other studies suggest that permanent myocardial damage is most likely to be prevented with *very high dosage* as well as *early administration* of these hormones [73, 45, 31, 40, 65, 78] Most studies thus far reported do not concern large enough groups of cases in which these treatment criteria are satisfied but the results are promising in regard to the possibility of avoiding chronic cardiac disease On the other hand, Harris et al [4] in a controlled study of 100 cases of rheumatic fever found no evidence that ACTH or cortisone favorably influenced cardiac manifestations regardless of the dosage or time of beginning treatment To counter this is the report of Wilson and Lim[1] showing a remarkable reduction in residual cardiac damage and an abbreviation in the duration of active carditis in patients treated with adrenocortical hormones for only seven days

Treatment Schedule Prompt hormone treatment is essential Prednisone (Meticorten) or prednisolone is administered in a minimal daily dose of 60 mg (20 mg or four tablets every eight hours) orally If necessary this dose is increased until a satisfactory response is attained Occasionally in very ill patients 100 mg of corticotropin is administered daily in a slow intravenous drip of 5 per cent glucose in distilled water for several days if necessary to obtain the desired clinical response If oral medication cannot be taken and intravenous corticotropin is not essential hydrocortisone can be given intravenously or intramuscularly in daily doses of 300 mg Oral medication is begun as soon as it is tolerated The daily dose of prednisone (60 mg in divided doses) is continued for four weeks provided the clinical course is satisfactory with respect to fever arthritis and laboratory findings Thereafter the dose may be diminished by 2 5 mg or one half tablet daily, but the previous effective dosage is resumed if symptoms and signs recur I prefer a schedule in which the dosage is reduced by 15 mg or three tablets daily at five-day intervals because the effect of a diminished dosage is often apparent only after this period

Clinical progress and activity of the disease are measured by the control of clinical features and determination of the erythrocyte sedimentation time and if available by the C reactive protein These laboratory tests usually do not return to normal for two to four weeks It is uncertain whether their return to normal is due entirely to suppression of rheumatic inflammation or to the effect of the hormones on the plasma proteins which influence these laboratory tests However, neither subsidence of clinical manifestations nor the disappearance of leukocytosis and C reactive protein and return to normal sedi

mentation rate denote that the basic rheumatic disease is inactive so long as the hormones are being administered

As a rule, the hormones are discontinued after eight to twelve weeks of treatment provided there are no clinical or laboratory signs of activity If the drugs are omitted too soon, e g , after only a week or two following suppression of the clinical picture and laboratory signs there is usually a reappearance of the florid manifestations of active rheumatic fever until treatment is resumed This represents a relapse or recrudescence of rheumatic fever On the other hand if treatment is discontinued after six to eight weeks or more of suppression of the disease mild fever, increased sedimentation rate and a positive test for C-reactive protein may reappear, persist only two or three days and disappear spontaneously. The latter occurrence has been termed a "rebound" phenomenon and has been interpreted as the response to mild residual rheumatic activity which becomes apparent when exogenous hormone has been discontinued and the patient's own inhibited adrenal cortex has not yet resumed its normal activity A similar rebound has been reported after discontinuation of salicylate treatment of rheumatic fever[35] In practice, the reappearance of rheumatic phenomena after at least six weeks of suppression by adequate dosage of the hormone should be regarded as a "rebound" and hormone should be withheld for at least five days unless the clinical features are severe Increasing severity and persistence of manifestations beyond that interval would denote an actual relapse and the need for resuming hormone therapy The administration of salicylates together with the hormones when the dosage of the latter is being diminished and continued salicylate therapy for two or three weeks after discontinuation of cortisone or related drugs may avert the rebound phenomenon Any frank relapse following suppressive therapy with salicylates or steroid hormones usually occurs within a week or two and virtually always within two months after discontinuing therapy[10] Thereafter the reappearance of rheumatic fever is associated with immunologic evidence of a new streptococcal infection[102] and therefore indicates a recurrent attack of rheumatic fever rather than a relapse

When ACTH, cortisone or hydrocortisone is administered in high dosage, sodium intake should be restricted to 50 to 200 mg daily A more liberal sodium allowance or no sodium restriction may be permissible when prednisone (Meticorten) is employed, provided there is no evidence of heart failure Evidence of sodium water retention or congestive heart failure should be combated by digitalization a low sodium intake and injections of mercurial diuretics To counteract possible potassium depletion due to the hormone especially when the latter is given in combination with mercurial diuretic therapy, enteric coated tablets of potassium chloride 1 gm two or three times daily, or 1 teaspoonful of potassium triplex (Lilly) may be given three times daily In addition antibiotic therapy should be administered at the onset for ten days to eradicate any living group A streptococci in the upper respiratory tract and thereafter continuous administration of prophylactic doses of sulfadiazine or penicillin should be undertaken (p 857), at the same time that hormone treatment is administered

Toxic or side effects of cortisone and related hormones include moon face weight gain with abnormally located fat deposits acneiform eruption hirsutism, and, with some of the hormones sodium water retention Less common effects include glycosuria, pigmentation striae, enlargement of the liver (fatty liver) peptic ulcer, and psychiatric complications As a rule all these manifestations except occasionally the psychiatric disappear when the hormone is discontinued However, Smith and Good[93] reported an alarmingly high incidence of important side actions in 11 children with rheumatic fever treated for a long time with high doses of prednisone (up to 100 mg per square meter body surface area per day for 40 to 171 days) Osteoporosis and compression fractures occurred in 3 In 9 patients there were marked and prolonged 'rebound phenomena ' In 5 of these there occurred a peculiar syndrome lasting 4 to 14 days characterized by intense pruritus and painful cutaneous lesions like erythema nodosum Two children developed panniculitis Two developed congestive heart failure without other clinical evidence of rheumatic fever, 9 to 60 days after cessation of prednisone therapy In one fatal case perivascular inflammation fibrinoid occlusion of multiple venules and subcutaneous fat necrosis, but no evidence

of active rheumatic carditis was found at autopsy

Aminopyrine Aminopyrine is quite effective in rapidly reducing fever and relieving the joint symptoms of rheumatic fever It possesses the advantages of producing neither the local gastric irritation nor the toxic effects of salicylates and does not require the simultaneous administration of sodium bicarbonate but there is danger of agranulocytosis in sensitive persons

The dose of aminopyrine is about one third that of the salicylates In *adults* 2 to 3 gm daily may be given in divided doses at four hour intervals in children 1 5 to 2 gm daily [96]

Digitalis is indicated and effective in the treatment of acute rheumatic fever when there is associated heart failure with or without atrial fibrillation Its administration in children is discussed on page 261 Sutton and Wyckoff[107] have reported beneficial effects in children with right sided congestive heart failure active rheumatic infection and normal sinus rhythm similar favorable results with digitalis were obtained by Walsh and Sprague[111] and Nadas and associates [80] Often the therapeutic effects are not striking or are absent and the rapid heart rate is unmodified because of the activity of a severe rheumatic disease Furthermore for the same reason there is a tendency to increase the dose of digitalis to dangerous levels, there are frequent instances of digitalis toxicity including the production of premature beats heart block atrial fibrillation ventricular tachycardia or even fibrillation

Mercurial diuretics should be administered when heart failure is present as discussed in Chapter 11 The usual dose in children is 0 5 to 1 cc

Oxygen therapy is indicated in the presence of severe respiratory distress or cyanosis due to pulmonary infarction or pneumonitis or to heart failure with pulmonary congestion or pulmonary edema

Morphine is rarely indicated and should be administered with caution It is occasionally desirable for the intense dyspnea of acute pulmonary edema or for very severe pain at the onset of rheumatic fever before salicylates or hormones become effective Codeine may be needed to control precordial pain or cough Sedatives or soporifics are frequently beneficial during the most acute phases of the disease

Antibiotics Sulfonamides and Penicillin (see Prophylaxis p 856)

CONVALESCENCE AND REHABILITATION

Convalescent Homes and Sanatoria

Convalescence does not properly begin until all signs of rheumatic activity have disappeared Discharge from a hospital ward to make room for more acutely ill patients does not necessarily denote that the rheumatic patient is ready for convalescence Neither does removal to a convalescent home label the patient as convalescent if he still shows active rheumatic disease So long as there is activity the patient is properly a bed patient

In cognizance of the problems of the rheumatic child organizations in this country and in England have undertaken to care for convalescent cardiacs in special convalescent homes or hospitals In such institutions there are not only the advantages of continued and prolonged medical and nursing care for the patient but also opportunities for controlled study of the disease for research for prophylactic treatment and for the early discovery and treatment of rheumatic reactivations In addition the patient receives instruction in the rules of hygiene the psychologic advantages of group play and exercise schooling and occupational therapy during the intermediate period between active illness and the resumption of a relatively normal life

Resumption of Physical Activity

Physical activity may be resumed during convalescence but it should be increased more gradually than after other febrile diseases As a rule physical activity is not undertaken until there has been a two week period during which in the absence of suppressive drugs *there is no fever carditis arthritis or other* clinical or laboratory evidence of rheumatic activity On the other hand these strict criteria may necessitate such prolonged bed rest that cardiac anxiety neuroses are induced

Ordinarily the rate of progress of physical activity is determined in part by the presence and extent of cardiac damage and especially by the clinical response of the patient to increasing activity Various exercise tests have been employed to gauge progress and as a guide to the degree of activity permissible With the aid of a step-test Karpovich and associates[55] devised a program of physical reconditioning for soldiers convalescing from rheumatic fever Graded exercises were given

according to the response to the exercise test. They were able to begin these exercises safely within two weeks after clinical cessation of rheumatic activity and to reduce the conventional delay in beginning reconditioning from an average of 77 to an average of 16 days without any increase in cardiac damage.

TREATMENT OF THE CHRONIC INACTIVE STAGE OF RHEUMATIC HEART DISEASE

Essentially this involves the management of patients with rheumatic valvular heart disease (Chapters 26 to 29). When atrial fibrillation, heart failure or bacterial endocarditis develops, treatment follows the principles set down elsewhere under those headings. Aside from these and other complications the *patient with inactive rheumatic cardiovalvular* disease may rarely seek medical attention, and then only for some unrelated condition. Treatment during this period consists of instruction in hygienic living, avoidance of streptococcal and other infections, advice as to sociologic and economic problems, and, not the least, optimistic encouragement.

Exercise

When the stage of convalescence is passed and circulatory compensation is attained, the problem of exercise is not formidable. Restriction of physical exertion, formerly stressed as a vital point in the treatment of inactive heart disease, does not appear warranted when there is satisfactory compensation. For some time after an acute attack, a moderate degree of dyspnea, tachycardia and palpitation may result purely from prolonged bed rest and lack of physical training, independent of cardiac disease. Prolonged overprotection from physical exercise, even after rheumatic activity has ceased, serves only to protract the abnormal symptoms produced by even slight exertion. Except for the most rigorous sports involving unusual speed and endurance, such as rowing, long distance running, tennis, I do not believe it important or wise to restrict the well compensated inactive rheumatic cardiac patient. A moderate degree of consistent physical activity is of advantage in bringing about the efficiency of circulatory, respiratory and metabolic economies which result from training and which would appear to be of special value to the cardiac patient. So long as there are no evidences of circulatory failure, moderate exercise is of as much value to the rheumatic cardiac as to the normal person. The degree and amount of exercise permitted depends on the individual's symptomatic response, undue fatigue and dyspnea being the stop signals.

Prophylaxis

Antibiotic Treatment of Group A Streptococcus Pharyngitis.[84,85,51,21,13] Active antibiotic treatment of Group A streptococcus infections and prevention of such streptococcal infections with the aid of antibacterial agents have recently become the most aggressively employed measures in the prophylaxis of rheumatic fever. Such treatment is based on the current widespread belief that the Group A streptococcus is the inciting agent in the initial attack of rheumatic fever and its recurrent activations.

It is strongly urged that all attacks of Group A streptococcal infection of the upper respiratory tract in children be vigorously treated with antibiotics which are capable of completely eradicating the streptococci. Routine throat cultures are impracticable but the diagnosis can often be made on such clinical criteria as sudden onset of fever, soreness of throat, especially on swallowing, intense redness of the pharyngeal mucosa and pharyngeal exudate, and cervical lymphadenitis. In one series, an accurate diagnosis of streptococcal sore throat was attained in 70 per cent by clinical criteria alone.[1] Antibiotic therapy for streptococcal sore throat should be given at least to all children between the ages of 4 and 14, and up to the age of 21 in those who have had a previous attack of rheumatic fever.

Treatment should begin as early as possible, preferably within 48 hours, and continued for ten days; however, there is evidence that rheumatic fever may be prevented by such treatment even when administered as late as the ninth day after the onset of the streptococcal infection.[20]

Penicillin, chlortetracycline (Aureomycin), oxytetracycline (Terramycin), tetracycline (Achromycin) and erythromycin are equally beneficial in their clinical effect on acute streptococcal sore throat. But for the prevention of rheumatic fever the streptococci must be actually eliminated. This is accomplished by penicillin and probably by erythromycin, but less certainly or consistently by the other antibiotics. Studies of the efficacy of various antibiotics in the actual prevention of rheumatic fever showed that penicillin reduced

attacks of rheumatic fever by 91 per cent[114] chlortetracycline by 74 per cent[82] and oxytetracycline by 66 per cent[11] but the differences may be due in part to differences in relative dosage and duration of drug administration Other studies have shown that adequate penicillin treatment of hemolytic streptococcal sore throat has reduced the incidence of clinically overt rheumatic fever by 95 per cent or more[29 31]

Penicillin may be administered as a single intramuscular injection of *600 000 units of benzathine penicillin (Bicillin)* in children or 900 000 in young adults Adequate penicillin levels are maintained for the desired period[114 11 31] Or *300 000 units of aqueous procaine penicillin* may be given daily intramuscularly for ten days or procaine penicillin with aluminum monostearate in oil 300 000 every third day for 3 doses in children, or 600 000 every third day for 3 doses in young adults Or *400 000 units of buffered penicillin* may be given orally twice daily for ten days Oral doses of 500 000 to 1 million units of penicillin daily have been found effective in the care of streptococcal pharyngitis and in eradicating the carrier state by several groups of investigators[82 113] Chlortetracycline oxytetracycline tetracycline or erythromycin[4] 2 gm daily in divided dosage should be reserved only for those who are hypersensitive to penicillin until its consistent bactericidal effectiveness is established Sulfonamides are unsatisfactory since they are bacteriostatic and they do not completely eradicate the hemolytic streptococci

Antibacterial Prophylaxis against Group A Streptococcal Sore Throat[84 88 100] Continuous maintenance of antistreptococcal prophylaxis has been effected by the use of the sulfonamides oral penicillin or long acting penicillin (benzathine penicillin) in patients known to have rheumatic fever Prophylactic antibacterial therapy should be maintained for a period of five years after the last attack of rheumatic fever or preferably prophylaxis should be maintained to the age of 25 Studies of bacterial throat flora during chemoprophylaxis of rheumatic fever have thus far shown no evidence of danger of secondary bacterial or fungal complications[75]

Sulfonamide Prophylaxis Sulfonamides have been found to diminish sharply the occurrence of streptococcal infections including scarlet fever[116] and to reduce the incidence of rheumatic fever recurrence by 80 to 90 per cent[89] The sulfonamides possess the advantage of easy administration good absorption and inexpensiveness Toxicity including fever nausea vomiting dermatoses and leukopenia (rarely agranulocytosis) occurred relatively frequently after sulfanilamide but much less commonly since the use of sulfadiazine or Gantrisin[16 89] Sulfonamide resistant strains have developed and caused outbreaks of pharyngitis as a result of mass prophylaxis in military establishments but this is rare and may be controlled by shifting to other antibiotics Finally the sulfonamides are bacteriostatic and merely suppress hemolytic streptococcal infections Unless sulfonamide prophylaxis is continuous throughout the year, there is a rapid reappearance of hemolytic streptococci in the pharynx or nasopharynx when sulfonamides are discontinued If a hemolytic streptococcal infection has occurred the streptococci should first be eradicated with penicillin before sulfonamide prophylaxis is initiated

Sulfadiazine or Gantrisin is administered orally in a daily dose of 0 5 gm for those below 60 lbs and 1 gm daily for those above that weight[16] It is given throughout the year Continuous therapy is more likely to be carried out conscientiously if the daily dose is given as a single dose each morning

Penicillin Prophylaxis *Oral Penicillin* Oral buffered penicillin, 200 000 to 250 000 units is given once daily preferably before breakfast It has been shown that once hemolytic streptococci have been eliminated from the throat by larger doses of penicillin prophylaxis against streptococcal infection and consequent rheumatic recurrences can be effectively carried out by small continuous doses of oral penicillin[48 47 122 7]

Toxic reactions are very uncommon (0 5 to 2 per cent[7 113]) and usually mild There may be urticaria angioneurotic edema and rarely a reaction similar to serum sickness The disadvantages of oral penicillin prophylaxis include uncertain absorption of the penicillin its costliness and the difficulty of maintaining uninterrupted prophylaxis[100]

Repository Penicillin A single intramuscular injection of 1 200 000 units of benzathine penicillin (N N -dibenzylethylenediamine dipenicillin G) is capable of eradicating hemolytic streptococci from carriers and when repeated once every four weeks prevents

recurrences of Group A streptococcal pharyngitis and of rheumatic fever [30, 103, 72, 77] The choice between oral penicillin and benzathine penicillin intramuscularly will depend on personal preference as between daily continuous oral medication and monthly injections their relative costs and especially on the routine which is most likely to be followed conscientiously

In summary any attack of Group A streptococcal pharyngitis in rheumatic individuals should be treated with 400,000 units of oral penicillin two times daily for 10 days or with one intramuscular injection of 600 000 to 1 200,000 units of benzathine penicillin (Bicillin) Prevention of further streptococcal infections in the individual with previous rheumatic fever or rheumatic heart disease should be undertaken by administering 0 5 to 1 gm of sulfadiazine or Gantrisin daily, 250 000 units of oral penicillin or oral benzathine penicillin daily or 1 200,000 units of benzathine intramuscularly once a month until the age of 25, or for at least five years after the last attack of rheumatic fever

Psychotherapy

Few things are more terrifying than the sense of impending doom which comes to an individual when he learns that he is suffering from heart disease But experience with other chronic illnesses beginning in youth, such as diabetes and tuberculosis has demonstrated the advantages of teaching patients to understand their illness and of enlisting their valuable cooperation Cooperation of the parents, physician psychiatrist and social worker is often necessary to aid the child in adjusting to his physical incapacity during his illness, to the frequent need to be in a hospital away from home, to the prolonged limitation of activity during convalescence and possible restrictions thereafter, and to the threat of a permanent handicap and a shortened life [57, 8]

Whenever the patient appears either for follow-up examination or for incidental extracardiac complaints so long as the heart is functioning satisfactorily, the physician should not overlook these opportunities for commenting on how well the heart is behaving Such encouragement is of prodigious value to the patient s mental outlook, while failure to comment may leave him with a sense of prolonged depression and with neurotic symptoms Only occasionally one encounters a patient who is in no danger of a neurosis but who must be struck with the fear of imminent death in order to obtain the mildest degree of cooperation

The well compensated rheumatic cardiac may suffer from a variety of symptoms particularly aches and pains and abdominal distress which are really of a functional nature but which he fears may be related to his cardiac disease Reassurance as to his cardiac status and discovery of the basis of the symptoms generally lead to their control

Advice on Occupation, Marriage Pregnancy and Childbirth

The rheumatic cardiac usually reaches the chronic inactive stage of his disease at an early age Thus he often expects from his physician advice as to the choice of a suitable occupation and as to marriage Married women patients want to know the dangers of pregnancy and childbirth Unfortunately the choice of an occupation is not a free one but is conditioned by social and economic factors, and by chance as well as by ability and opportunity for training To the extent that choice is possible the occupation chosen should permit control of hours of work and working conditions This usually means self employment either as a business proprietor or in some profession When employed by others the work should not entail long or irregular hours severe physical or mental stress, or exposure to dampness drafts extremes or sudden changes of temperature or undue crowding The education and cooperation of employers in the most efficient use of rheumatic cardiacs should be helpful The establishment of work classification units has been of great value in rehabilitating the rheumatic as well as other cardiac patients with respect to restoring them to the most suitable gainful employment [21a, 8a]

The patient s question as to the advisability of marriage is usually a rhetorical one Generally the patient comes for advice when marriage is already pending and then he comes only for acquiescence in his decision The physician s task can only be to evaluate the patient's cardiovascular status and to inform him as to the probable outlook in terms of that status and available limited knowledge of prognosis

Pregnancy and *childbirth* are discussed in Chapter 47

THE TREATMENT OF CHOREA

This is essentially a problem in *nursing care*. It is important to maintain nutrition, avoid overstrain and injury, assure cleanliness of the mouth and skin and obtain as much mental and physical comfort as possible. Rest in a bed with sideboards is obligatory if there is marked loss of motor control. The sideboards as well as the head and foot supports should be well padded. Special attention to the patient's needs for defecation or urination is necessary, especially if the child cannot make his desires known because of speech disturbance. The nurse will look for sores, injuries, toothache, etc., which the patient cannot reveal by speech and which may serve to exaggerate his mental and emotional irritability. Patience and encouraging assistance are invaluable in feeding the child if the all important nutrition is to be maintained. When this is too difficult or too trying for the patient, it is wise to resort to nasal feeding.

Sedatives are useful to reduce exaggerated activity in the daytime and to obtain sleep at night.

Salicylates are often employed but are not indicated unless there is fever or arthritis. The effect of adrenal cortical hormones is not yet established but they have appeared to be beneficial in a number of cases and are worthy of trial. After many years of use of Nirvanol and/or artificial pyrexia the value of these therapeutic agents remains unproven.

Chapter 34

BACTERIAL ENDOCARDITIS

Bacterial endocarditis is a disease due to bacterial infection of the valvular and mural endocardium The causative organisms can usually be demonstrated during life by blood cultures, and post mortem by spreads of the endocardial vegetations The clinical picture is that of a general infection (septicemia) with endocardial embolic and local vascular symptoms of variable prominence Detailed descriptions may be found in the publications of Osler [145] Schottmuller [173] Libman [118] Blumer [11] Thayer [184] Perry [150] Libman and Friedberg [122] and Kerr[109]

Bacterial endocarditis is a frequent and important cardiac ailment ranking in incidence next to coronary hypertensive and rheumatic heart disease In many localities it is encountered much more frequently than cardiovascular syphilis Its frequency in various localities depends on the frequency of rheumatic heart disease of which it is usually a complication Bacterial endocarditis was reported to develop in about 10 to 25 per cent of the cases of rheumatic heart disease [22] [89] In the series of 1000 patients with rheumatic heart disease followed by Bland and Jones,[10] 10 per cent of 202 fatalities were due to bacterial endocarditis

Bacterial endocarditis was formerly subdivided into acute and subacute bacterial endocarditis of which the latter was much more common In general the cases were considered to be acute if their duration was less than six weeks and subacute if longer than that period This division is not a sharp one because the time of onset is usually difficult to establish and because there is considerable overlapping in the clinical bacteriologic and pathologic features of the two forms On the other hand this classification was not entirely arbitrary because the acute and subacute cases are generally due to distinctly different organisms Occasionally organisms usually associated with the acute disease produce a subacute bacterial endocarditis and those generally associated with the latter may produce an acute bacterial endocarditis The acute and subacute forms usually present distinct pathologic and clinical differences which justify their separation In general in subacute bacterial endocarditis the original focus is uncertain or practically asymptomatic and the clinical picture is due essentially to the endocardial lesions and their complications In acute bacterial endocarditis the endocardial infection is often secondary to a gross apparent focus (often of a surgical nature) or to some other primary disease with bacteremia, and the clinical picture of the endocarditis is dominated and obscured by the initial focus and the bacteremia As early diagnosis and effective treatment have become more widespread the distinction between acute and subacute bacterial endocarditis is becoming academic Nomenclature should be based on the etiologic agent e g Streptococcus viridans endocarditis gonococcal endocarditis, and so on

ETIOLOGY

CAUSATIVE ORGANISMS

Bacterial endocarditis is due, in about 95 per cent of cases, to (1) the Streptococcus viridans (salivarius mitis), (2) the Streptococcus fecalis (enterococcus) or (3) the Micrococcus (Staphylococcus aureus or albus)

Non Hemolytic Streptococci Streptococcus Viridans

Streptococci are classified according to their effects on blood agar plates [176] The streptococci producing colonies surrounded by a clear zone of hemolysis are termed hemolytic or beta streptococci They are virtually identical with Group A or D streptococci according to the classification of Lancefield [114] They correspond to the long-chained Streptococcus pyogenes of former terminologies, which may

cause an acute bacterial endocarditis but very rarely the subacute form Streptococci forming colonies without a sharp clear zone of hemolysis are termed non hemolytic streptococci and subdivided into *Streptococcus viridans or alpha* if the colony is surrounded by a zone of greenish discoloration with or without partial hemolysis, and *Streptococcus anhemolyticus or gamma* if there is neither greenish discoloration nor hemolysis around the colonies on blood agar plates

Varieties of Non hemolytic Streptococci Of the non hemolytic streptococci responsible for subacute bacterial endocarditis, the Streptococcus viridans causes most cases but gamma streptococci (sometimes called indifferent streptococci) may also cause the disease The Streptococcus viridans (alpha) is the organism frequently found in the oral cavity and was therefore formerly termed the Streptococcus salivarius Another organism of the oral cavity termed Streptococcus mitis is also a Streptococcus viridans Loewe Plummer and associates[128] segregated a special non hemolytic streptococcus which they termed Streptococcus s b e and which was responsible for 40 out of 115 consecutive case of subacute bacterial endocarditis This organism produced greening on blood agar in 24 hours hydrolyzed arginine in 48 hours, fermented inulin in a week and did not produce large mucoid colonies on sucrose agar

The non hemolytic streptococci are characterized by a low degree of virulence in contrast with the microorganisms usually responsible for acute bacterial endocarditis The former are generally common saprophytic inhabitants of the mouth, upper respiratory and gastro intestinal tract and possess a low pathogenicity for laboratory animals The usual habitat of the Streptococcus viridans in the naso pharynx and oropharynx, and often in infected tonsils and apices of infected teeth, suggests that most of the cases of subacute bacterial endocarditis result following accidental passage of this organism from the oral or pharyngeal cavity into the blood stream

Streptococcus Fecalis (Enterococcus) (p 875)

A special group of non hemolytic streptococci which are responsible for bacterial endocarditis with increasing frequency are the enterococci These are usually of the gamma type of streptococcus, and because they are commonly found in the intestinal tract are often called Streptococcus fecalis Streptococcus liquefaciens, Streptococcus durans and Streptococcus zymogenes are other species of enterococci The enterococci have been characterized by their heat resistance (60° for thirty minutes), by their fermentation of esculin which is turned black, and by their growth in the presence of 6 5 per cent sodium chloride They usually appear in pairs of ovoid cocci, or occasionally in short chains Unlike the Streptococcus viridans, the enterococcus ferments mannitol The enterococcus is of special interest because it is often much more resistant to penicillin than the Streptococcus viridans When classified serologically according to typo-specific carbohydrate antigenic substance the enterococci are found to fall in the Group D streptococci of Lancefield[1?] *On the other hand, the alpha streptococci* (viridans) fall into a number of species of types, some of which belong to Group D

Staphylococci (Micrococci)

Concomitant with the increase in resistant strains of staphylococci (micrococci)[178] more and more cases of staphylococcus endocarditis are being encountered Staphylococci have been reported as the cause of bacterial endocarditis in 2 to 28 per cent of reported series of cases (p 875) In my experience they account now for at least 10 per cent of cases, but the actual incidence may be less because a disproportionate number of patients with endocarditis due to staphylococci are apt to be seen by a consultant or in a teaching hospital

Other Causative Organisms

About 5 per cent of the clinical cases of bacterial endocarditis are due to a great variety of microorganisms other than the Streptococcus viridans, Streptococcus fecalis or micrococci[181]

One group is composed of the *virulent, so-called pyogenic organisms* which tend to cause distinctive lesions and either an acute or subacute clinical course These organisms include the hemolytic streptococci (Lancefield's group A) pneumococci, Neisseria gonorrhoeae,[134] N meningitidis,[51] E coli[56] Aerobacter aerogenes, [183] B proteus Salmonella organisms[193, 181] the *paracolon bacillus*[?] Gaffkya tetragena[13] *Pseu*domonas aeruginosa (B pyocyaneus)[137] *Kleb*siella pneumoniae (Friedlander's bacillus), pi rilla and B anthracis The causative staph ylococci streptococci A or pneumococci are usually aerobic but may be anaerobic[1?] The several varieties of organisms responsible for brucellosis (undulant fever), i e, Brucella

abortus melitensis and suis may also cause subacute or occasionally acute bacterial endocarditis [60] [illegible]

Another group of causative organisms are common *saprophytic inhabitants* of the human body but which by chance invade the blood stream and may produce bacterial endocarditis if they find conditions favorable for localization and growth on the cardiac valves These organisms include the *Hemophilus influenzae*[163] and parainfluenzae[31] the gram negative *Neisseria pharyngis group*[97] (N pharyngis sicca N catarrhalis and N flava) and the *Corynebacteria* (diphtheroids) Like the nonhemolytic streptococci most of these are common saprophytes of the upper respiratory tract and oral cavity Diphtheroids must be distinguished from a diphtheroid phase of a nonhemolytic streptococcus

Joachim and Polayes[97] observed the development of subacute bacterial endocarditis due to a yeast (*Candida or Monilia parakrusei*) in a morphine addict who had injected intravenously a contaminated solution of morphine Similar cases of mycotic endocarditis were documented by others[209, 113, 200] There are other reports of subacute bacterial endocarditis due to higher bacteria yeasts or fungi,[8] including cases due to Actinomyces bovis[201] and Histoplasma capsulatum[75] A variety of special media and techniques may be necessary to isolate the causative organisms in these cases The Erysipelothrix rhusiopathiae of swine erysipelas may cause erysipeloid and a complicating subacute bacterial endocarditis in humans who handle infected fish or who make buttons of fish bones[167] Rat-bite fever with complicating subacute bacterial endocarditis may be caused either by the Streptobacillus moniliformis[1, 2, 75] or by the Spirillum minus[84] Rarely bacilli of the subtilis group clostridia Micrococcus tetragenus Diplococcus mucosus Diplococcus crassus B necrophorus (B fusiformis), Doederlein s bacillus or C diphtheriae[18] may cause subacute bacterial endocarditis Hoeprich and Chernoff[85] reported a case of subacute bacterial endocarditis due to the gram-positive bacillus Listeria *monocytogenes* cured by 4 million units of penicillin and 2 gm of streptomycin daily for about four weeks The tubercle bacillus attacks the endocardium rarely but only as part of a generalized miliary tuberculosis or by extension of pericardial and myocardial tuberculosis

Mixed Infections and Reinfections

Mixed infections occur occasionally and may present difficulties in the interpretation and treatment of a given case[144] I have seen combined infections with Streptococcus viridans and the pneumococcus S viridans and Staphylococcus aureus S viridans and diphtheroids the Staphylococcus aureus and the enterococcus Staphylococcus albus and enterococcu Combined infection with S viridans and H parainfluenzae was reported by Olinger[142] The combination of Brucella bacteremia and Streptococcus viridans endocarditis was reported by Quinn and Brown[157] but the course and findings suggest that Streptococcus viridans may have been only a transient invader of the blood stream One of the organisms may be rapidly eradicated by antibiotic therapy but the disease may continue because of persistence of the other causative organism which requires larger dosage more prolonged treatment or streptomycin or other antibiotics instead of penicillin

There are already numerous instances of reinfection causing subacute bacterial endocarditis following cure with penicillin That the new attack is due to a fresh infection is certain when the latter attack is caused by a different organism from the one responsible for the former However reinfection with the same species of organism rather than a relapse may be assumed as probable if three months elapse after all clinical and laboratory evidence of the infection has disappeared The more conservatives demand a free interval of a year In one patient I have seen a bacterial endocarditis due to Staphylococcus aureus cured by penicillin a second attack one year later due to a microaerophilic streptococcus likewise cured by penicillin and a third attack six months later due to a Streptococcus viridans from which he also recovered

PREDISPOSING FACTORS

Previous Valvular Disease

Rheumatic Cardiovalvular Disease Subacute bacterial endocarditis usually involves a heart with an acquired valvular defect due to rheumatic fever Even before 1900 Kelynack[105] had found bacterial endocarditis often associated with preexisting valvular disease, and shortly afterward Glynn[66] emphasized this relationship in a study of 61 cases of bacterial endo-

in 60 per cent In my postmortem observations, evidence of rheumatic heart disease was present in 79 per cent of 100 consecutive cases of subacute bacterial endocarditis A similar incidence of underlying rheumatic cardiovalvular disease was noted by Seabury [174] while Christian [3] recorded 134 instances (89 3 per cent) of rheumatic heart disease in 150 consecutive cases of subacute bacterial endocarditis Subacute bacterial endocarditis may develop in hearts with active or inactive rheumatic disease Aschoff bodies have been encountered in about 40 per cent of the hearts with subacute bacterial endocarditis[191, 7] but a similar incidence of Aschoff bodies may be observed in chronic rheumatic heart disease without bacterial endocarditis Bacterial endocarditis occurs less frequently with very severe mitral stenosis than in cases with milder mitral valvular disease or aortic insufficiency [187]

Bicuspid Aortic Valve Of special interest is the association of subacute bacterial endocarditis with bicuspid aortic valves Lewis and Grant[117] noted that more than 23 per cent of males who reached adult life with this abnormality died of subacute bacterial endocarditis Furthermore, in a consecutive series of 31 cases of subacute bacterial endocarditis a congenital' bicuspid aortic valve was found in 26 per cent However in a subsequent study from the same hospital, Wauchope [90] found that only 6 (11 5 per cent) of 52 cases with aortic bicuspid valves developed subacute bacterial endocarditis and 2 of these 6 had other congenital abnormalities as well Wauchope also observed that there were only 5 instances of bicuspid aortic valves among 95 cases of subacute bacterial endocarditis

While Lewis and Grant[117] considered the bicuspid aortic valve to be a congenital malformation, Gross[71] presented evidence that the majority of bicuspid aortic valves are actually deformed cusps due to healed rheumatic infection Koletsky[111] arrived at a similar conclusion as a result of his studies of 50 bicuspid aortic valves, 40 of which were rheumatic and 10 of congenital origin In 8 of the 50 (16 per cent) there was a superimposed bacterial endocarditis—acute or subacute According to Koletsky, bicuspid aortic valves are encountered in 6 to 12 per cent of cases of bacterial endocarditis

Syphilitic Aortic Valvular Disease Occasionally bacterial endocarditis originates in valves deformed by syphilis [99] In Christian's [3] series of 150 cases of subacute bacterial endocarditis there was 1 instance of syphilitic aortitis and 3 of combined rheumatic and syphilitic cardiovalvular disease Koletsky[112] also stressed the simultaneous presence of rheumatic disease in most instances of combined bacterial endocarditis and syphilitic cardiovascular disease and doubted the significance of syphilis as a predisposing factor The infrequency of bacterial endocarditis in syphilitic aortic insufficiency may be due at least in part to the relative infrequency of syphilitic as compared with rheumatic valvular disease There is also a difference in anatomic lesions, for in syphilis there is neither a true valvulitis nor verrucous alteration to trap bacteria as in rheumatic fever

Congenital Cardiovascular Abnormalities

Congenital cardiovascular anomalies are next in importance to rheumatic deformities in predisposing to subacute bacterial endocarditis Cardiovascular anomalies are present in less than 10 per cent of the latter cases Conversely Gelfman and Levine[60] noted that bacterial endocarditis occurred in 6 5 per cent of all cases of congenital cardiac defects and in 16 5 per cent of those patients who survived the age of two

Of the grosser congenital cardiac lesions the patent ductus arteriosus is most frequently involved in my experience The vegetations produce an endarteritis of the pulmonary artery and of the ductus Some observers have found that the interventricular septal defect is more often complicated by bacterial endocarditis e g, Gelfman and Levine[60] noted bacterial endocarditis in 42 per cent of the cases of ventricular septal defects as compared with 28 6 per cent of the cases of patent ductus However the much higher incidence of the latter anomaly accounts for a significantly greater absolute number of cases of bacterial endocarditis with patent ductus arteriosus. The relation of bacterial endocarditis to bicuspid aortic valves has been discussed Jouve[104] believes that pulmonary stenosis is the congenital cardiac lesion most frequently complicated by bacterial endocarditis this may occur in cases of tetralogy of Fallot or in uncomplicated pulmonic stenosis

Bacterial endocarditis complicates a congenital subaortic stenosis more frequently than recorded figures indicate [199] Bacterial vegetations of the aorta are not uncommon in

cases of congenital coarctation Properly speaking these are instances of subacute bacterial aortitis but the clinical picture and course are essentially identical with that of subacute bacterial endocarditis Subaortic stenosis coarctation and bicuspid aortic valve may all be present in the same case In cases of interatrial septal defects there is a striking rarity of subacute bacterial endocarditis

Arteriovenous Aneurysm

Rarely a traumatic arteriovenous aneurysm is complicated by a bacterial endarteritis similar to that complicating a patent ductus arteriosus [117] The bacterial endarteritis usually is further complicated by a bacterial endocarditis if antibiotic or surgical treatment (p 695) is not instituted early

Operative Procedures—Dental Extraction and Tonsillectomy

It has been repeatedly noted that subacute bacterial endocarditis develops following the extraction of a tooth or the removal of tonsils especially in subjects with rheumatic or congenital cardiac defects [94, 134] The Streptococcus viridans is the common organism found in infected tonsils and dental apical abscesses and may be thrust into the blood stream by the operative procedure Okell and Elliott[141] observed a transient bacteremia (preponderantly Streptococcus viridans) following dental extraction in 72 per cent of patients with septic mouths and in 32 per cent of subjects without obvious infection of the oral cavity Similar observations have been made by others [152] Burket and Burn [9] demonstrated the dental origin of the bacteremia by implanting a non pathogen (Serratia marcescens) about the teeth and recovering it from the blood stream following dental extraction Transient bacteremias have also been observed following tonsillectomy [45] Such transitory bacteremias are rarely significant in the normal individual but in persons with cardiovascular abnormalities the microorganisms may localize about the endocardial defects and set up a bacterial endocarditis It is also probable that less decisive traumata than extraction of teeth or tonsillectomy e g brushing or filling of teeth chewing etc may initiate transient bacteremias especially in patients with dental or gingival infection

Among operative procedures those on the genitourinary tract (cystotomy prostatectomy transurethral resection and even cystoscopy and catheterization) have in my experience been responsible for inducing not only transient bacterial invasion of the blood stream but also subacute bacterial endocarditis The causative organism in these cases is usually the enterococcus the Friedlander bacillus (Klebsiella pneumoniae) Escherichia coli Pseudomonas aeruginosa (B pyocyaneus) or rarely B proteus Induced abortions have several times in my experience accounted for the development of acute or subacute bacterial endocarditis Anaerobic streptococci enterococci and Staphylococcus aureus have been the usual causative organisms but in one case there was a mixed infection with enterococcus and Staphylococcus aureus The staphylococcus and occasionally other bacteria have been responsible for endocarditis following mitral commissurotomy [3] and other cardiovascular operations

The possibility that infections of the intestinal tract especially those associated with diarrhea, or even drastic purgation or enemata may precipitate bacteremia and bacterial endocarditis is not far fetched Enterococcic infections are particularly likely to have their portal of entry in the intestine

Respiratory Infections

Because the Streptococcus viridans and Hemophilus influenzae organisms the common causative agents of subacute bacterial endocarditis, are frequent normal inhabitants of the upper respiratory tract their invasion of the blood stream and implantation on deformed valves may be facilitated during an upper respiratory infection Infections of the upper respiratory tract together with dental infections and tonsillectomy have been indicted as precipitating factors in over 70 per cent of cases of subacute bacterial endocarditis [134, 192] In some instances however the patient reports the disease to have followed a cold' or the grippe when actually the so-called grippal episode was itself the manifestation of bacterial endocarditis

Pregnancy and Puerperium

Bacterial endocarditis may have its onset during pregnancy or shortly after childbirth [34] During pregnancy the relationship is probably coincidental However childbirth itself may be associated with transient bacteremia especially when there is pelvic inflammatory disease In patients cured of bacterial endocarditis before or during pregnancy, the remainder of pregnancy and childbirth followed uneventfully [149]

Myocardial Infarction

Bacterial endocarditis has occurred very rarely in patients following myocardial infarction, superimposed on a concomitant aortic insufficiency, it has developed on a mitral valve made insufficient by rupture of an infarcted papillary muscle and in a mural thrombus which became infected

Age and Sex

The highest incidence is in the third and fourth decades, and also commonly in the second But bacterial endocarditis may occur at almost any age from early childhood to late in life I have seen it in a man of 74 It is perhaps wise to stress the occurrence of bacterial endocarditis in the elderly because the disease may be atypical and usually overlooked in these individuals[198] Many cases have been reported in children but rarely under the age of 5

There is a somewhat higher incidence in males than in females[1 2 11 174]

PATHOGENESIS

Portal of Infection

The development of subacute bacterial endocarditis is dependent on the entrance of microorganisms into the blood stream Because the common causative organisms are inhabitants of the mouth and upper respiratory tract, the portal of entry is believed to be located in infected foci about the teeth tonsils nasopharynx and oropharynx The demonstration of transient bacteremias following dental extractions and tonsillectomy and the clinical observations that bacterial endocarditis often follows extraction of teeth or tonsillectomy support this localization of the portal of entry The portal of entry may also be located in the urinary, genital intestinal or biliary tract in cases of enterococcus (Strepto*coccus fecalis) endocarditis*

Experimental Endocarditis

Bacterial endocarditis has been produced experimentally by the intravenous injection of a variety of organisms The disease may be induced by repeated intravenous injection of non hemolytic streptococci from cases of bacterial endocarditis or other human sources[1 1 29] But as a rule experimental bacterial endocarditis is produced more readily if a cardiac valve is damaged first[83] if the bacteria are injected together with coarse particles which aid valvular implantation, or if casein pituitrin or other substances are first injected, presumably to modify the immunologic response or alter the surface of the valve in such a manner as to promote bacterial adhesion[139]

Bacterial endocarditis has also been produced by the preliminary creation of a large arteriovenous fistula in dogs, followed after an interval by the intravenous injection of small numbers of beta hemolytic streptococci[125 158] Rats exposed to a simulated altitude of 25,000 feet develop valvular lesions and on subsequent intravenous injections of nonhemolytic streptococci develop bacterial endocarditis[83] This may be due to predisposition caused by anoxia and polycythemia

These experimental data correspond to clinical observations that previous valvular damage and bacteremia are the two main factors *responsible for the development of* subacute bacterial endocarditis but that the former is not essential The frequency with which rheumatic cardiovalvular disease precedes bacterial endocarditis suggests that immunologic factors may be of some significance but the bacterial endocarditis may develop on normal valves or in hearts with congenital anomalies in which immunologic alterations are not apparently concerned

Method of Implantation of Bacteria on Valves

It is probable that the bacteremia which initiates bacterial endocarditis is usually of very brief duration and occurs either in the course of ordinary physiologic activities as a result of infections of the oral cavity upper respiratory, intestinal or genitourinary tracts or because of operative procedures in these regions Occasionally the responsible bacteremia is more persistent and a part of a general infection (undulant fever, gonococcemia or meningococcemia)

The circulating bacteria are implanted on valves, mural *endocardium* or vascular intima by way of the general blood stream Platelet thrombi on previously damaged valves or recent valvular vegetations aid in the localization of the infection[69 72] The development of a fibrin wall may provide a medium of growth at the same time that *it protects* against bactericidal substances

But the localization and implantation of bacteria are determined chiefly by mechanical factors of impact and perhaps contact[47 2] The bacteria appear to settle and multiply wherever they are sprayed *forcefully* on a receptive area This is often determined by changes in

pressure dynamics and stream flow induced by valvular stenoses and insufficiencies or by cardiovascular shunts In hearts with a patent ventricular septum the endocarditis appears on the endocardium of the pulmonary conus of the right ventricle opposite the septal defect through which a stream of bacteria laden blood is sprayed against the opposite wall In cases of patent ductus the endarteritis begins in the pulmonary artery as if it were forcibly sprayed there through the open ductus In these instances as in valves altered by rheumatic fever tension changes in the mural endocardium or vascular intima may favor bacterial implantation However implantation may occur on apparently normal valvular or mural endocardium but this is more likely in the acute bacterial forms of endocarditis due to more virulent organisms and more persistent bacteremias

PATHOLOGY

THE HEART

Valves and Vegetations

The most striking feature is the presence of *vegetations* on the valves and on the parietal endocardium These may be discrete like rheumatic verrucae but are usually larger They may also be flat and granular or occasionally exuberant fungating or cauliflower vegetations Rarely the latter are large enough to occlude a valvular orifice The two important characteristics of these vegetations are (a) the presence of bacteria which are constantly swept into the blood stream and which are responsible for the fever toxemia and bacteremia of the disease and (b) their friability which accounts for the fragmentation of particles which are disseminated as embolic bacterial masses

Microscopically the vegetations have a broad base of altered degenerated valvular substance with blood platelet thrombi accumulations of bacterial masses all overlaid by a fibrin and erythrocyte coating Sometimes the vegetation has a characteristic appearance resembling necrotic liver cords [7] Polymorphonuclear leukocytes which abound in acute bacterial vegetations are few or absent in the subacute cases The underlying valvular cusp is the site of a diffuse destructive process with an inflammatory exudate of lymphocytes, mononuclear cells and some polymorphonuclear leukocytes Sometimes there is a striking infiltration of large mononuclear cells consisting of histiocytes and fibroblasts

Localization of Vegetations

The vegetations are situated predominantly on the left side of the heart except when there is a congenital communication between the two sides The vegetations are localized chiefly to the valvular leaflets the mitral being affected in about 80 per cent of the cases the aortic in 60 per cent both in 40 per cent The aortic valve is most likely to be involved in cases of primary bacterial endocarditis i e without antecedent disease The pulmonic valve is occasionally affected perhaps with more than casual frequency in the gonococcal cases The tricuspid valve may be affected simultaneously with the aortic or mitral[1-3] but it seems to have been the site of predilection in cases of Staphylococcus albus and aureus endocarditis induced by intravenous injection of contaminated heroin In one case of interatrial defect which I observed the tricuspid valve was the only one infected with bacterial vegetations

The vegetations may also be situated on the chordae tendineae or on the mural endocardium especially of the left atrium or left ventricle and occasionally on the interventricular septum or pulmonary conus of the right ventricle or on vascular intima Bacterial involvement of the chordae may lead to necrosis and rupture and their loose ends may be seen dangling unattached The aortic valvular vegetations frequently spread by contiguity along the ventricular endocardium and produce moth-eaten bacterial lesions on the ventricular surface of the anterior mitral cusp They may also extend to the distal surfaces of the aortic cusps and involve the sinuses of Valsalva and the adjacent aortic intima In the left atrium bacterial vegetations may produce a characteristic nodular plaque-like lesion with a coarse sharkskin appearance [7] often superimposed on a previous rheumatic atrial lesion

Local Complications of Bacterial Vegetations

The destructive effect of the bacterial vegetative lesions leads to *complications* including *mycotic aneurysms perforations of valve cusps rupture of chordae tendineae perforations of interventricular septa or sinus of Valsalva*

Necrosis of valvular substance may lead to local ulceration aneurysmal pouches or occasionally to perforation of cusps [170] Bacterial endocarditis may increase the anatomic de

formity and functional impairment previously present or initiate a valvular insufficiency or rarely a stenosis. Extension of the bacterial infection to the septum may involve the conduction system. I have several times observed ulceration of a mycotic aneurysm at the base of the aortic valve extend into the pericardial space between the roots of the aorta and pulmonary artery and produce a clinically apparent purulent pericarditis. Bacterial necrosis of the sinus of Valsalva may lead to aneurysm formation and occasionally to perforation into the right atrium or right ventricle with characteristic clinical symptoms and signs of a communication between two vessels or chambers of different pressures (p 773). Rarely aortic and very rarely tricuspid vegetations may burrow into the subjacent myocardium and produce a perforation of the interventricular septum or septum fibrosum.

Healing of Vegetations

Healing of vegetations of subacute bacterial endocarditis were noted by Harbitz,[78] Osler[145] and others, and carefully studied by Libman[1 0] and by Gross and Fried.[72] In recent years healed lesions have been noted at various periods following bacterial sterilization by means of penicillin, when death resulted from some cause other than persistent infection.[164, 136, 99, 29] Healing begins early in the deeper parts of the vegetation and is characterized by disappearance of the valvular inflammatory reaction and bacteria, marked capillarization of the subjacent valve and a fibroblastic reaction. The dilated capillaries may communicate with the cardiac chambers and produce a characteristic "spongy" lesion consisting of wide anastomosing cavernous channels. The fibroblastic reaction leads to partial or complete organization and hyalinization of the vegetations often with calcification. If bacteria are present they lose their staining quality and cannot be cultured. Eventually the small remnant of the hyalinized and fibrotic vegetation becomes covered with an endothelial layer. In the penicillin-treated cases complete healing occurs in about three months after clinical control of the infection.

Myocardial Lesions

Interest in myocardial lesions has been heightened because of the frequency of cardiac failure despite control of the bacterial infection by antibiotics.

Two types of myocardial lesions may be noted:[33, 17, 151] (a) vascular lesions consisting of bacterial embolization of arterioles and capillaries, necrosis of the walls of these small vessels and surrounding inflammatory reactions, (b) extravascular lesions characterized chiefly by minute infarctions due to the above vascular lesions and foci of polymorphonuclear leukocytes or mononuclear cells. Perivascular fibrosis and organization of minute infarcts are common.[16] Small foreign body granulomata surrounding a central deposit of calcium (embolic) have been described in fatal cases treated with sulfonamides and penicillin.[169] Suppurative lesions are uncommon but occur in the cases due to pyogenic microorganisms. The so-called Bracht-Wachter[16] lesions are focal collections of lymphocytic and mononuclear cells. They are not characteristic and are of dubious significance. Occasionally bacterial embolization involves the larger coronary arteries[146, 21] and may produce gross myocardial infarction[196] or sudden death. Not infrequently there are Aschoff bodies and other lesions due to coexisting rheumatic myocarditis.

Pericardial Lesions

Pericardial involvement is uncommon in subacute bacterial endocarditis but there may be lesions of a previous or concomitant *rheumatic* inflammation. Occasionally a diffuse pericarditis is due to an associated pneumonia or complicating uremia. A specific gross suppurative pericarditis may, however, be due to extension of the bacterial infection from an aortic valve and sinus of Valsalva to the pericardial wedge between the aorta and pulmonary artery. In one such case I observed *500 cc* of serosanguineous pericardial fluid.

KIDNEY

The renal lesions are of three types: (1) focal "embolic" glomerulonephritis, (2) diffuse glomerulonephritis and (3) infarcts. There is evidence that penicillin therapy has diminished the incidence of renal lesions in bacterial endocarditis, especially of diffuse glomerulonephritis.[177] Grossly the kidney may present diffuse petechial hemorrhages which produce the so called "flea bitten" appearance and depressed, yellowish sharply demarcated areas of infarction.

1 The *focal embolic glomerulonephritis* (the Lohlein Baehr) lesion was first described by Lohlein[1 9] and studied in detail by Baehr[4] who observed it in 23 of 25 cases of bacterial endocarditis due to the *Streptococcus viridans*

It may also occur in cases due to the H influenzae

Microscopically the feature of the lesion is the necrosis of only a portion of glomerular vessel wall and the presence of a fibrinoid plug in the lumen of the corresponding glomerular branch [24] The lesion has generally been regarded as embolic but it is more probable that local vascular inflammation and closure are responsible [25] Since bacteria are not found in the lesions they may represent an immunologic reaction to the bacterial infection The swollen, necrotic portion of glomerulus becomes granular, undergoes hyalinization and organization and becomes adherent to the parietal layer of Bowman s capsule or subjacent interstitial tissue, its sides being covered by a reflection of the epithelium from Bowman s capsule A characteristic pyramidal or wedge-shaped lesion is produced Few or many glomeruli may be involved When numerous glomeruli are involved renal insufficiency results In the bacteria free stage only the healed hyaline (fibrous) form of this lesion is observed [4]

2 *Acute or subacute glomerulonephritis* was formerly described as infrequent in the active stage of Streptococcus viridans endocarditis but was encountered commonly in the cases due to the gonococcus or pyogenic organisms However according to Christian[23] a diffuse proliferative glomerulonephritis was encountered in 80 per cent of the kidneys of 61 cases of subacute bacterial endocarditis which he studied A diffuse glomerulonephritis was common in the bacteria free cases described by Libman[1 3] and in cases of healing by penicillin [29]

3 *Infarcts* occur in about 90 per cent of untreated cases but are seen uncommonly when treatment is instituted relatively early One or more infarcts may be present They are generally bland but in the cases due to the enterococcus purulent infarcts have been noted

SPLEEN

The spleen is almost invariably enlarged, sometimes remarkably so The usual weight is between 200 and 500 gm but I have seen spleens over 600 gm independent of other splenic disease The spleen contains one or more anemic infarcts in 40 to 60 per cent of the cases Suppuration occurs rarely A perisplenitis with adhesion to the diaphragm may be associated Rupture of the spleen has been reported [107] On section the spleen presents the picture of a subacute or chronic splenic tumor The malpighian bodies are frequently enlarged and prominent and in the bacteria free stage may be visible as grayish punctate dots which give the spleen a characteristic aspect

Microscopically there is hyperplasia of the lymphoid follicles with conspicuous secondary follicles There is a considerable proliferation of the reticulum cells and occasionally of the sinus endothelium [110] In the red pulp the granulocytes are overshadowed by lymphocytes plasma cells and free histiocytes showing phagocytosis The intersinusoidal cords of Billroth are widened There may be foci of necrosis of the reticulum or of the center of the follicles as well as mononuclear cellular collections Focal or diffuse fibrosis of the fibrillar reticulum probably represents a healing or late stage of the disease Jouve[107] has also described a sclerosis of the lymphoid follicles and splenic tissues

CENTRAL NERVOUS SYSTEM

Lesions of the brain are frequent and widespread in uncontrolled cases [36] There is often a diffuse meningoencephalitis due to disseminated bacterial embolization of arterioles and capillaries [109 110] Local closure may also occur secondary to an arteritis and intimal proliferation with or without thrombosis There is a diffuse or perivascular proliferation of micro- and macroglial cells and of astrocytes without polymorphonuclear cells or lymphocytes Ganglion cells undergo ischemic degeneration The meningoencephalitis may involve the cerebrum cerebellum or cerebral ganglia Occasionally the spinal cord is involved in a similar process and a funicular myelosis has been described

Embolic lesions of the large cerebral arteries are common in fatal cases Bacterial emboli lead to mycotic aneurysms and thrombosis Cerebral intraventricular or subarachnoid hemorrhage may result from rupture of a mycotic aneurysm while encephalomalacia is a consequence of vascular (embolic) occlusion Occasionally small or large cerebral abscesses are encountered probably due to autolysis with secondary polymorphonuclear invasion of the infarcted areas

LIVER

The liver is considerably enlarged and engorged This is due essentially to chronic pas

sive congestion which is seen in most fatal cases In addition there is fatty infiltration and focal necrosis There may be enlargement and desquamation of the Kupffer cells and focal accumulations of histiocytes [7]

LUNGS

Congestion, pulmonary emboli and infarctions and bronchopneumonia may be encountered Less often there are pleural effusions or hemorrhages

BONE MARROW

There may be considerable regeneration in both the active and bacteria free stages

ARTERIAL LESIONS MYCOTIC ANEURYSMS

Arterial lesions consist of embolization or arteritis Bacterial emboli affect the large or small vessels of the brain, the extremities, the spleen the kidney, the lungs, or of the hepatic or gastrointestinal tracts Embolization of the lung may arise independently from venous thrombi in the lower extremities or from bacterial vegetations on the right side of the heart in congenital cardiac lesions or endocarditis of the tricuspid or pulmonic valves Vascular occlusion results in infarction or gangrene

Bacterial embolization also results in destruction of portions of a vessel wall with weakening of its structure and the formation of so called mycotic (bacterial) aneurysms [162] Most probably necrosis of the wall is secondary to infected emboli which arrive by way of the vasa vasorum and not by direct implantation on the intimal surface with secondary growth and extension

Many of the cutaneous lesions formerly considered the result of vascular embolization, are probably due to local inflammatory changes in the walls of capillaries or arterioles, possibly immunologic responses to the infection Thus the Osler node is essentially a vascular lesion in which one or more arterioles are occluded by intense intimal proliferation [131, 113, 23] Neighboring capillaries and arterioles show endothelial proliferation and desquamation, thrombosis or necrosis There is a perivascular inflammation of polymorphonuclear leukocytes and histiocytes and a diffuse cellular infiltration in the dermis and about the sebaceous glands and nerve endings The white-centered petechiae in the skin and the so-called focal "embolic glomerular lesion may also be due to local vascular inflammation rather than to embolization

CLINICAL FEATURES

MODE OF ONSET AND GENERAL COURSE

The onset is usually insidious Often the patient is known to have a rheumatic or congenital cardiac defect from which he has suffered little or not at all Most frequently there is only fatigability, weakness or lassitude, anorexia and low grade fever Moderate frontal headache often accompanies the fever A considerable loss of weight may be noted Fever, associated with joint and muscle pains is frequently suggestive of an attack of "grippe" Or symptoms of the disease develop insidiously after a tooth extraction, tonsillectomy, cystoscopy, genitourinary operation or childbirth Symptoms of heart failure are occasionally the first evidences of the disease Almost any other symptom of the disease may be the first manifestation, but urinary, cerebral and digestive disturbances may be particularly mentioned

Occasionally the onset is acute, owing generally to an embolic thrust in a cerebral, abdominal or peripheral vessel Thus hemiplegias local paralysis of an extremity, blindness due to embolism of the retinal vessel sharp pain in the abdomen or loin due to splenic or renal infarction may suddenly reveal the presence of a bacterial endocarditis in an apparently well person I recently observed a 60 year old woman in whom the first symptom was aphasia without paralysis, which developed while she was in the subway on her way to work Because of her age the aphasia was thought to be due to atherosclerotic cerebral thrombosis and she was admitted to the neurologic service The true nature of the disease was recognized upon the discovery of mitral stenosis and low grade fever *Toone*,[131] Seabury[174] and others have called attention to the relative frequency with which patients with subacute bacterial endocarditis are admitted to the neurologic service of a hospital because of cerebral manifestations at the onset

The onset may also occur acutely with chills and high fever This is particularly frequent in the acute cases due to the *Streptococcus hemolyticus* staphylococcus, pneumococcus *E coli*, and similar pyogenic organisms

The further course of the disease is variable and depends essentially on the speed with

which adequate treatment is instituted or serious embolic complications occur In the absence of such treatment or complications the patient runs either a prolonged subfebrile course with progressive weakness and anemia or a rapid acute course Eventually if there is no treatment or if treatment is unsuccessful death results from cardiac failure a cerebral accident uremia or an intercurrent infection The duration is less than a month or two in the acute cases due to pyogenic organisms or occasionally in the subacute disease when the course is abbreviated by an embolic lesion with resulting cerebral or subarachnoid hemorrhage Usually there are repeated evidences of embolization and numerous organs are involved before the fatal complication occurs During this period the patient may have periods of apyrexia and even of tolerable comfort

SYMPTOMS AND SIGNS

These may be classified into three groups (1) general or toxemic (2) embolic and vascular (3) cardiac With early diagnosis and treatment, very few of these symptoms should develop

1 General or Toxemic Symptoms

The general symptoms result from the toxemia of the bacterial infection Fever is the most constant It may be continuous remittent intermittent or completely irregular As a rule the daily temperature peaks range between 101 and 103° Periods of subfebrile temperature for weeks at a time are occasionally observed in the subacute cases Periods of apyrexia may be noted occasionally in patients with renal insufficiency and rarely in others Shaking chills occur in the acute cases occasionally There may be profuse sweats In patients who suffer chills the temperature is likely to be higher than that described above It may reach 104 to 105 F with sharp septic swings A daily double-peaked rise in the temperature curve (double quotidian type of fever) has been described as characteristic of meningococcic endocarditis [51] but also of gonococcic endocarditis [III] Headache is common Often in uncomplicated cases frontal headaches associated with an afternoon rise in temperature are the only symptoms

Progressive anemia is a characteristic feature unless effective treatment is instituted early Certain other symptoms are due partly to the fever and toxemia and partly to the anemia These include weakness, breathlessness and easy fatigability

2 Embolic and Vascular Manifestations

The embolic symptoms are the specific evidences of this disease Seabury's[174] review of the clinical history of 165 cases of subacute bacterial endocarditis disclosed that embolization occurred at the onset in 6 7 per cent But as a rule embolization occurs later when the disease is fairly advanced Only closures and aneurysms of large vessel with resulting infarctions of organs paralysis of extremities or cerebral accidents can be definitely included under this heading Other symptoms whose embolic nature is not certain are very helpful in the diagnosis and include white-centered petechiae and Osler nodes The latter may produce painful fingers or toes which are sometimes the earliest symptom or chief complaint

3 Cardiac Signs

The cardiac signs are essentially those indicating a valvular lesion or a congenital cardiovascular deformity Usually there are murmurs and other signs of mitral stenosis or aortic insufficiency due to known rheumatic infection There may be signs of a patent ductus arteriosus a ventricular septal defect subaortic stenosis or a coarctation of the aorta Sometimes there are changes in the character and sites of these murmurs or new murmurs appear during observation of the patient Occasionally a new rasping murmur is observed with dramatic suddenness due to a rupture of a chorda tendinea or perforation of a valve cusp I have repeatedly observed the development of the characteristic signs of aortic insufficiency in persons with subacute bacterial endocarditis in whom the valves were previously normal A murmur is sometimes absent when the endocarditis is confined to the right side of the heart and involves a previously normal valve [6]

SYMPTOMS OF INDIVIDUAL ORGAN SYSTEMS

Skin and Mucous Membranes

Pallor is almost invariably obvious A characteristic appearance of the patient is often produced by a muddy pallor to which Libman has applied the descriptive term café au lait'

The most frequent skin lesions are *petechiae* those with so-called white centers (actually yellowish gray) being especially significant The white centers are not raised in the subacute cases as they are in some of the acute

bacterial cases The petechiae are most frequently and best observed in the conjunctiva, especially of the lower lid, in the fundus, in the skin about the clavicles, and in the oral mucosa particularly on the soft and hard palates In ambulant patients, petechiae may also be found in the lower extremities A characteristic feature is the occurrence of the petechiae in crops which disappear after several days and recur at a later period However isolated petechiae are also common

Even more specific are tender cutaneous lesions termed *Osler nodes*[115] These are small raised swollen areas about the size of a pea but they may be larger or as small as a pinhead Characteristically they have a bluish tint but they may be pink or red, and rarely possess a blanched center Most commonly they occur in the pads of the fingers or toes, in the thenar or hypothenar eminences or the soles of the feet and rarely on the sides of the fingers or on the webs between the toes[1] The essential feature of these lesions is that they are always tender. The patient may note their sudden onset because of the pain produced In fact painful fingers due to Osler nodes may be one of the chief complaints The Osler node usually lasts one to several days but may disappear in a few hours According to Libman[10] it is pathognomonic of subacute bacterial endocarditis

The Osler node must be distinguished from the *Janeway lesion*,[93] which is more characteristic of acute bacterial endocarditis but is occasionally seen in subacute bacterial endocarditis This is a small erythematous or hemorrhagic lesion which is sometimes raised and nodular but never painful In subacute bacterial endocarditis it is more apt to appear as an erythematous lesion without a hemorrhagic or purple center It usually occurs in the palms of the hands or the soles of the feet

A rather characteristic lesion of the fingers which may be embolic or toxic, is the so called splinter hemorrhage[11] These are vertical hemorrhagic streaks in the skin under the nails

Pustular lesions may occur in staphylococcus or gonococcus endocarditis or endocarditis due to other pyogenic microorganisms Crops of macules and papules have been described in meningococcal and gonococcal endocarditis Occasionally there are large, extensive purpuric lesions which may or may not be associated with thrombocytopenia, prolonged bleeding time and other typical blood findings of purpura hemorrhagica

Kidneys

Hematuria, usually microscopic but occasionally gross, is commonly observed at some stage of the disease As microscopic hematuria is very significant for diagnosis in a doubtful case and as only a few red blood cells may be present in casual specimens careful and repeated examinations should be made on centrifuged specimens of urine Albuminuria is almost invariable, even when no glomerular lesions or infarcts are found

Renal insufficiency occurs infrequently since effective therapy is available Usually renal insufficiency is denoted by a slight or moderate azotemia (urea nitrogen 25 to 75 mg/100 cc) and a fixation of urinary specific gravity to 1 010 by the concentration test Even in the presence of renal insufficiency the blood pressure remains low Renal insufficiency may be due to extensive glomerular embolization or to subacute diffuse glomerulonephritis A nephrotic syndrome occurs rarely

Gross infarctions may be associated with pain as well as with hematuria and albuminuria The pain may be located in the loin It may radiate anteriorly and into the groin as a result of the passage of blood clots along the ureter Tenesmus and frequency of urination also occur

Spleen

A large spleen is clinically palpable in about two thirds of patients But even a large spleen may not be palpable either because the enlargement is very moderate or because the spleen is fixed to the diaphragm by adhesions Splenic infarction may be characterized by sharp sudden pain in the left hypochondrium or the left lower axilla which may radiate to the left shoulder or precordium There may be local tenderness and rigidity over the splenic region, and occasionally a rub is heard so that a pleurisy is diagnosed In rare cases the infarcted spleen may rupture and lead to peritonitis, or peritoneal hemorrhage and sudden death Sudden death may also result from rupture of a bacterial aneurysm of the splenic artery

Heart

The presence of old cardiac murmurs and the development of new ones due to the bacterial infection have been mentioned However, there may be no cardiac murmurs throughout the course of the disease

Cardiac failure is relatively rare at the time bacterial endocarditis begins, i.e., subacute bacterial endocarditis usually attacks the well compensated cardiac patient. On the other hand, congestive heart failure occurs commonly after the development of the bacterial infection. Heart failure is due to destruction of valve tissue, especially with the production of aortic insufficiency, and to myocardial damage caused by bacterial myocarditis and embolic vascular lesions.

Cardiac failure has become the most important complication of bacterial endocarditis since the advent of antibacterial treatment with penicillin. For heart failure is often responsible for death even when the bacterial infection is eradicated.[19, 93, 105]

Disturbances of conduction are uncommon in contrast with their frequency in rheumatic fever[166, 37] but they have been reported to occur frequently in the cases due to pyogenic organisms and especially in brucella endocarditis. Patients with established atrial fibrillation are not likely to develop the disease.[1, 197] However, exceptions do occur. In the cases of prolonged duration which have become bacteria free, and in those in which congestive heart failure develops, atrial fibrillation is as common as in uncomplicated chronic rheumatic valvular disease. The most frequent disturbance in rhythm is a prolongation of the atrioventricular conduction (P-R interval 0.21 to 0.36 second), which occurs in about 15 per cent of the cases. Rarely there is widening and notching of the QRS complex. Complete heart block and bundle branch block may be due to the pressure of a bacterial aneurysm of the sinus of Valsalva on the interventricular septum. *It has been noted particularly in cases* of brucella endocarditis (p. 876). In one such case which I observed at autopsy there was partial heart block ending fatally with Adams-Stokes syndrome due to complete heart block. Heart block and Adams-Stokes syndrome in bacterial endocarditis have disappeared following penicillin therapy.[205]

A *pericardial rub* is rarely heard in subacute *bacterial endocarditis, but it may be present if* there is uremia, or rupture or extension of a mycotic aneurysm into the pericardium.

Coronary occlusion may occur as a result of bacterial emboli from endocardial vegetations.[146] In two such cases which I observed recently the lesion was found post mortem but there were no obvious clinical manifestations. Such emboli may be responsible for sudden death or rarely for myocardial infarction.[196]

Central Nervous System

Cerebral symptoms are a prominent feature of the disease.[166] They may occur at the onset or at any subsequent stage of the disease. The symptoms may resemble those of meningitis or encephalitis.[131] Meningitis is more common in the acute (especially pneumococcal endocarditis) than in the subacute cases. Paralyses are common. Usually the symptoms result from embolic occlusion of a large cerebral vessel.[139] Rupture of an embolic aneurysm not infrequently causes a subarachnoid hemorrhage or fatal hemorrhage into the brain substance or intraventricular spaces.

Encephalopathies may dominate the clinical picture. Usually they are associated with evidences of a meningeal reaction. There may be delirium, somnolence or stupor. When there are blurred vision, vertigo, diplopia, salivation, ocular paralyses, masked facies and muscular twitchings, the picture resembles an encephalitis. Paralyses of the upper motor neurone type are not uncommon. Clinically they appear as a crossed hemiplegia or a monoplegia with or without aphasia. They are caused by a bacterial embolus to a branch of the middle cerebral artery. Flaccid paralyses occur rarely, perhaps as a result of a funicular myelitis. The clinical picture may resemble that of poliomyelitis.

Respiratory Tract

Cough, chest pain, dyspnea and bloody expectoration may be due to pulmonary embolism. This is especially common in cases of bacterial endocarditis with vegetations on the *tricuspid valve, in right-sided bacterial endo*carditis associated with interventricular septal defect and in bacterial pulmonary endarteritis complicating patent ductus arteriosus.[150] Pulmonary emboli may also be secondary to venous thrombi in the lower extremities. Occasionally cough and expectoration result from a complicating bronchopneumonia. Pulmonary symptoms may also be due to left *heart failure*.

Extremities

Clubbing of the fingers is eventually present in about two thirds of the fatal cases in my experience. Cotton[30] first called attention to this symptom, having found that of 63 cardiac patients with this abnormality 44 had definite evidence of bacterial endocarditis. Blumer[11]

noted clubbed fingers in 18 of 48 cases Clubbing of the toes is also frequent

Joint pains are not uncommon or there may be less localized pain in the extremities Pain in the fingers, due to Osler nodes or a subungual hemorrhage, has been mentioned Arthralgias are especially common in the cases of endocarditis due to brucella or meningococcus and arthritis is common in subacute gonococcal endocarditis

Cases of ball valve thrombus occluding the mitral stenosis with consequent bluish necrosis of fingers, toes and tip of the nose have been reported[171]

Sudden pain, loss of function coldness, pallor or cyanosis results from embolization of a large vessel to an extremity Gangrene may follow

Eyes

White-centered petechiae in the conjunctiva are frequent and important for diagnosis They may occur singly or in crops lasting several days Petechiae with and without white centers are also encountered in the retina Often these petechiae have a characteristic boat shaped appearance[41] White-centered retinal hemorrhages may also be observed in cases of leukemia, severe anemia, scurvy and various bacteremias Whitish lesions known as Roth spots are observed both in acute and subacute bacterial endocarditis as well as in other diseases with severe anemia[18]

Optic neuritis and even choked disk have been described as toxic manifestations of the disease[11 37] Usually vision appears unimpaired Kauntze[108] reported 7 cases of subacute bacterial endocarditis in which optic neuritis occurred at the onset or as an early manifestation The neuritis is attributed to vascular occlusion and impairment of blood supply to the nerve The cases with papilledema which I have observed have been associated with meningeal symptoms, a serous meningitis or subarachnoid hemorrhage The finding of optic neuritis in association with other neurologic abnormalities is often responsible for diagnostic error

Sudden blindness may result from embolism of the central retinal artery I have also seen a patient in whom fever and a quadrant defect in the visual field (due to embolism of a retinal arterial branch) were the only manifestations of subacute bacterial endocarditis

The *pathologic changes* in the retina and choroid have been described by Dienst and Gartner[40] They include papillitis edema and cellular infiltrations surrounding the retinal blood vessels and the optic nerve The choroid is especially involved with dense foci of cellular infiltrations, chiefly small round cells

Vessels

Embolization and arteritis are important manifestations Gross embolization with infarctions generally involves the extremities the spleen, the kidneys the lungs and the brain The symptoms have been described in connection with the organs affected Tender swellings of the walls of arteries have been described

Blood

A positive blood culture of the causative organisms is obtained in 80 to 90 per cent of cases This is discussed under etiology and diagnosis

Anemia is a feature of the disease[148] In about 10 per cent of cases the anemia is intense, the hemoglobin falling below 7 gm and the erythrocytes below 2 5 million In patients with purpura I have seen the hemoglobin as low as 3 4 gm The red blood count is usually between 2 5 and 4 million When the infection is controlled by antibiotics there is a rapid increase in hemoglobin and erythrocyte level I observed two cases of hemolytic anemia with positive Coombs test in patients with bacterial endocarditis Whether this was due to the bacterial endocarditis, to drugs administered or to independent factors is uncertain The hemolytic anemia disappeared in one of the patients after prednisone therapy

Leukocytosis is, in my experience, not characteristic unless there is some complication More than one third of the patients I have studied have had a white count under 10,000 Seabury[174] encountered leukocyte counts between 5000 and 10,000 in 53 4 per cent of his cases It is important to emphasize this because many physicians tend to exclude subacute bacterial endocarditis as a diagnostic possibility when the white blood count is not elevated Thayer's[181] series shows that counts above and below 15,000 are equally frequent I have observed that the highest count (20 000 to 40 000) occurred with meningeal and cerebral complications White counts between 15 000 and 25,000 were generally associated with embolism or a concomitant pulmonary infarction When a leukocytosis was present independent of these *conditions*, it was of mild degree (10,000 to 14 000), and the poly

morphonuclear leukocytes were between 65 and 88 per cent with a "shift to the left" in the Schilling hemogram Occasionally there is a leukopenia

There may be a pronounced monocytosis[172] Sometimes the blood contains large phagocytic cells varying in size between 10 and 80 micra[183] These macrophages, histiocytes or endothelial cells as they have been variously termed may dominate the blood picture and are helpful in confirming the diagnosis[185] I do not believe however, that they are pathognomonic or that they are frequently observed

The *blood platelets* are usually normal Not infrequently they are reduced in number and rarely to such low levels that they may produce purpuric manifestations

There is often an elevation of the blood proteins due entirely to an *increase in the serum gamma globulin fraction* The latter accounts for the frequently positive formol gel reaction and for frequently positive cephalin cholesterol flocculation and thymol turbidity tests in subacute bacterial endocarditis Cold precipitable serum globulins (cryoglobulins) were found in 42 of 50 cases of bacterial endocarditis at some time during the period of observation[45]

The *sedimentation rate* of erythrocytes is distinctly accelerated in subacute bacterial endocarditis Increased serum globulin and fibrinogen account for this finding

INDIVIDUAL TYPES OF ENDOCARDITIS

Although the essential features of bacterial endocarditis are similar regardless of the causative microorganism certain features related to some of the individual organisms are worthy of mention

Staphylococcus Endocarditis[41 5]

This type of endocarditis is important because of its increasing frequency and the increasing number of resistant strains of staphylococci Levinson et al[116] reported that of 64 patients with bacterial endocarditis, the staphylococcus was the cause in 18 (28 per cent) In 9 cases the organism was a coagulase positive Staphylococcus aureus and in 9 a Staphylococcus albus Most of the organisms in both groups were highly resistant and there was a 66 per cent mortality with each variety of staphylococcus The fatal cases of staphylococcus endocarditis ran an acute course death usually occurring within one to four weeks Of 13 cases of staphylococcus endocarditis observed between 1949 and 1953 Fisher et al[5] found 42 per cent penicillin resistant, the survival rate was 54 per cent

In acute cases of staphylococcus endocarditis, the disease may follow a furuncle carbuncle abscess or osteomyelitis, especially after traumatization, or it may occur after catheterization or cystoscopy In such cases there are often chills and high fever sweats, prostration petechiae with raised white centers arthritis and a suppurative pneumonia purulent pericarditis or metastatic abscess to the myocardium kidney spleen brain etc Even in the absence of gross infection staphylococci are often present in abundance on the skin and in the nose where they may be harmless but not after introduction into the blood stream of susceptible individuals In a number of cases staphylococci have been introduced into the blood stream by intravenous injection of heroin by addicts[8] Endocarditis in such cases has occurred often in the absence of previous valvular disease and there has been a tendency for localization of the bacterial vegetation to the tricuspid valve

Enterococcus Endocarditis[94 93]

The enterococci formerly responsible for 4 or 5 per cent of the cases of bacterial endocarditis are now responsible for at least 10 to 15 per cent Others have reported the incidence to be about 20 per cent[93] Enterococcus endocarditis is important also because of its high resistance to doses of penicillin which are generally effective in Streptococcus viridans endocarditis Enterococcus endocarditis is most likely to occur following disease or manipulation of the genitourinary tract,[12 60 93] (cystoscopy transurethral resection) occasionally after a septic abortion and rarely in relation to ulcerative lesions of the colon It has followed peripheral abscess and dental extraction, but has occurred also in the absence of overt disease, manipulation or operation Enterococcus endocarditis frequently but in a minority of cases involves previously normal valves Most of the patients are men The onset and course may be acute or subacute more frequently the latter in my experience Suppurative lesions were somewhat more common than in Streptococcus viridans endocarditis but I have not noted this since the vigorous use of antibiotics

Brucella Endocarditis

Relatively few cases of endocarditis due to Brucella organisms have been reported [179, 80, 68] but they deserve comment because of certain purported characteristic features [illegible] As a rule, the patients are males whose occupations bring them in contact with Brucella microorganisms In most cases the aortic valve was involved Of special interest is the frequent occurrence in cases due to Brucella abortus of bacterial aneurysms of the sinus of Valsalva with spread of infection through the aortic wall into the atrial septum, ventricular septum, myocardium or pericardium [illegible] [illegible] The tricuspid valve is involved relatively frequently Disturbances of conduction are common due to septal involvement There is usually a persistent leukopenia In cases due to Brucella melitensis, unlike those due to Brucella abortus, there is usually no previous valvular lesion and rarely aneurysm of the sinus of Valsalva or conduction disturbance Nevertheless, I doubt that Brucella abortus endocarditis represents a distinct entity on the basis of the reported cases, as claimed by Hart et al [80]

Pneumococcus endocarditis is now rare It follows a pneumococcus (lobar) pneumonia or other pneumococcus infections (arthritis, otitis media) The triad of pneumococcus pneumonia, cardiac murmur and meningitis denotes pneumococcus endocarditis, but this is a late stage Undue persistence of fever after pneumonia or recurrence of fever after a brief free interval in a patient with a cardiac murmur should suggest the presence of endocarditis, and blood cultures should be made

Endocarditis due to the Streptobacillus moniliformis or to the Spirillum minus may be suspected when the clinical picture of subacute bacterial endocarditis with multiple arthritis and macular or papular erythema occurs in an individual with a history of rat-bite or of intimate contact with rats In the cases due to Spirillum minus, the incubation period is longer (more than ten days) The local bite lesion is likely to flare up with the development of endocarditis Arthritis is usually absent, and the skin lesions are larger and papular while in the cases due to the streptobacillus the skin lesions are morbilliform and petechial But the clinical picture may be similar in both and both respond to penicillin therapy The causative organisms may be better grown in an atmosphere containing CO_2 than aerobically

Erysipelothrix Endocarditis

A history of handling fish, game or cheese or of polishing fish bones in button making and the presence of an erysipeloid skin lesion together with the clinical picture of bacterial endocarditis, suggest that the latter is due to the erysipelothrix

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The complete diagnosis of subacute bacterial endocarditis is based on the presence of (1) a valvular defect or congenital cardiovascular lesion, denoted by a murmur, (2) a febrile course, (3) embolic phenomena (4) a positive blood culture However, the urgency of early diagnosis and early institution of specific therapy demands an alteration in our criteria for diagnosis

Importance of Early Diagnosis

Despite the availability of curative antibiotics, there is still a substantial mortality of about 25 per cent in cases of bacterial endocarditis In addition, congestive heart failure and, less frequently, cerebral infarction or renal insufficiency, developing during the active bacterial infection cause serious disability and shorten life, even when the infection is cured A study of cases with complications and/or a fatal ending indicated that most of these were due to erroneous or late diagnosis [14] Delay or error in diagnosis was most often due to dependence on development of the full clinical picture before the diagnosis of bacterial endocarditis was seriously considered or rejection of the diagnosis because blood cultures were negative It became apparent that anemia, splenomegaly, clubbing and renal and splenic infarcts were relatively late symptoms Furthermore heart failure cerebral embolism, renal insufficiency and pericarditis were usually irreversible manifestations which were often responsible for fatalities even though adequate antibiotic treatment was instituted An analysis of past cases and subsequent experience have indicated that the highest recovery rate with minimal complication occurs only if the diagnosis is made and treatment instituted within two weeks after the onset of fever, and that accurate diagnosis within this early period is possible on the basis of minimal, early manifestations Hence minimal diagnostic criteria have been set up

Diagnosis By Minimal Criteria

The diagnosis of subacute bacterial endocarditis should be assumed as most probable whenever

a patient with an organic cardiac murmur experiences fever, without apparent cause for more than one week.[63] Often, at this stage a meticulous search will provide strong diagnostic confirmation in the finding of white-centered petechiae in the conjunctiva fundus or palate or Osler nodes A positive blood culture is desirable for definite diagnosis, and as a guide to the choice of antibiotic and dosage in treatment of the disease However, treatment need not await isolation of the causative organism if the diagnosis is based on the above criteria Most common febrile diseases due to infections of the upper respiratory tract or other cause clearly reveal their nature or subside within a week If the fever persists and its origin is still obscure at the end of that period in a patient with a cardiac murmur a blood culture agglutination tests and other laboratory or roentgenologic studies should be made to confirm the tentative diagnosis of subacute bacterial endocarditis or to discover some other cause of the fever But unless or until some other cause is definitely demonstrated treatment should be undertaken for bacterial endocarditis Experience has taught that regardless of theoretical possibilities the diagnosis of bacterial endocarditis based on the above criteria is virtually always correct However the fever should be unequivocal (101 or higher) I have repeatedly seen these criteria misused in that the patient either had no organic murmur had unexplained fever for only a few days or had borderline fever (temperature up to 100°) Yet the diagnosis of bacterial endocarditis was supposedly based on these criteria The word ' unexplained in the above criteria is often neglected A patient with rheumatic valvular disease and fever who has a follicular tonsillitis does not have unexplained fever and bacterial endocarditis need not be invoked to explain it Bacterial endocarditis may occasionally be encountered in the absence of fever and in the absence of a cardiac murmur But in such cases the diagnosis cannot be made on the above criteria a positive blood culture must be obtained or other characteristic features of the disease must be present to justify the diagnosis

It should be stressed that if the diagnosis of bacterial endocarditis is considered most probable on the basis of the above criteria of a cardiac murmur and unexplained fever for more than a week, *80 to 90 per cent of possible* error or delay in diagnosis will be avoided provided only that blood cultures are taken For this is the percentage of cases in which the probable diagnosis will be confirmed by positive blood cultures The commonest cause of delay in diagnosis and treatment is failure to take blood cultures early enough because *the diagnosis of bacterial endocarditis is not* seriously considered If blood cultures are taken on two or three successive days when the temperature is highest and are negative, treatment for bacterial endocarditis should be undertaken while other diagnostic investigations are continued In the experience of Griffith and Levinson,[70] less than 3 per cent of the positive blood cultures were obtained after negative ones on the first two days

There is little risk that prolonged treatment will be undertaken unnecessarily If the diagnosis is in error, e g if the fever is due to rheumatic fever, there will be no response to the antibiotics and they can be discontinued If there is a prompt clinical response and one regards it as coincidence the antibiotic may be discontinued after four days If the fever recurs it is highly probable that the diagnosis of bacterial endocarditis was correct and that the clinical response was due to the antibiotic

Unexplained Fever in Heart Failure and in Rheumatic Children

There are two circumstances which may alter diagnostic probabilities If heart failure is definitely present long *before* the onset of the unexplained fever then other causes are more probable than bacterial endocarditis e g, pulmonary embolism or patchy bronchopneumonia In these circumstances of established heart failure the diagnosis of bacterial endocarditis must be based on positive blood cultures

A second modifying circumstance in the use of the criteria . unexplained fever for more than a week in association with an organic valvular murmur ' is the occurrence of these signs in children or teenagers who have experienced *a clinical attack of rheumatic fever* within five years In these patients recurrent rheumatic fever is at least as probable as bacterial endocarditis As a rule, however, in rheumatic fever there will be other distinctive features besides fever If not blood cultures will usually be positive if the fever is due to bacterial endocarditis If there are no distinctive *manifestations of rheumatic fever and blood* cultures are negative a therapeutic trial with

antibiotics may be made, the fever will not be controlled if it is due to rheumatic fever But the diagnosis of rheumatic fever will almost always prove erroneous in cases of prolonged unexplained fever in the adult

Diagnosis in the Absence of Murmur

In the absence of a cardiac murmur, the diagnosis may be extremely difficult The diagnosis depends on taking of blood cultures in all cases of unexplained fever and on the search for white-centered petechiae Osler nodes, hematuria splenomegaly, clubbed fingers or embolic phenomena The development of an organic cardiac murmur, not present previously is often the clue to diagnosis, but unfortunately a late one In doubtful cases of prolonged unexplained fever without a cardiac murmur it may be preferable to give the patient a therapeutic trial with penicillin as if he had bacterial endocarditis than to await serious and irreversible evidences of the disease

Blood Cultures

Blood cultures are important both for diagnosis and for determination of the causative organism and its sensitivity to specific antibiotics as a basis for effective treatment With proper technique positive blood cultures are obtained in 80 to 90 per cent of the cases of bacterial endocarditis The importance of the above-mentioned minimal diagnostic criteria would become readily apparent if they served only the purpose of initiating blood cultures after a week to ten days of unexplained fever in the patient with a cardiac murmur For then at least the 80 to 90 per cent of cases with positive blood cultures will be diagnosed and treated early Too often the delay in diagnosis is due to delay in taking blood cultures because the ' characteristic (late) symptoms have not yet appeared For management of the cases with negative blood culture, see page 884

Successful blood cultures require the use of aseptic techniques adequate amounts of blood (preferably 20 to 25 cc), a variety of fluid and solid media, some of which are enriched with dextrose, tomato liver, hormones ascitic fluid etc , anaerobic as well as aerobic conditions of growth prompt incubation and prolonged observation As a rule a positive culture will reveal growth within one to four days, but occasionally I have observed growth only after two or three weeks

Negative blood cultures in definite cases of subacute bacterial endocarditis[107] may be due either to improper technique or to absence or paucity of microorganisms in the blood at the moment of collecting the sample A positive blood culture requires the escape of a large number of bacteria into the blood from the focus on the valvular or mural endocardium Sometimes a positive culture of Streptococcus viridans may be obtained in the absence of bacterial endocarditis e g , in about 6 per cent of cases of rheumatic fever and other unrelated diseases according to Lichtman and Gross[1,4] Such transient bacterial invasions of the blood stream in normal individuals have also been noted following the extraction of teeth or tonsils Usually, however, in such cases the streptococci grow only in fluid media whereas in bacterial endocarditis they also appear in numerous colonies on the solid media

Differential Diagnosis

Subacute bacterial endocarditis must be distinguished from a host of diseases responsible for more or less prolonged fever and from numerous systemic diseases which are simulated by embolization of various organs

The most common errors are the diagnoses of "grippe," "virus infection' or influenza early in the course of the fever and active rheumatic fever when the fever persists In the *adult* with rheumatic heart disease bacterial endocarditis not rheumatic fever is almost always responsible for such fever A search for white-centered petechiae Osler nodes splenomegaly and microscopic hematuria, and cultures of the blood will usually distinguish subacute bacterial endocarditis Acute disseminated lupus erythematosus may resemble subacute bacterial endocarditis in the presence of prolonged fever, albuminuria and hematuria The finding of L E cells in the blood or marrow is diagnostic[79]

When the clinical picture is dominated by embolic involvement of a given organ, the following diagnostic errors are common (1) the diagnosis of a cerebral thrombosis or hemorrhage or meningitis when the onset or dominant symptoms are due to cerebral emboli m or rupture of a cerebral mycotic aneurysm (2) the diagnosis of chronic pyelonephritis chronic renal tuberculosis, glomerulonephritis or renal calculus disease with urinary infection when the onset or dominant manifestations of subacute bacterial endocarditis are due to renal vascular emboli or glomerular vascular lesions[109] In all such cases the finding of a cardiac murmur should put the examiner on

guard as to the possibility of a bacterial endocarditis Blood cultures and the search for other clinical manifestations will usually confirm this tentative diagnosis

Congestive heart failure may dominate the clinical picture and the causative bacterial endocarditis may be overlooked A careful history may disclose that continued fever preceded the heart failure and careful examination may disclose white centered petechiae splenomegaly etc Blood cultures must be taken in all cases of heart failure with continued fever

Difficulties in diagnosis arise because multiple diseases in elderly people mask the endocarditis In particular (1) occult neoplasm is diagnosed because of anorexia, weight loss anemia and fever, (2) congestive failure is diagnosed and attributed to coronary atherosclerosis or rheumatic cardiovalvular disease and (3) a cerebrovascular accident is diagnosed and attributed to cerebral atherosclerosis and infarction Despite these difficulties, the diagnosis will not be overlooked if the possibility of bacterial endocarditis is considered whenever there is a cardiac murmur and fever and if thereupon blood cultures are made as well as careful repeated observation for white centered petechiae Osler nodes and splenomegaly

The Bacteria Free Stage

Prior to the antibiotic era Libman[120] described a number of cases in the ' bacteria free stage presumably due to spontaneous healing The essential findings were a cardiac murmur, unexplained severe anemia brown pigmentation of the face splenomegaly and/or renal insufficiency Post-mortem examination revealed healed bacterial vegetations without bacteria similar to those vegetations now found sterilized and healed with the aid of antibiotics [124]

Recovered cases due to early adequate penicillin therapy should be distinguished from the spontaneous bacteria free stage because there need be neither heart failure renal insufficiency anemia nor splenomegaly Only the original valvular defect and subsequent bacterial damage remain However when treatment is delayed or the bacterial damage to valves myocardium or kidneys is too extensive by the time sterilization is accomplished with antibiotics persistent cardiac failure or renal insufficiency may develop as in the spontaneously bacteria free cases

TREATMENT

PRINCIPLES OF ANTIBIOTIC TREATMENT

The following principles should guide the use of antibiotics in treating subacute bacterial endocarditis

(1) Treatment should begin as early as possible before fatal or irremediable complications occur

(2) Adequate dosage should be administered i e , amounts which are suitable in each case to destroy the responsible organism found by blood culture The effective dosage is determined and modified by sensitivity tests repeated blood cultures and observation of the clinical course

(3) Antibiotic treatment should be continued long enough to sterilize completely all bacterial vegetations and all possible embolic foci

The rarity of spontaneous cure in bacterial endocarditis strongly indicates that the host s defense mechanisms are incapable of overcoming the infection by themselves This is probably due in large measure to the characteristics of the bacterial vegetation, in which bacteria are deeply enclosed in thick layers of fibrin which limit access of leukocytes and antibodies from the blood stream The relative avascularity of the subjacent valve tissue also prevents significant reaction of the host Because of the impotence of host factors cure depends almost exclusively on the exhibition of antibiotics in sufficient dosage to kill all the microorganisms before resistant strains appear Mere inhibition of growth of the organisms (bacteriostasis) is ineffective as they resume growth and multiplication as soon as the antibiotics are discontinued ■

Because of the nature of bacterial vegetation larger doses of antibiotic appear necessary to kill the microorganisms in vivo than in vitro Furthermore, antibiotics alone or in combination which sterilize microorganisms in broth cultures are ineffective when applied to the same organisms contained in infected clots [80] Chemical effects of the fibrin or mechanical impediment to diffusion of the antibiotic may account for the difference For these reasons also larger doses of an antibiotic are more effective than small doses in killing bacteria in clots even when both are equally effective in fluid media ■

Experimental studies of Eagle and associ

ates[47, 48] indicate that elimination of microorganisms from an infected focus depends on a sufficiently high concentration and on an adequate time of contact of this effective concentration of antibiotic with the organisms. They calculated that concentrations of 5 to 20 times that which inhibits growth of microorganisms in vitro are required to destroy these bacteria in vivo. Their studies and the studies of Weinstein et al.[203] on implanted fibrin clots in rabbits indicated, however, that effective concentrations of antibiotics need not be continuously present in order to eliminate the infection.

COMMENCEMENT OF TREATMENT

Early treatment demands early diagnosis (p. 876). When unexplained fever in a patient with a cardiac murmur has persisted for more than a week, blood cultures are made on two successive days, and therapy is begun immediately after blood is drawn for the second culture. If two properly performed blood cultures are negative, further blood or marrow cultures will rarely be positive. While the results of the blood cultures are awaited and treatment is initiated, other indicated diagnostic studies are carried out.

Treatment is begun with 2,400,000 units of aqueous procaine penicillin daily and 1 gm. each of streptomycin and dihydrostreptomycin in combination, all intramuscularly. If the blood culture is positive, the sensitivity of the organism to penicillin is determined. The choice of antibiotics and their dosage may be altered if necessary, according to these findings. If the blood cultures are negative, the clinical diagnosis should be reviewed. If bacterial endocarditis still appears probable, the dosage is continued if there is a favorable therapeutic response or increased if the response is unsatisfactory. Blood cultures should be repeated at weekly intervals or when there is a sharp rise in temperature.

SENSITIVITY OF THE CAUSATIVE ORGANISM

The sensitivity of the causative organism is determined in vitro by serial dilution in test tubes.[194] After incubating 1 cc. of the bacterial suspension with successive dilutions of antibiotic in different test tubes, one notes the lowest concentration of the antibiotic which inhibits growth of the organism as indicated by the absence of turbidity. That concentration is termed the sensitivity of the organism to the given antibiotic.

The sensitivity determined by this method is a measure of the concentration of antibiotic which is bacteriostatic for the given organism. However, to effect a cure in bacterial endocarditis it is necessary to attain levels which are bactericidal, i.e., actually kill the microorganisms, not merely inhibit their growth. In practice, one commonly attempts to attain plasma concentrations of antibiotic which are at least five, and preferably ten times as high as the bacteriostatic level determined by the sensitivity test. Usually such levels are bactericidal.

But when this empiric measure is ineffective, bactericidal levels should be determined directly. This is accomplished by mixing 1 cc. of the bacterial suspension with successive dilutions of the antibiotic. After a period to permit growth, the cultures on which there is no growth are subcultured into fresh media. Growth now occurs in those tubes in which the concentration was merely bacteriostatic. No growth occurs in those tubes in which the penicillin concentration was bactericidal. As a rule, particularly with respect to penicillin and the non-hemolytic streptococcus, these bactericidal levels in vitro correspond fairly well to the concentrations which are effective in vivo. But clinical effectiveness is the final determinant of adequacy of antibiotic dosage, not the in vitro bacteriostatic or bactericidal sensitivity.

DETERMINATION OF SERUM LEVEL OF PENICILLIN AND BACTERICIDAL EFFECT OF SERUM

The penicillin level in the blood can be determined after therapy is begun. Of a series of tubes containing 0.8, 0.7, 0.6 cc. of serum, etc., each is made up to 1 cc. with broth and mixed with a 1 cc. suspension of a young culture of the test organism. The 2 cc. mixtures are incubated for 24 hours and the lowest concentration of serum required to inhibit the growth of the standard organism is observed. Since the sensitivity of the standard organism is known in terms of Oxford units, it is possible to calculate the number of Oxford units of penicillin per cubic centimeter of serum. Or else the same procedure is repeated using known concentrations of penicillin in broth in place of the body fluid. If the amount of serum

and the known concentration of penicillin necessary to inhibit the same bacterium in the same test volume are equated, the concentration of penicillin in serum can be calculated Experience and knowledge of the dose of penicillin administered facilitate the arrangement, in advance of the proper range of serum dilutions to be used in the test

In some cases it is desirable to determine whether the concentration of penicillin in the plasma is actually capable of killing the causative microorganism The test is made as above to determine the bactericidal effect of various concentrations of antibiotic But instead of adding antibiotic, serum in various dilutions is used to determine its bactericidal effect on cultures of the causative organism It is desirable that the serum be bactericidal even when diluted 1 4

ANTIBIOTIC TREATMENT ACCORDING TO CAUSATIVE ORGANISM

Sensitive Non hemolytic Streptococci

Penicillin remains the drug of choice in the treatment of sensitive non hemolytic streptococci i e usually the Streptococcus viridans salivarius or mitis Sensitive non hemolytic streptococci may be arbitrarily regarded as those which are sensitive to 0 1 unit of penicillin per cubic centimeter or less Although a successful outcome of bacterial endocarditis due to a sensitive streptococcus would usually follow treatment with 1 million or 500 000 units a day experience has taught that a maximal percentage of successful results would be obtained if the dosage is about 1 or 2 5 million units a day [1] Formerly I administered 4 cc (1 200 000 units) of aqueous procaine penicillin intramuscularly every 12 hours for five or six weeks Or rarely 2 5 million units of aqueous potassium or sodium penicillin was dissolved in 1000 cc of 5 per cent glucose in water and administered continuously each 24 hour period for five or six weeks

In the past few years I have successfully treated bacterial endocarditis due to sensitive non hemolytic streptococci over a two week period only The earliest reports of effective therapy of bacterial endocarditis with penicillin indicated that an average dose of only 200 000 units of penicillin a day for only two weeks effected a cure in about 75 per cent of cases [126] But both dosage and duration of treatment were progressively increased in order to obtain maximal effectiveness More recently Hamburger and Stein[76] cured 10 of 12 patients with bacterial endocarditis due to sensitive microorganisms in 11 to 14 days by the administration of 15 to 16 million units of crystalline penicillin daily Geraci and Martin[64] cured 18 of 23 patients of bacterial endocarditis due to penicillin sensitive streptococci with 1 2 to 2 4 million units of penicillin and 1 2 to 2 4 gm of dihydrostreptomycin daily in divided doses This was supplemented by a report[6] of 23 additional consecutive patients with bacterial endocarditis caused by penicillin sensitive streptococci who were treated for two weeks with 1 million units of aqueous procaine penicillin and 1 gm of combined streptomycin-dihydrostreptomycin (0 5 gm each) administered intramuscularly every 12 hours Twenty patients recovered

I have been regularly treating all patients with bacterial endocarditis due to streptococci with sensitivities of 0 1 unit or less by administering 1,200 000 units of aqueous procaine penicillin and 0 5 gm each of streptomycin and dihydrostreptomycin (i e 1 gm of Distrycin or Combistrep) intramuscularly every 12 hours for two weeks In all cases of bacterial endocarditis the recommended antibiotic and dosage are continued only if there is clinical evidence of effectiveness Increased resistance of Streptococcus viridans (alpha) is rarely observed in the course of treatment [44] Neither has there been a significant change in penicillin susceptibility of these microorganisms in the past ten years [8]

The oral administration of penicillin has not hitherto been regarded as a satisfactory method of treating bacterial endocarditis because of incomplete or unpredictable absorption from the gastrointestinal tract The recently developed phenoxymethyl penicillin (penicillin V) was found to yield substantially higher and more prolonged blood levels of penicillin when given orally than penicillin G In two patients with endocarditis due to penicillin sensitive alpha hemolytic streptococci 12 million units of penicillin V orally each day (2 million units i e 4 tablets every 4 hours) for six weeks effected a cure [157] A third patient with endocarditis due to a more resistant organism was cured by a combination of penicillin V orally and streptomycin intramuscularly In a fourth case due to a penicillin resistant micrococcus penicillin V was ineffective

Clinical Response to Penicillin. In favorable

cases the patient's general condition improves and his appetite and sense of well being are restored within a day or two after treatment is begun Blood cultures may become sterile within 4 hours and usually within 24 hours Fever usually subsides by the end of a week, it may persist as long as penicillin is being administered, but at lower levels than before treatment In the absence of continued active bacterial endocarditis or of bacterial emboliza tion persistent fever may also be due to throm bophlebitis at the sites of venoclysis, inflammation at the sites of intramuscular injections, or concomitant intercurrent upper respiratory or other infection Petechiae and emboli usu ally cease after the first week of successful therapy but may recur for many weeks even in cases with favorable outcome Despite these exceptions persistent fever, embolization and petechiae should stimulate a review of the adequacy of penicillin dosage With a favor able response to penicillin, the hemoglobin rises, leukocytosis subsides and the sedimenta tion rate falls But the latter may not return to normal for several weeks after treatment is discontinued

The question of penicillin sensitivity has rarely been a problem Urticarial and other skin lesions may be controlled by the simul taneous administration of antihistamines orally or by injection [7] More severe lesions may require the simultaneous use of steroid hormones (prednisone, etc) Hypoallergenic peni illin O may be tried, but there is often cross sensitization It must be especially emphasized that bacterial endocarditis is a fatal dis ease and usually there is no substitute for penicillin to effect a cure Therefore, no his tory of penicillin sensitivity should be accepted as an adequate reason for withholding penicillin therapy unless one is certain that some other antibiotic is equally effective Rarely, gradual desensitization against penicillin may have to be undertaken but I have never found this necessary in an extensive experience with the treatment of bacterial endocarditis

Relatively Resistant Non hemolytic Streptococci—Enterococci (Streptococcus Fecalis)

When the causative streptococcus is sensitive to concentrations above 0 1 unit per cubic centimeter it may be classified as relatively resistant Most enterococci are sensitive to 1 to [illegible] units of penicillin per cubic centimeter, i e, they are 50 to 250 times as resistant to penicillin as the standard organism Even larger concentrations are required for a bac tericidal effect and many strains of enterococci are not completely destroyed by any reason able concentration of penicillin alone On the other hand, although streptomycin itself has no bacteriostatic effect on resistant entero cocci it has a potentiating effect on penicillin and the combination is bactericidal in vitro[illegible] and in vivo[illegible, 162, 127]

Bacterial endocarditis due to the enterococcus or other relatively resistant non hemolytic streptococcus is usually cured by the administration of 6 to 10 million units of penicillin daily, and 2 gm of streptomycin-dihydrostreptomycin mixture daily, for a period of six weeks As a rule, when the sensitivity is more than 2 units of penicillin per cubic centimeter, I administer 15 to 25 million units of penicillin daily with the 2 gm of streptomycin dihydrostreptomycin Occasionally, when the organism is inhibited by 5 units of penicillin per cc or more, or is not completely inhibited even by 10 units of penicillin per cc, it may be necessary to use massive doses of 50 to 100 million units of penicillin daily with the streptomycin Aside from these sensitivity studies the clinical response often determines the need for massive doses of penicillin In one patient with bacterial endocarditis due to a very resistant Streptococcus viridans, 25 million units of penicillin daily with 2 gm of streptomycin dihydrostreptomycin and 2 gm of Benemid orally for six weeks eliminated fever and resulted in negative blood cultures throughout the period of treatment However, there was a relapse in 19 days with recurrence of fever and positive blood cultures Cure was effected by a daily penicillin dosage of 50 to [illegible] million in combination with streptomycin and bacitracin

Ordinarily the larger doses of penicillin are best administered by dissolving the daily dose of aqueous potassium penicillin (available in 5 million unit vials) in 1000 cc of 5 per cent dextrose in water and administering by slow intravenous drip The total daily fluid intake is modified as indicated Streptomycin 0 5 gm and dihydrostreptomycin [illegible] 5 gm (1 gm of Distrycin or Combistrep) are administered intramuscularly every 12 hours during the period of penicillin therapy Except with very resistant organisms the streptomycin is dis continued after four weeks but the penicillin

is continued for six weeks With moderately resistant organisms the streptomycin-dihydrostreptomycin mixture may be reduced from 2 gm daily to 1 gm daily after two weeks

Occasionally with the enterococci of lesser resistance in which 6 million units of penicillin are given daily, the drug may be administered intramuscularly as concentrated penicillin (e g Abbocillin 800 000 units per cc) 2 cc (1,600 000 units) being given every 6 hours The streptomycin-dihydrostreptomycin is given simultaneously as above

When the penicillin streptomycin combination is ineffective or streptomycin or dihydrostreptomycin must be discontinued because of vestibular or auditory disturbances, respectively cure of enterococcus endocarditis can usually be accomplished by use of the abovementioned doses of *penicillin in combination with 60 000 units daily of bacitracin intramuscularly* [190] Renal function and urinary output must be followed carefully because of the nephrotoxicity of bacitracin

In rare instances other antibiotic combinations have been used and found effective in curing enterococcal endocarditis after penicillin combinations had failed In one case cure was effected by a combination of erythromycin (1 gm intravenously twice daily) chlortetracycline (0 5 gm every 6 hours) and streptomycin (0 5 gm intramuscularly twice daily) [188] Ahern and Kirby[1] reported cure of bacterial endocarditis due to a resistant Streptococcus viridans with 1 800 000 units of penicillin intramuscularly and 1 gm of chloramphenicol orally every six hours Erythromycin administered intravenously (4 gm daily) may be effective (p 886)

Probenecid (Benemid) Drugs which diminish the renal excretion of penicillin have been employed as adjuvant therapeutic agents to *obtain increased concentrations of penicillin in* the blood This is rarely necessary now because of the ready availability and ease of administering large doses of penicillin Benemid has been found capable of enhancing the penicillin blood level between two and three times when administered orally in doses of 0 5 gm [195, 12] every 6 hours for a total of 2 gm daily It does not increase the blood level of streptomycin or of the broad spectrum antibiotics Occasionally it produces nausea epigastric burning and other symptoms of indigestion

Staphylococcal Endocarditis

Penicillin alone, in a daily dose of 2 4 million units (1 200 000 units of aqueous procaine penicillin intramuscularly every 12 hours) for six weeks is effective in curing endocarditis due to sensitive staphylococci For the increasing number of cases due to highly resistant staphylococci (micrococci), i e resistant to penicillin, treatment is guided by studying the in vitro sensitivity to various antibiotics alone or in combination As a rule I begin by administering massive doses of penicillin (50 to 100 million units daily) together with erythromycin in doses of 3 to 4 gm daily and continue this if fever is controlled and blood cultures become negative The erythromycin may be given intravenously (p 886) If this antibiotic is ineffective I switch to chloramphenicol (Chloromycetin), chlortetracycline (Aureomycin), oxytetracycline (Terramycin) or tetracycline (Achromycin) according to the sensitivity studies Miller and associates[186] reported 3 cured cases of staphylococcal endocarditis 2 of them cured by means of chloramphenicol Not infrequently the simultaneous administration of two or more antibiotics is effective when none of these alone is curative Erythromycin and chloramphenicol given orally, or with bacitracin administered intramuscularly at the same time as this combination is given orally have been effective The addition of bacitracin cured a fulminating case of acute staphylococcal endocarditis after huge doses of penicillin and Aureomycin were ineffective by themselves [16] Johnson and Hurst[93] reported a cure of staphylococcus endocarditis treated with streptomycin, erythromycin and oxytetracycline the latter two given intravenously If these are ineffective, I administer 15 to 25 *million units* or more of penicillin daily in combination with 60 000 units of bacitracin daily intramuscularly Rarely penicillin and neomycin or neomycin alone may be effective when other antibiotics have failed [190] In acute cases of bacterial endocarditis the course may be so fulminating that there is no time to experiment and multiple antibiotics are used with successive addition of new antibiotics when a clinical response is not obtained Treatment is continued for six weeks after blood cultures become negative and the clinical manifestations are controlled

The treatment of endocarditis due to the rarer bacterial causes is noted in Table 8

Table 8 Antibiotics According to Causative Microorganism[15]

ANTIBIOTIC	DAILY DOSE	DURATION WEEKS
Sensitive Non hemolytic Streptococci (0 1 u /cc or less)		
Penicillin	2 400 000	4 to 6
Penicillin plus Streptomycin	2 400 000 plus 2 gm	2
Streptococcus fecalis and Other Resistant Non hemolytic Streptococci		
Penicillin plus Streptomycin plus Dihydrostreptomycin	6–75 million; 1 gm; 1 gm	4 to 6
Penicillin plus Bacitracin	6 to 75 million; 60 000	4 to 6
Staphylococcus (Penicillin-Sensitive)		
Penicillin	2 400 000	4 to 6
Staphylococcus (Penicillin Resistant)		
Aureomycin	3 to 4 gm	6
Chloramphenicol	3 to 4 gm	6
Penicillin plus Bacitracin	2 to 10 million; 60 000	4 to 6
Erythromycin	3 to 4 gm	4 to 6
Streptococcus hemolyticus		
Penicillin	2 400 000	4 to 6
Penicillin plus Streptomycin	6 000 000; 2 gm	4 to 6
Pneumococcus		
As for Streptococcus hemolyticus		
Meningococcus		
Penicillin plus Sulfonamides	2 400 000; 2 to 4 gm	4 to 6
Hemophilus influenzae parainfluenzae Klebsiella (Friedländer) Brucella		
Streptomycin plus Broad spectrum antibiotics	2 gm; 3 to 4 gm	2 to 6
Streptobacillus moniliformis Pasteurella		
Aureomycin or Terramycin or Achromycin	3 to 4 gm	4 to 6
Salmonella Pseudomonas Escherichia Aerobacter Proteus		
Chloramphenicol plus Streptomycin plus Neomycin	3 to 4 gm; 2 gm; 1 to 2 gm	4 to 6
Pseudomonas aeruginosa		
Polymyxin	2 to 5 mg /kg	4 to 6

TREATMENT OF ENDOCARDITIS IN CASES WITH NEGATIVE BLOOD CULTURES

Treatment is usually begun with 2 4 million units of penicillin and 2 gm of streptomycin combination daily, while the results of blood cultures are awaited If these are persistently negative, *one of three courses may be taken*

1 If the clinical response is satisfactory the treatment is continued *for two weeks* in the hope that we are dealing with a sensitive streptococcus If there is a relapse after the two weeks' course, retreatment is undertaken with larger doses of penicillin for a period of six weeks

2 If the clinical course is unsatisfactory and fever persists unabated 6 to 25 million units of penicillin daily are given in increasing doses in combination with the streptomycin until the fever is controlled If these increased doses are ineffective, various antibiotics are tried as if the causative organism were a resistant staphylococcus As a rule, there is a good clinical response with moderate doses of penicillin and streptomycin confirming the presence of bacterial endocarditis or else no response with any antibiotic indicating the need for a continuing search for some other cause of the fever

3 If there is a prompt clinical response and disappearance of fever and the skeptic thinks that this is coincidental he may discontinue the antibiotics after four days The temperature should remain normal if its fall was spontaneous, but will soon rise again if there is bacterial endocarditis and will be controlled again by the previously effective antibiotic In the latter circumstance treatment is resumed and completed as in cases of proven bacterial endocarditis

In the absence of positive blood cultures and a favorable response to penicillin and streptomycin other antibiotics are tried at random, but sometimes the clinical history may suggest the possible causative organism and indicate a choice of antibiotic Some of the factors in the history suggesting the causative organism are noted in Table 9

Table 9 Factors in History Suggesting Causative Organism[16]

Dental Extraction	*Boils Nail-biting*
Streptococcus viridans	Staphylococci
Streptococcus fecalis	*Epidermophytosis*
Intestinal Procedures	Staphylococci
Streptococcus fecalis	Streptococcus hemolyticus
Escherichia coli	
Urologic Procedures	*Narcotic Addicts*
Streptococcus fecalis	Staphylococci
Abortion	Yeasts
Streptococcus fecalis	*Exposure to Rats*
Staphylococcus aureus	Spirillum
Corynebacteria	Streptobacillus moniliformis
Anaerobic streptococci	
Cat Bite	
Pasteurella	

INDIVIDUAL ANTIBIOTICS

Penicillin

This is the drug of choice for the treatment of bacterial endocarditis due to streptococci (Str hemolyticus, Str viridans and enterococci), sensitive micrococci (staphylococci) pneumococci and gonococci

Streptomycin and Dihydrostreptomycin are rarely used alone but may be effective in doses of 2 gm daily for two to four weeks in cases due to Hemophilus influenzae[113] and parainfluenzae and Klebsiella (Friedlander's bacillus) They are widely used in combination with penicillin in cases due to non hemolytic streptococci especially enterococci Brucella endocarditis may be treated by streptomycin dihydrostreptomycin in combination with chlortetracycline[84] Resistance to streptomycin is less likely to develop when this antibiotic is used in combinations than when it is used alone The physician should be alert to the risk of damage to the vestibular nerve by streptomycin or to the auditory nerve by dihydrostreptomycin These complications have been extremely rare in my experience when the drugs were used in doses not exceeding 2 gm daily for four weeks There is evidence that the toxicity from both agents may be reduced without diminished effectiveness if the total dose is divided equally between the two preparations e g 0 5 gm of each every 12 hours

Broad Spectrum Antibiotics chlortetracycline[104, 84, 8] oxytetracycline[61] tetracycline[115] and chloramphenicol[104, 130] are bacteriostatic and not bactericidal in cases due to the Streptococcus viridans or enterococci Despite a good clinical response and negative blood cultures while these antibiotics are being administered, as a rule there is a relapse within a week after discontinuing therapy Regardless of reported sensitivity or temporary clinical response they should not be used as the primary drug in such cases even though they are occasionally effective[156, 84] They may be tried if large doses of penicillin with streptomycin have been ineffective The usual dose is 2 to 4 gm daily orally or 1 gm daily intravenously They may be effective against staphylococci (micrococci) and may be used as the primary drugs in occasional cases due to Streptobacillus moniliformis (Actinomyces muris) caused by a rat bite or Pasteurella endocarditis due to a cat bite Because chloramphenicol fell into disuse on account of reported bone marrow depression fewer strains of staphylococci appear to have developed resistance to this than to other broad spectrum antibiotics Chloramphenicol and other broad spectrum antibiotics are also employed in doses of 4 gm

daily in combination with streptomycin 2 gm daily in cases of bacterial endocarditis due to Brucella organisms Acute bacterial endocarditis due to C diphtheriae has been treated successfully by chloramphenicol in combination with penicillin and streptomycin[35]

Bacitracin (15 000 units intramuscularly every 6 hours) may be employed in combination with very large doses of penicillin in the treatment of endocarditis due to resistant staphylococci [illegible] or to enterococci resistant to penicillin and streptomycin A patient with diphtheroid endocarditis was cured by bacitracin after failing to respond to a combination of penicillin and streptomycin[210] Occasionally bacitracin causes anorexia, nausea or vomiting, and in one patient I treated with large doses of penicillin and bacitracin it may have been responsible for a hemolytic anemia The common risk is renal damage and the urinary output and blood urea nitrogen should be followed carefully Albuminuria is not a contraindication to its continued administration

Erythromycin (Erythrocin, Ilotycin) is antimicrobial chiefly against gram positive microorganisms, its range of effectiveness resembling that of penicillin It may be effective orally (2 to 4 gm daily for six weeks) in the treatment of staphylococcus endocarditis resistant to penicillin, particularly when used in combination with chloramphenicol streptomycin or bacitracin *Erythromycin lactobionate* may be given intravenously in doses of 300 to 500 mg every 6 to 8 hours But the action of erythromycin alone is predominantly bacteriostatic, not bactericidal[100] Furthermore, increase in the resistance of staphylococci has been noted[74] *Erythromycin glucoheptonate* may be administered intravenously Bishop et al[9] reported recovery in a case of subacute bacterial endocarditis due to an extremely resistant non hemolytic streptococcus as a result of therapy with this erythromycin, given by a continuous intravenous drip in a daily dosage of 4 gm for six weeks after numerous antibiotics had failed

Neomycin sulfate administered in doses of 250 to 500 mg intramuscularly every [illegible] hours may be considered in the treatment of endocarditis caused by Salmonella, Pseudomonas, Escherichia, Aerobacter, Klebsiella and Proteus vulgaris In combination with large doses of penicillin it may be effective against otherwise resistant staphylococci Reed and Wellman[180] reported cure of a patient with endocarditis caused by a staphylococcus resistant to all other common antibiotics, by the administration of 250 mg neomycin intramuscularly every 6 hours for one week and 125 mg every 4 hours for an additional four weeks Some hearing impairment developed Neomycin is a toxic drug, to be used only in otherwise fatal cases which do not respond to safer antibiotics It may produce deafness or renal insufficiency[102] The total daily dosage of 2 gm is given in divided doses intramuscularly at 6 hour intervals

Polymyxin is another toxic antibiotic which may be considered if one encounters a case of bacterial endocarditis due to gram negative bacilli, especially Pseudomonas aeruginosa (B pyocyaneus) One may give 2 to 5 mg per kilogram intramuscularly daily in four to six divided doses, but no individual dose should exceed 1 mg kg body weight Careful observation should be made for possible renal toxicity The drug must be discontinued if there is [illegible] sharp reduction in urinary output or a rise in the blood urea nitrogen

Sulfonamides may be employed in combination with broad spectrum antibiotics and penicillin in cases of meningococcic endocarditis

SURGICAL TREATMENT

Ligation and section of a patent ductus arteriosus has cured patients with subacute bacterial endarteritis associated with this congenital defect[188] Surgical ligation cures not only the infection in the ductus and pulmonary artery but also the anatomic and the resulting physiologic and clinical disturbances If the causative organism is sensitive treatment should begin with antibiotics and surgical ligation should be performed at a later date to eliminate existing symptoms and to avoid subsequent reinfection or circulatory disturbances

Resection of an infected arteriovenous aneurysm has cured cases of subacute bacterial endarteritis engrafted on the aneurysm[77, 187, 181] Delayed treatment may mean secondary infection of the heart valves with bacterial endocarditis as well as endarteritis As with an infected patent ductus, antibiotic therapy should be instituted if the organism *is* sensitive Later, excision of the aneurysm is indicated to avoid reinfection and circulatory insufficiency

Mycotic emboli and aneurysm occasionally require surgical removal or excision while the general infection is controlled by antibiotic therapy The successful excision of a mycotic aneurysm of the brachial artery following cure of a bacterial endocarditis was reported by Hurwitz and Arst [91]

Splenectomy was followed by cure in 3 patients with typical bacterial endocarditis in whom fever and positive blood cultures had persisted despite high blood levels of anti biotics because of infected splenic infarcts [1-5]

PROPHYLACTIC TREATMENT

Prophylactic treatment is indicated in all subjects with rheumatic cardiovalvular or with congenital heart disease, for they are the ones likely to contract bacterial endocarditis Manipulations and operative procedures, es pecially dental extractions tonsillectomy, cystoscopy, lithotomy or prostatectomy, cu *rettage or childbirth are likely to inject organ* isms into the blood stream which lodge on a valve or blood vessel and form bacterial vege tations Penicillin should be administered shortly before and for 48 hours after the pro cedure However the dosage and duration of treatment are empirical and the effectiveness of therapy is uncertain Fifty thousand units of penicillin intramuscularly every two hours in the 24 hours *preceding* dental extraction failed to prevent bacteremia although it diminished its incidence [85] I now recommend that 4 cc of Combiotic (600 000 units of pro caine penicillin, 200 000 units of aqueous peni cillin and [illegible] gm of streptomycin) be given in tramuscularly one half hour before the actual procedure since the invasion of the blood stream is transient and occurs within a few minutes after the manipulation Larger doses may be required to prevent growth of resistant organisms The same dose should be repeated 24 hours later Pressman and Bender[154] have recommended in addition that extraction trauma be minimized not more than one tooth being extracted at a time with minimum rocking and that local antibiotic be intro duced into the gingival sulcus by means of a troche of penicillin sulfadiazine and bacitra cin one-half hour before extraction The American Heart Association now recommends the administration of 600 000 units of aqueous penicillin and 600 000 units of procaine peni cillin in oil containing 2 per cent aluminum monostearate administered intramuscularly 30 minutes before the operative procedure As a less desirable alternative buffered penicillin may be administered orally 250 000 to 500 000 units one half hour before each meal and at bedtime beginning 24 hours prior to operation and continuing for five days At the time of operation an additional 250 000 units should be given Broad spectrum antibiotics should be used prophylactically in patients who are sensitive to penicillin or about to undergo surgery of the urinary or lower intestinal tract in full dosage for five days beginning the day before the surgical procedure

In patients who undergo genitourinary procedures, prophylactic antibiotics should be given with special awareness of the danger of enterococcal endocarditis in those with or without preexistent valvular disease One million units of penicillin and 1 gm of strepto mycin should be given one hour before the procedure and repeated every 12 hours until *24 hours after the manipulation and operation* are completed and the catheter removed

Patients who are already suffering from bacterial endocarditis should be carefully ex amined for foci of infection The necessary extraction of teeth or tonsils drainage of sinuses or urologic procedures should be per formed while the patient continues to receive effective antibiotic treatment

PROGNOSIS

The outlook has dramatically improved since penicillin became available Through 1945 *elimination of the infection* was achieved in 107 (81 7 per cent) of 131 cases reported by six different groups of observers At the pres ent time it is probable that the infection can be controlled in about 90 to 95 per cent if death does not occur before two weeks of treatment but recoveries are actually being effected in only about 65 to 75 per cent of cases [33, 42, 140, 11] In Wagner's[19] review of 469 cases of subacute bacterial endocarditis only 4 5 per cent were therapeutic failures due to the resistance of the organism Since blood levels of 35 units per cubic centimeter of peni cillin or more can be attained with huge doses of this drug and since other antibiotics are available it is probable that the number of resistant organisms causing bacterial endo carditis will become minimal

The *percentage of clinical recoveries* is smaller than the percentage of bacteriologic cures Wagner[192] collected 371 reported recoveries

(71 3 per cent) among 469 cases Christie[5] collected 81 recoveries (55 per cent) among the first 147 unselected cases treated in Great Britain Jones et al[93] found reports of 266 recoveries (65 5 per cent) among 406 cases In an analysis of 52 treated cases Newman et al[140] observed that although 69 per cent were cured of their bacterial infection, one third of those cured died of heart failure one third were alive but disabled by the residuals of the disease and only 23 per cent of the adequately treated cases were returned to an asymptomatic state

At first therapeutic failures were due chiefly to inadequate dosage and high resistance of the organism with consequent persistence of the infection At present the most important *cause of failure is delay in treatment* [illegible][5] Priest et al[156] found that the average duration of the disease before the beginning of treatment was 9 2 weeks in a group of recovered cases and 22 5 weeks in a group of fatal cases During the period of delay progressive valvular damage and toxic, vascular and inflammatory lesions of the heart muscle lead to irreversible heart failure, extensive vascular renal damage leads to uremia, or suppurative embolic lesions suppurative pericarditis or deep seated valvular or myocardial suppuration causes sudden death or uncontrollable infection[21, 3] Bunn and Cook[19] reported that rupture of the aortic valve caused death in 6 of 15 fatal cases Thus the outlook becomes more and more favorable the earlier the diagnosis is made and adequate treatment begun

Assuming that adequate blood levels of penicillin can be obtained to inhibit growth of the causative organism, there is no close relationship between the degree of sensitivity of the organism and the likelihood of recovery The presence of complications before treatment is begun such as heart failure frequent and serious embolizations, suppurative pericarditis or ruptured valves denotes a poor prognosis Recovery may occur despite previous failures with penicillin, provided that the causative organism is sensitive to practical doses of antibiotics and no incurable complications have developed Age and sex are usually insignificant for prognosis, but patients beyond the age of 50 are not as likely to recover as younger persons Recoveries occur about equally when the disease complicates rheumatic or congenital lesions

Relapses usually occur, if at all, in the first four weeks after discontinuing treatment Rarely relapses seem to develop as late as three months afterward Clinical and bacteriologic cure for six months after treatment almost always denotes permanent recovery from the given attack Christie[25] estimated that a slight risk, amounting to about 2 per cent per annum, of relapse or reinfection, remained

If recovery occurs without serious complications, the ultimate outlook is determined, not by the residuals of the bacterial infection, but by the nature and severity of the preexisting cardiac disease and subsequent disease[135, 140] The long term outlook is favorable if the patient recovers from the bacterial endocarditis with no heart failure, renal insufficiency, serious embolic complication or free aortic *regurgitation which was not previously present*

Cause of Death

In the fatal cases, death is most commonly due to congestive heart failure This may develop during or after treatment Other causes of death are renal insufficiency and uremia, embolization, especially rupture of mycotic aneurysms of the cerebral vessels with subarachnoid or cerebral hemorrhage, and persistent infection Sudden death is uncommon but may be due to coronary or cerebral embolism or rarely to heart block with ventricular standstill, or to rupture of a splenic infarct

Chapter 35

SYPHILIS OF THE HEART AND AORTA

Education, public health measures and drugs have sharply reduced the incidence of syphilis As the incidence has diminished and as early syphilis has been effectively treated, cardiovascular syphilis has become scarce It probably accounts for less than one half of 1 per cent of heart disease in most parts of the United States except the south Even in the south the incidence of syphilitic cardiovascular disease has been sharply reduced

Syphilitic heart disease is rarely a primary disease of the heart resulting from gummatous or diffuse inflammatory lesions of the myocardium In the vast majority of cases clinical syphilitic heart disease is secondary to syphilitic infection of the aorta (luetic aortitis) and its complications

Syphilitic aortitis has been found at autopsy in more than 75 per cent of untreated cases of syphilis[illegible] Clinically, however, evidence of cardiovascular involvement is observed in only 10 per cent of patients with late syphilis[93, 8]

ETIOLOGY OF AORTIC SYPHILIS

Cause and Pathway of Infection

The organism responsible for cardiovascular syphilis is the Treponema pallidum (Spirochaeta pallida) The organisms enter the blood stream early in the disease, for excision of the chancre does not prevent the development of secondary and tertiary syphilitic lesions The treponemata localize frequently in the ascending aorta but only very rarely in the myocardium It is probable that the spirochetes reach the lungs where they are filtered out into the mediastinal lymph nodes From there they are borne by retrograde extension into the perivascular lymph spaces around the vasa vasorum of the ascending aorta[84] The lymphatic spread of the microorganisms explains their predilection for the aorta and the rarity of endocardial and myocardial lesions for the microorganisms do not attack the cardiovascular system from within the heart or great vessels

The Latent Period Between ten and twenty five years often elapse between the onset of the primary syphilitic infection and the appearance of clinical manifestations of cardiovascular disease This so-called latent period does not denote quiescence of the infection It is more probable that progressive inflammation, tissue destruction and scar formation occur from the onset, but that clinical symptoms and signs appear only when the aortic lesions are sufficiently severe and extensive or involve the coronary ostia and aortic valves

Occasionally the latent interval is relatively short[85] In a study of 142 individuals with syphilis of the aorta in whom the onset of the infection could be determined accurately there were 3 patients who developed clinical syphilitic aortitis within five years[17] In rare instances syphilitic aortic aneurysm or insufficiency occurred within a year or two after the primary infection[43] The appearance of clinical manifestations of cardiovascular syphilis should be regarded not as the beginning but as the advanced stage of a protracted progressive disease of the aorta

Age and Sex Syphilitic heart disease is most frequent between the ages of 35 and 55[107] However, acquired cardiovascular syphilis has been reported beyond the age of 70[113] and as early as 20 Cardiovascular syphilis affects males predominantly in the ratio of between 2 to 1 and 5 to 1 This has been attributed to the higher incidence of primary syphilis among men to the greater stress of their physical work, to greater indulgence in tobacco and alcohol and to constitutional differences

Other Etiologic Factors. There is a much higher incidence in this country among Negroes than among white individuals.[11] It is probable that this is due not to racial differ

ences but to the poorer economic and social status of the former Among both groups syphilitic heart disease is encountered with increasing frequency the lower the social level and the greater the hardship

Inadequacy of Early Antisyphilitic Therapy

Failure to treat early syphilis and inadequate treatment are prime factors in the occurrence of cardiovascular syphilis Studies of patients with cardio-aortic syphilis indicate that almost all of them had no antisyphilitic treatment at all or only sporadic inadequate therapy [16] Moreover comparative studies of the course of patients with and without completely satisfactory antiluetic therapy disclose a much lower incidence of cardiovascular syphilis in the properly treated group [5]

Association of Cardio-aortic Syphilis and Syphilis of the Central Nervous System

Straub's[97] emphasis on the frequent association of luetic aortitis with neurosyphilis was influential in demonstrating the syphilitic nature of the aortitis In a report by Cole and associates [18] there were 642 patients with cardiovascular syphilis of whom 43 per cent also had syphilis of the central nervous system Conversely studies of patients with neurosyphilis have disclosed that a significant per centage have evidence of syphilitic aortitis and its complications [9]

Cardio aortic Disease in Congenital Syphilis

Aortitis, myocarditis cardiac gummata and cardioaortic aneurysms have been *reported in* congenital syphilis [109] Most of these were clinically insignificant occurring in infants who died shortly after birth Congenital syphilis rarely produces cardio aortic lesions of the type seen in acquired syphilis In 4000 post-mortem examinations at the Johns Hopkins Hospital Norris[7] found only 2 instances of luetic aortitis which were presumably of congenital origin McCulloch[69] found that only 8 of 32 syphilitics dying before the age of 2 showed syphilitic cardiac lesions at autopsy None of his patients up to the age of 15 developed clinical evidences of cardiovascular syphilis Dominguez and associates[29] described clinical and postmortem observations on an 18 year old girl with distinct signs of aortic aneurysm and aortic insufficiency caused by congenital syphilis

PATHOLOGY OF CARDIO AORTIC SYPHILIS

The lesions of cardio aortic syphilis include those which originate in the aorta and those which arise directly in the myocardium The former consist of luetic aortitis and its complications namely insufficiency of the aortic valve stenosis or occlusion of the coronary orifices and aortic aneurysm The primary myocardial lesions are gummata and syphilitic myocarditis The endocardium and pericardium are rarely involved and then only by extension of the above myocardial and aortic lesions

SYPHILITIC AORTITIS

Gross Pathology

The naked eye appearance of syphilitic aortitis is generally sufficiently characteristic to permit a definite diagnosis on gross examination Often syphilitic aortitis is associated with atherosclerosis and calcification The distinctive features are (1) the bluish gray or porcelain gray intimal plaques, (2) the wrinkling and puckering of the inner aspect of the aorta with a tendency to form radial or parallel grooves the latter in the direction of the long axis of the aorta, (3) the sharp transverse demarcation of the aortic lesions ending at the origins of the vessels of the neck at the level of the diaphragm or at the origin of the renal arteries (4) the localization of the most extensive lesions to the ascending aorta above the sinuses of Valsalva, and the progressive diminution of le ions as one proceeds along the course of the transverse and descending *thoracic aorta*

The wall of the aorta is irregularly thickened by the plaques and thinned out where it is grooved and puckered It may be so thin that it becomes translucent When the lesions are extensive the aorta loses its elasticity and becomes widened and flaccid This widening is irregular and may be localized particularly to the ascending aorta, or it may be diffuse Rarely there is a gummatous type of aortitis [104]

Microscopic Pathology

1 **Adventitial Changes** The primary lesion probably occurs around the vasa vasorum of the adventitia There are perivascular infiltrations of lymphocytes and plasma cells and occasionally of epitheloid or histiocytic cells The lumen of these small ves els becomes narrowed or obliterated by a proliferation of its intimal layer, which becomes fibrotic and elastified (endarteritis obliterans) There may be localized or diffuse inflammatory changes consisting of granulation tissue and round

cells which form miliary gummata. The involved areas become replaced by scar tissue and by new vessels, both of which extend into the media.

2. **Changes in the Media.** The media has long been considered the site of the most prominent and most significant lesions,[28] whence the term "productive mesaortitis"[34] has been applied to this disease. It is probable that the medial lesions arise chiefly as a result of damage to the nutrient vasa vasorum and only in part through direct inflammatory changes in the media. The essential lesion is a necrosis of muscle and elastic tissue with the formation of scars markedly distorting the architecture of this vessel layer. These scars are often of a stellate form. Throughout the media there is an infiltration of round cells, plasma cells and fibroblasts. The thinning of the aortic wall and its loss of elasticity are essentially due to the destruction of the medial layer, while the wrinkled, puckered appearance is the result of the contraction of scar tissue extending from the adventitia to the intima.

3. **Intimal Changes.** There are intimal thickenings consisting of scar tissue and elastic elements. There may also be scattered inflammatory cells and capillaries which have extended from the media. Unless there is associated atherosclerosis, there is no lipoid or lime. However, atherosclerosis is frequently combined with syphilitic aortitis.

NON SYPHILITIC DISEASES OF THE AORTA

Inflammatory lesions of the aorta have been described by Siegmund[88] in a variety of infectious diseases, particularly scarlet fever, pharyngitis, subacute bacterial endocarditis. The aortic lesions of rheumatic fever have been described previously (p. 820). When extensive and severe, they may occasionally simulate syphilitic aortitis. Of special interest is the disease termed medionecrosis aortae idiopathica cystica.[■, 46] Microscopic examination reveals necrosis of the media with mucoid and cystic softening.[55] The lesions are situated in the ascending aorta and may lead to aneurysm of the sinus of Valsalva (p. 773) or to rupture of the aorta with dissecting aneurysm[8] (p. 555).

COMPLICATIONS OF SYPHILITIC AORTITIS

1. Coronary Artery Stenosis and Occlusion. The most intense syphilitic aortic lesions are situated so close to the mouths of the coronary vessels that these orifices are frequently implicated in the disease process. The incidence of severe narrowing or occlusion of the coronary ostia in luetic aortitis is at least 10 to 25 per cent.[61, 7, 50] By careful measurement with a calibrated metal cone inserted into the vessel openings Bruenn[4] demonstrated that narrowing occurred in 31 per cent of his cases of luetic aortitis. That the coronary ostia are not involved even more frequently is due to the fact that they are usually located within the sinuses of Valsalva, while the lesions of syphilitic aortitis tend to occur just above this level ("supravalvular sclerosis").[63] Not infrequently the coronary orifices have an anomalous origin higher up on the aorta, above the sinuses of Valsalva; in such instances they are almost always embedded within the syphilitic process. When the syphilitic process tends to extend downward so as to involve the commissures of the aortic valve, the incidence of severe coronary ostial stenosis or occlusion becomes very high. Thus coronary ostial stenosis and occlusion are frequently associated with aortic insufficiency, a point worth remembering in interpreting clinical symptoms.

The mouths of the coronary vessels become narrowed by encroachment of the raised intimal plaques upon their margins or by extension of the aortic syphilitic process into that portion of the coronary artery lying within the aortic wall, with subsequent contraction of resulting scar tissue. Stenosis of either one or both orifices may occur and virtually complete occlusion is not rare.[10] The syphilitic process rarely, if ever, extends beyond the aortic openings into the vessels themselves and then only for 1 to 2 cm.[71] But aneurysms of the proximal portion of the coronary arteries have been reported.[■]

Despite the relative frequency of syphilitic coronary stenosis or occlusion, resulting myocardial infarction is rare.[■, 64, 53] In a series of 185 cases of myocardial infarction only 3 were due to syphilitic coronary ostial occlusion.[7] These 3 cases were found in a series of 193 showing luetic aortitis at autopsy, 40 of them with coronary ostial stenosis. On the other hand, Love and Warner,[63] in a study of 10 cases with coronary ostial stenosis, found 8 with pronounced fibrosis of the myocardium and 4 with acute myocardial infarction. Rarely, sudden death in cases of luetic aortitis

is due to coronary embolism of one main artery arising in an associated atheromatous mural thrombus while the other coronary ostium is narrowed by the syphilitic process [77]

2 Syphilitic Aortic Insufficiency

Aortic insufficiency is the result of an extension of a luetic aortitis to the valve commissures and cusps and not of direct valvular involvement At postmortem examination aortic insufficiency is found in 20 to 35 per cent of cases of luetic aortitis [65]

The earliest, the most significant and the most diagnostic gross anatomic feature of luetic aortic insufficiency is the widening of the commissures of the aortic valves This is the chief factor in the production of insufficiency It is probably due to necrosis scarring and consequent dilatation of the aortic ring [29] The commissural spaces between the cusps may become as wide as 0 5 to 1 cm The free margin of the cusps may be everted rolled and retracted and the cusp itself stiffened and shortened This shortening and retraction is a second factor contributing to lack of coaptation of the cusps and resulting regurgitation Aortic stenosis does not occur in syphilis unless rheumatic valvulitis or calcification of the cusps is associated The combination of rheumatic and syphilitic aortic valvular disease has been documented [8] Bacterial endocarditis rarely complicates syphilitic aortic insufficiency unless there are associated rheumatic lesions (p 864)

Rarely there is an extension of the syphilitic aortitis by way of the annulus fibrosus not only to the aortic valve but also to the anterior mitral cusp[92] and to the septum fibrosum [90]

The heart itself becomes considerably enlarged due to dilatation and hypertrophy of the left ventricle especially its outflow tract

3 Aortic Aneurysm

Aortic aneurysm is a complication resulting from a severe and extensive luetic aortitis It has been found at autopsy in 10 to 30 per cent of cases of luetic aortitis In Martland's[63] series dealing with cases of sudden death it occurred in 38 per cent of the cases of cardiovascular syphilis The aortic wall becomes weakened as a result of the destruction of muscle and elastica in its medial layer When this is extensive and severe the continued blood pressure with its systolic accentuation serves gradually to dilate the vessel When there is a pronounced localized dilatation, a saccular aneurysm is formed

Saccular aneurysms may be multiple or single They most frequently involve the ascending aorta less often the arch, the descending and abdominal aorta in that order of incidence The aneurysmal sac may be filled with laminated thrombus which sometimes occludes a small perforation and on rare occasions is the origin of emboli The great danger of aneurysm is perforation, but most of the symptoms when present result from pressure on neighboring vital structures The pressure may be great enough to erode bone

SYPHILITIC MYOCARDITIS

Primary syphilitic disease of the myocardium was classified by Virchow[100] into the gummatous and fibrous varieties The fibrous lesions are non specific and there is doubt that they represent a distinct form of syphilitic myocarditis

Primary syphilitic myocarditis is uncommon and is confined to gummatous lesions There may be localized gummata or a diffuse gummatous myocarditis Sohval[91] was able to collect 97 authentic cases of cardiac gummata and only 7 of diffuse gummatous myocarditis The great majority of gummata occur at the base of the left ventricle and of the interventricular septum [95] Gummata situated in the interventricular septum may involve the bundle of His or one of its branches [95] A gumma may result in cardiac aneurysm may lead to rupture of a papillary muscle or of the heart wall or rarely occludes a valvular orifice

The diffuse gummatous myocarditis consists essentially of miliary or submiliary gummatous lesions with syphilitic granulation tissue and eventual scarring Although these lesions are rare they occasionally produce a distinct clinical picture one resembling acute myocardial infarction in a case reported by Reifenstein

CLINICAL FEATURES

UNCOMPLICATED SYPHILITIC AORTITIS

Symptoms

Syphilitic aortitis is an asymptomatic lesion The symptoms attributed to it are probably all due to its complications—coronary ostial stenosis aortic insufficiency or aneurysm—or to associated coronary atherosclerosis

Physical Signs

It is questionable whether there are distinctive physical signs of uncomplicated luetic aortitis. A *loud bell like or tambour like second aortic sound* (bruit de tabourka) has been described as characteristic. However, it may be absent and a similar sound is frequently heard in cases of hypertension and aortic atherosclerosis. Similarly a rough *aortic systolic murmur* may be due to syphilitic or atherosclerotic changes and dilatation of the ascending aorta. Both of these signs may be suggestive of syphilitic aortitis if they occur in subjects under 40 with a positive serologic reaction for syphilis and without hypertension or any other disease that may cause aortic dilatation.

CORONARY STENOSIS OR OCCLUSION

The clinical features of coronary ostial stenosis or occlusion sometimes cannot be separated from those of the commonly associated aortic insufficiency.

The slow progression of ostial stenosis permits the development of an extensive collateral circulation chiefly through extracardiac anastomoses.[11] Hence there are frequently no symptoms referable to coronary ostial stenosis even when the stenosis is severe and involves both main arteries.

As a rule severe coronary ostial stenosis is characterized by *angina pectoris* indistinguishable from that due to advanced coronary atherosclerosis except that it appears at a relatively earlier age. The clinical picture of acute myocardial infarction is seen rarely. *Sudden death* from ostial stenosis or atresia is not infrequent. By causing relative myocardial anoxia and not infrequently myocardial fibrosis, coronary ostial narrowing may induce or contribute to the development of heart failure, especially when the size and work of the heart are increased by a concomitant aortic insufficiency.

SYPHILITIC AORTIC INSUFFICIENCY

Cardiac pain and dyspnea are the most frequent symptoms associated with syphilitic aortic insufficiency. However, the cardiac pain is probably most often due to coronary ostial stenosis. In Bruenn's[6] series of 39 cases of the latter, 34 (87 per cent) revealed simultaneous aortic insufficiency. The infrequency of cardiac pain in rheumatic aortic insufficiency has been mentioned.

For relatively long periods cases of syphilitic aortic insufficiency may be well compensated. But even during this stage there may be palpitation, pounding in the ears or uncomfortable pulsations in the head and neck.

Left-sided heart failure probably develops not only because of the strain of the aortic valvular insufficiency but also because the development of coronary ostial stenosis prevents the increased blood flow required for the nutrition and work of the hypertrophied heart. This is analogous to the development of heart failure in compensated rheumatic aortic insufficiency when atherosclerosis narrows or occludes the coronary arteries. In syphilitic patients beyond the age of 50 coronary atherosclerosis as well as ostial stenosis may be an important factor in inducing both angina pectoris and congestive heart failure.

Paroxysmal dyspnea especially at night is an early and frequent symptom[6] ('syphilitic asthma'). Exertional dyspnea is also an early symptom of left ventricular failure in syphilitic aortic insufficiency. Sooner or later orthopnea, cough and weakness are associated. Attacks of acute pulmonary edema are not uncommon. Within a few years frank evidences of right sided failure also appear.

The physical signs of aortic insufficiency have been described (p 688).

ANEURYSM OF THE AORTA

Aneurysm of the aorta may remain asymptomatic for many years up to the final blow out. Symptoms occur as a result of pressure on neighboring organs or of perforation. The perforation is usually *into the pericardial or left pleural cavity*, the left bronchus, the esophagus or trachea, and occasionally into the right pleural cavity, right bronchus, the superior vena cava, pulmonary artery or externally.[4] Aneurysms of the sinus of Valsalva usually perforate into the right atrium and ventricle. Sudden death is common.

Aneurysm of the Ascending Aorta and the Aortic Arch

Aneurysms of the ascending aorta have been distinguished as "aneurysms of physical signs" in contrast to those of the arch which are termed "aneurysms of symptoms." The ascending aorta is most frequently involved. Since the ascending aorta is entirely within the pericardial sac, rupture occurs most frequently into that cavity. As it enlarges the

aneurysm usually extends anteriorly upward and to the right compressing the right bronchus and lung the superior vena cava and the second or third ribs to the right of the sternum Occasionally it produces pulmonary stenosis by compressing the pulmonary artery [7] It may attain enormous bulk and appear as a visible tumor in the first or second right interspace near the right sternoclavicular joint Occasionally such a visible tumor may be seen oozing blood from a superficial erosion and rarely the aneurysm ruptures externally

Aneurysms of the arch usually compress the trachea the esophagus the left bronchus the left recurrent laryngeal nerve and the sympathetic nerves When the aneurysm is essentially confined to the arch pressure on these structures is likely to produce symptoms quite early Patients with this lesion often first consult the laryngologist the gastroenterologist or the specialist in pulmonary disease

Symptoms *Chest pain* and *cough* are the commonest complaints The pain is often persistent and may be due to pressure of the aneurysmal sac on adjacent nerves or to the erosion of bone The cough which is dry at first and may have a brassy quality results from pressure on the trachea or main bronchus The brassy quality is ascribed to involvement of the recurrent laryngeal nerve Later in the disease the cough is associated with expectoration and more rarely with hemoptysis These are due to bronchostenosis and secondary infection with resulting atelectasis and bronchiectasis The clinical picture produced has been termed aneurysmal phthisis

Pulmonary and pleural symptoms may actually dominate the clinical picture of aortic aneurysm [8] Atelectasis bronchopneumonia abscess or bronchiectasis may arise not only from tracheal or bronchial compression but also from direct invasion of the lung by the aneurysm Tuberculosis may be associated Pleural complications arise as a result of rupture into the pleural cavity compression of the pulmonary or azygos veins or extension of pulmonary infection to the overlying pleura

Dyspnea is due to pressure on the trachea or on a bronchus Inspiratory stridor may develop *Hoarseness* results from paralysis of the left recurrent laryngeal nerve *Hemoptysis* may result from erosion of the trachea bronchus or pulmonary tissue or from bronchiectasis due to stenosis of a bronchus with secondary infection *Dysphagia* is due to partial obstruction of the esophagus When there is pain on swallowing it is probable that the esophageal mucosa has been eroded by the aneurysm Rarely pressure on the phrenic or sympathetic nerve produces symptoms such as hiccup diaphragmatic paralysis or unilateral absence of sweating of the face

Physical Signs The signs are essentially those of an expanding pulsating mediastinal tumor Inspection and palpation may reveal a pulsation in the anterior chest wall in the second or third right interspaces occasionally higher up or to the left Rarely a bloody tumor mass is visible on the chest wall There may be inequality of the pupils with dilatation of the right due to pressure on the cervical sympathetic chain Occasionally unilateral exophthalmos also results Suffusion of the face neck and upper extremities with cyanosis and edema may be produced by pressure on the great veins The edema and cyanosis may be localized to the right arm if the pressure is confined to the subclavian vein but this is rare

A systolic thrill and a *diastolic shock* may be palpated over the mass As a result of pressure of the aneurysm on the bronchi a *tracheal tug* synchronous with the heart beat may be felt as a downward pull at the thyroid or cricoid cartilage There may be an *inequality of pulses* usually the right one is diminished in amplitude delayed or obliterated by partial interclusion of the orifice of the innominate artery or aneurysmal involvement of that vessel itself There is a corresponding difference in blood pressure in the two arms

The heart is not enlarged as a result of aneurysm itself Systolic murmurs are often present over the aneurysm Diastolic murmurs are due to associated aortic insufficiency

Distinctive features permitting a clinical diagnosis appear when an aneurysm of the aorta perforates into the pulmonary artery[11] or into the superior vena cava [12] or when an aneurysm of the sinus of Valsalva perforates into the right atrium[4] or ventricle[11] (p 773) There is a loud continuous bruit with systolic accentuation and a palpable thrill as in arteriovenous fistulas Cardiac enlargement electrocardiographic signs of right ventricular strain and congestive heart failure appear quickly and usually lead to a rapid end Perforation into the superior vena cava is dis

closed also by cyanosis and edema of the face and neck, venous engorgement in the upper half of the body and pulsations in the cervical veins[67] In instances of perforation into the right atrium there may be visible double pulsations in the jugular veins resembling those of tricuspid stenosis The development of chronic cor pulmonale due to compression of the pulmonary artery by an aortic aneurysm has been reported[30]

Aneurysm of the Descending Aorta

Because of their location aneurysms of the descending aorta may reach immense size and may almost completely fill the left thoracic cavity before they produce symptoms either by pressure on neighboring organs or by perforation One is often surprised to find a huge thoracic mass on roentgenologic examination of a patient who has complained of few or no symptoms

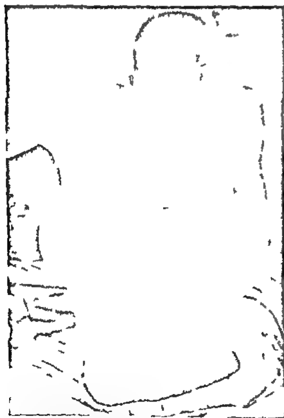

Fig 141 Huge syphilitic aneurysm of descending thoracic aorta visible on external surface of left posterior chest wall

As with aneurysms of the arch, the chief symptoms are chest pain dyspnea and cough Pleural effusion, hydrothorax and hemothorax rarely develop Dysphagia is an occasional symptom resulting from pressure on the esophagus An important sign of a large aneurysm of the descending aorta, and one often overlooked, is a visible pulsation on the posterior chest wall either below and to the left of the left scapula or somewhat higher in the interscapular region Rarely the aneurysm produces a visible pulsating mass in the left interscapular region (Fig 141)

Aneurysm of the Abdominal Aorta

Aneurysms of the abdominal aorta are generally considered to be predominantly atherosclerotic, syphilis being responsible for only 9 per cent in the series reported by Mills and Horton[70b] Atherosclerosis was responsible for 97 of 102 cases of abdominal aneurysm in the series reported by Estes[■] However, in other collected series of abdominal aneurysms in which there were more Negroes and somewhat younger individuals, syphilis was responsible for 50 to 80 per cent of the cases[47, 44] Syphilitic aneurysms occur predominantly in subjects below the age of 50 and almost exclusively below the age of 60[67] Atherosclerotic abdominal aneurysms occur predominantly in subjects beyond the age of 60 and almost never before 50 The syphilitic aneurysm usually occurs at the level of the celiac axis

The *commonest symptom* of syphilitic abdominal aneurysm is pain in the abdomen or back It may be paroxysmal, or constant and boring There may be root pains radiating from the back to the upper abdomen These and other symptoms result from erosion of the vertebrae, pressure on the spinal cord gastrointestinal tract ureter or other abdominal structures Death is usually caused by rupture of the sac into the peritoneal cavity gastrointestinal tract or retroperitoneal space Most abdominal aortic aneurysms are asymptomatic

Examination may reveal an expansile pulsating mass palpable thrill and audible bruit and occasionally a difference in the femoral pulsations Roentgenologic examination may disclose an abdominal mass with or without calcification and erosion of the anterior vertebral bodies from the eleventh thoracic to the second lumbar

GUMMATA OF THE HEART AND GUMMATOUS MYOCARDITIS

Cardiac gummata and gummatous myocarditis usually produce no clinical picture Rarely a gummatous aneurysm may per

with evidence of syphilitic aortic insufficiency who also suffers from angina pectoris Even under these circumstances the cardiac pain may be due to a concomitant coronary athero sclerosis especially in patients beyond the age of 50

cedures was reported positive in 75 to 95 per cent of the cases [13, 18] suggesting that in about 15 per cent of the cases of cardiovascular syphilis the serologic reaction may be nega tive However, this does not apply to more modern serologic tests and techniques for per

B Angiocardiogram of same Aneurysmal mass continuous with aorta and extending posteriorly (Arrow)

Diagnosis of Syphilitic Aortic Insufficiency

This diagnosis has been discussed in the chapter on aortic insufficiency (p 692) The syphilitic etiology of the valvular lesion is suggested by a positive Wassermann reaction absence of a cardiac murmur in childhood and absence of mitral stenosis and by the associa tion of angina pectoris The association of both syphilitic and rheumatic valvular disease has been noted [8]

Diagnosis of Syphilitic Aortic Aneurysm

This is essentially a radiologic problem (p 899) Occasionally there is a visible or palpable pul ating mass in the first or second right interspace or in the left scapular region The possibility of aortic aneurysm should be considered in any patient who has definitely had syphilis and who suffers from chest pain dyspnea cough especially a brassy cough hoarseness severe abdominal pain or pa ralysis of the recurrent laryngeal nerve The value of contrast angiocardiography has been mentioned

The Wassermann and Related Reactions in Cardiovascular Syphilis

The blood serologic reaction for syphilis as obtained by the Wassermann, or similar pro forming them It is probable that less than two or even less than one per cent of cases of cardiovascular syphilis have a negative sero logic reaction for syphilis The syphilitic na ture of cardiovascular lesions may be con firmed by the detection of treponemal im mobilizing antibodies in the blood even when the serologic reactions are negative [37] In 342 cases of cardiovascular syphilis in which the spinal fluid was studied by the Clinical Co-operative Group [18] significant abnormalities were found in 56 per cent Thus evidence of syphilis of the central nervous system should suggest a careful search for cardiovascular lues and vice versa

PROGNOSIS

In a large percentage of cases of cardio vascular syphilis evidence of this disease is a coincidental finding at autopsy Of 1040 in stances of cardiovascular syphilis studied at necropsy by Welty [101] the syphilitic lesion was a direct or important contributing cause of death in only 339 cases Rich and Webster [80] concluded that uncomplicated syphilitic aor titis carried a favorable prognosis as suggested by a relatively low death rate in a group of

of pneumoperitoneum injection of air into the colon, or by administering a Seidlitz powder Erosion of the upper lumbar vertebrae or of their transverse processes may be seen, especially in lateral views[6] In aneurysms of the thoracic aorta there may be concave erosions of the ribs or sternum as well as of the vertebrae Pleural or pulmonary abnormalities and rarely paralysis of one leaf of the diaphragm may be observed as a result of pressure of the aneurysm on neighboring structures

The roentgenologic findings in aortic insufficiency have been described elsewhere (p 689) Coronary ostial stenosis, per se and causes no radiologic abnormalities

Diagnosis of Uncomplicated Aortitis

This is a difficult diagnosis and its criteria are not well defined It may be considered when there is radiologic evidence of dilatation and/or calcification of the ascending aorta in a patient who is below the age of 40 has definitely had syphilis and is free from hypertension or rheumatic valvular disease[30] Accessory diagnostic findings may include a hollow or bell-like accentuated aortic second sound and an aortic systolic murmur In patients beyond the age of 40, but with all the other findings, the diagnosis may be arteriosclerosis or syphilitic aortitis

Fig 142 Syphilitic aneurysm of ascending aorta.

Angiocardiography

Angiocardiography has greatly facilitated the diagnosis of aortic aneurysms and especially their differentiation from mediastinal tumors[64 ** 12] (Fig 143) Merten et al have reported 9 cases of syphilitic aortic sinus aneurysms diagnosed during life by angiocardiography[70]

Definition of the exact site and extent of aneurysms of the aorta may be greatly facilitated by *aortography*[52]

Diagnosis of Syphilitic Coronary Ostial Stenosis or Occlusion

This may be considered in a patient with the above evidence of syphilitic aortitis, or

lessened and the duration of life was two to five times as great in the treated group as in the untreated

TREATMENT OF CARDIOVASCULAR SYPHILIS

Prophylaxis

Available data indicate that cardiovascular syphilis may be largely prevented by prompt case finding and adequate treatment and observation of early syphilis[23] Most of the data apply to treatment by arsenicals bismuth and mercurials prior to the widespread use of penicillin There is substantial evidence that the adequate early treatment of syphilis greatly reduces the incidence of syphilitic aortitis and its complications Treatment of early syphilis is now begun with the intramuscular administration, at multiple sites of 2 4 million units of a long acting penicillin Benzathine penicillin G fortified with procaine penicillin may be used, or procaine penicillin in oil with 2 per cent aluminum monostearate This is followed by four injections at four day intervals of 600 000 units of either of the latter preparations at each injection

Specific Therapy of Syphilitic Cardiovascular Disease

The aim of specific therapy in cardiovascular syphilis is to relieve the patient s symptoms and prolong his life without undue risk Specific therapy is given because cardiovascular syphilis denotes a persistently active inflammatory lesion which it is hoped can be controlled by antiluetic drugs In a pathologic study of 45 treated and untreated cases of syphilitic aortitis Webster and Reader[10] found persistent syphilitic inflammatory activity in all of 19 untreated cases and in only 3 of 19 adequately treated ones Although antisyphilitic therapy may control the active inflammation it cannot be expected to alter significantly certain irreversible lesions due to necrosis of muscle and elastic tissue and scar formation

Penicillin has now replaced all other drugs as the preferred therapeutic agent [4, ■] The preliminary administraton of bismuth or mercury designed to prevent a Jarisch Herxheimer reaction or therapeutic shock is no longer considered necessary or advantageous[22]

Uncomplicated syphilitic aortitis does not produce clinical symptoms and is not a definitely diagnosable entity The treatment of *syphilitic aortic insufficiency* and/or *coronary ostial stenosis* consists in the intramuscular administration of a total of 6 to 12 million units of penicillin[■] Six hundred thousand units of procaine penicillin in oil with 2 per cent aluminum monostearate or benzathine penicillin with procaine penicillin are administered daily for a period of 10 to 20 days or 600 000 units may be administered twice weekly for 5 to 10 weeks

This may be followed by relief of angina pectoris or nocturnal dyspnea and improved well being[2, ■] Except for mild fever in a few cases there are no significant reactions suggesting therapeutic shock[3]

Heart Failure and Angina Pectoris

Penicillin is given as described above and these complications are treated as described in Chapters 11 and 18

Surgical Treatment

The surgical treatment of aortic aneurysms has undergone remarkable advances and is now directed toward removal of the lesion and restoration of function[5] The treatment of aneurysms with polyethylene wrapping containing dicetyl phosphate to stimulate a protective fibrous tissue encasing[23] reinforcement of aneurysms with non absorbable polyvinyl sponge (Ivalon) electrothermic coagulation and the 'pack method of intrasaccular wiring[60] gave some favorable but inconstant results Thromboendarterectomy[101, 61, 16] has given some brilliant results in aneurysm of the terminal abdominal aorta which is usually of atherosclerotic etiology At the present time the preferred treatment of aortic aneurysm syphilitic or atherosclerotic is the excision of the aneurysm and suture of the aorta with graft replacement if necessary A major problem is the need to occlude the aorta during excision of the aneurysm graft replacement and suturing Below the level of the renal arteries the aorta may be occluded for adequate periods of one hour or more but occlusion of the aorta for aneurysms at higher levels for more than 20 minutes is usually associated with considerable risk Occasionally in syphilitic sacculated aneurysms a tangential resection is possible and the circulation in the major part of the lumen of the aorta need not be cut off[1] Recently there have been a number of reports of definitive cures of aortic aneurysm in all parts of the aorta with freeze dried graft replacement and restoration of continuity of the aorta[■, ■] Schafer and Hardin[84] reported the use of temporary polyethylene

elderly patients followed for an average period of seven years, and by the low incidence of the development of aortic insufficiency. Similarly the favorable course of uncomplicated syphilitic aortitis is suggested by the fact that this lesion is found post mortem in a large majority of persons with longstanding syphilis of whom only 5 to 10 per cent have had clinical evidence of the disease.

But even among those who eventually develop clinical evidence of cardiovascular syphilis there is an asymptomatic stage of considerable duration. According to the studies of syphilitic aortic insufficiency reported by McDermott[70] and associates this asymptomatic phase varies between two and ten years with an average of six years. Similarly Hubert[4] reported that of 137 patients with syphilitic aortitis 47 were completely free of symptoms after six and a half year; and Reader et al[78] found 16 of 27 patients with syphilitic aortic insufficiency who were asymptomatic and mostly working after five years of observation. The existence of a long asymptomatic period is suggested by the finding of virtually complete closure of both coronary ostia in the hearts of individuals who were asymptomatic and at work until a relatively brief period before death. It is also remarkable how often an aortic aneurysm reaches enormous size before it produces symptoms.

The further course and duration of life after the onset of symptoms is quite variable. It was formerly stated that this symptomatic phase was an ominously progressive one with death in one to three years. However, even Grant[38] found that the case fatality rate in syphilitic aortic insufficiency was only 64 per cent after ten years. Kampmeier and Coombs[49] in a study of the records of 163 patients with syphilitic aortic insufficiency, found that about 55 per cent died in the first three years after the onset of symptoms, 20 per cent died in three to twelve years, while the remainder were still alive, almost half of them, for an average period of ten years. The duration of the symptomatic phase in the group of patients with syphilitic aortic insufficiency studied by Reader et al[8] varied between two and fourteen years with an average of 5.6 years. In a series of 1020 patients with syphilitic aortic insufficiency followed in the New York and Johns Hopkins hospitals for a period of twenty years[103] 43 per cent of the New York group and 33 per cent of the patients at Johns Hopkins hospital survived ten years and 30 per cent of the former group and 20 per cent of the latter survived fifteen years. Twenty-one per cent of those over 60 at the time of diagnosis survived ten years. The survival time was much greater for those who were asymptomatic than for those with clinical symptoms at the time of diagnosis.

In general the outlook for uncomplicated syphilitic aortitis is much better than for cases with aortic insufficiency, aneurysm or coronary ostial stenosis. The outlook becomes distinctly more ominous when subjective symptoms appear, especially angina pectoris and those due to congestive heart failure or to aneurysmal compression of vital structures. In the presence of heart failure the mortality rate increases substantially and the duration of life averages two to three years. However 9 of 30 surviving patients studied by Reader et al[78] had suffered from congestive heart failure three to nine years previously and had responded to treatment. In the series reported by Webster et al[103] 28 per cent of those with angina pectoris and 6 per cent of those with heart failure survived for ten years. The outlook in cases of syphilitic aortic aneurysm is very poor once symptoms appear,[3] the average period of survival varying from 9 to 17 months with involvement of the ascending aorta, 6 to 9 months for the transverse aorta and 8 to 20 months for the descending aorta.[49] In cases of luetic aortitis complicated either by aneurysm, coronary ostial stenosis or aortic insufficiency there is always the danger of sudden death.[58, 67] The prognosis is worse in Negroes than in white patients. Patients engaged in occupations involving arduous physical exertion have a relatively unfavorable outlook.

Relation of Antisyphilitic Treatment to Prognosis

It is generally believed that adequate early treatment of syphilis greatly reduces the incidence of luetic aortitis and of its serious complications.[13, 101, 68] On the other hand there is less certainty as to the effectiveness of antisyphilitic therapy given after the clinical recognition of syphilitic aortitis. However, the studies of Padget and Moore[71] and the cooperative clinical report of Cole et al[18] suggested that after regular adequate treatment of cardiovascular syphilis with an arsenical and a heavy metal the mortality rate during the period of treatment was substantially

Chapter 36

THE HEART IN INFECTIONS

Rheumatic fever and syphilis are the only infections responsible for common clinical forms of cardiovascular disease. These have been discussed in previous chapters. Almost all of the microorganisms are capable at times of producing a bacterial endocarditis and less commonly a purulent pericarditis and myocardial lesions. The endocarditis and pericarditis are due to local implantation and growth of microorganisms while the myocardial changes may be due either to the presence of these organisms or to toxic or metabolic disturbances or embolic vascular occlusions caused by the infection.

This chapter is concerned with the cardiac abnormalities associated with a variety of more or less specific infections or infectious diseases other than those mentioned above.[1] Diphtheria is the classic example of an infection accompanied by sufficient anatomic change in the heart to account for clinical heart disease. In almost all of the other infections evidence of cardiac involvement consists either of electrocardiographic changes which are usually non specific and transient or of relatively mild and non specific myocardial lesions which are found in fatal cases.

Clinically circulatory disturbances are uncommon or overshadowed by other manifestations of the infection. Acute circulatory failure (shock) is much more common than congestive heart failure. The latter is more likely to occur in patients with previous cardiac disease. Except for occasional instances of permanent heart block following diphtheria or of progressive heart failure due to myocardial involvement in schistosomiasis, chronic heart disease rarely results from any of the infections to be discussed. However, acute heart failure and unexpected deaths following certain infections have been attributed to myocardial involvement. During convalescence from many infectious diseases, dyspnea, precordial pain, extreme fatigability, symptoms resembling those of neurocirculatory asthenia are not infrequent. It is improbable that they are due to myocardial disease. Recent stress on microscopic lesions in fatal cases of acute infectious diseases (other than rheumatic fever, syphilis or diphtheria) and on the frequency of electrocardiographic changes tends to exaggerate the importance of myocardial involvement in these diseases.

THE HEART IN DIPHTHERIA

Incidence of Acute Myocarditis

Acute myocarditis is said to occur in 10 to 25 per cent of cases of diphtheria, the incidence being particularly high in epidemics with severe forms of the disease. But diphtheritic myocarditis is very rare in the United States because of the extreme reduction in the incidence of diphtheria and the early effective treatment. Myocarditis may complicate cutaneous[18] as well as faucial diphtheria and is often associated with cranial nerve involvement. Wesselhoeft[20] noted a mortality rate of 11.3 per cent in a series of 15,490 cases of diphtheria, 59.4 per cent of these deaths were due to acute myocarditis.

Pathogenesis of Cardiovascular Disturbances

The circulatory disturbances in cases of diphtheria are due to the action of the exotoxin of the Klebs-Loeffler bacillus and not to the microorganism itself. The cardiac damage observed microscopically is likewise due to toxic effects on the muscle fibers, but the myocardial changes have been attributed also to toxic damage to the smallest coronary vessels with secondary myocardial anoxia.[14]

Pathology

Fahr[13] described three types of change in the heart: (1) fatty degeneration, (2) myolysis and (3) interstitial inflammation. Severe fatty hyaline and other degenerative or necrotic changes in the muscle fibers occur near the end of the first and beginning of the second week.[13, 3, 16] Interstitial changes usually

represent a secondary reaction to the parenchymal damage and appear in the latter half of the second week of the disease[26] But interstitial myocarditis without parenchymal change has also been described[27] The interstitial inflammatory alterations consist of edema and focal or diffuse infiltrations of lymphocytes neutrophilic and eosinophilic leukocytes monocytes and fibroblasts The so-called toxic myolysis[12] denotes a solution of the muscle fibers the sarcolemma is seen to surround a clear or hyaline substance without cross striations or nuclei Reparative changes appearing during the second week are represented by fibroblasts granulation tissue young collagen fibers and later by well formed scars Scar formation is usually well established after three weeks[12]

CLINICAL FEATURES

Early Circulatory Disturbances

Acute circulatory failure may occur in the first few days Electrocardiographic changes are usually absent Tachycardia occurs commonly Cough and cyanosis are usually due to respiratory obstruction by a diphtheritic membrane and not to myocardial failure

Late (Convalescent) Cardiovascular Abnormalities

Near the end of the first and during the second week cardiovascular abnormalities may be due to an acute myocarditis Occasionally severe cardiovascular symptoms appear four to seven weeks after the onset of diphtheria particularly in cases of cutaneous diphtheria[13] The clinical evidences of diphtheritic myocarditis are (1) electrocardiographic changes (2) cardiac signs (3) cardiac shock and more rarely (4) congestive heart failure

Electrocardiographic Changes. Electrocardiographic abnormalities are usually the earliest evidence of acute myocarditis and have been noted by Burkhardt et al[8] in 20 per cent of 140 cases by Altschuler et al[2] in 24 per cent of 600 cases and even more frequently by other observers[3 5]

The earliest change is a mild saucer shaped depression of the ST segment[4] and by far the commonest change is a lowering or inversion of the T wave in two or more leads[2]

Although conduction disturbances are much less frequent they are more distinctive of diphtheritic myocarditis and denote a serious prognosis Complete heart block has been considered characteristic but prolongation of the P R interval and more severe grades of partial heart block have been described[6 8] Intraventricular conduction disturbances including bundle branch block occur as commonly as complete heart block[11 1] Since complete heart block in diphtheria may be associated with a normal or rapid ventricular rate as well as with the more usual bradycardia, it may be overlooked on physical examination As a rule the heart block persists less than a week Complete heart block is usually ominous All of the 11 patients with this disturbance in the series of Burkhardt et al[8] succumbed in Begg s[6] series 8 of 12 patients with complete heart block died Bundle branch block is similarly serious there was a fatal outcome in 4 of 6 cases observed by Begg[6] and in all 4 of those recorded by Cookson[11]

If the patient recovers the electrocardiographic abnormalities including the severe conduction disturbances usually disappear rapidly However bundle branch block or complete heart block said to have followed diphtheria has been reported as still present after intervals of between five and forty two years[18 6 20]

Among other electrocardiographic changes recorded in cases of diphtheria are sinus tachycardia or bradycardia transient extrasystoles and nodal rhythm paroxysmal tachycardias[6] atrial fibrillation following complete heart block,[24] atrial flutter with varying grades of heart block,[4] prolongation of the Q T interval[7] and postdiphtheritic ventricular fibrillation with recovery[17]

Cardiac Signs Tachycardia is usually present in the first week of diphtheria even when there is no myocardial involvement With the development of acute myocarditis there is often a gradual or sharp reduction in the heart rate which may result in a mild or pronounced *bradycardia* In the third week of the disease tachycardia may reappear in cases with myocarditis Heart rates below 40 indicate the presence of complete heart block but the latter may be associated with a normal heart rate or a slight tachycardia *Gallop rhythm* is an important sign of diphtheritic myocarditis with extensive myocardial damage and heart failure Occasionally there is *cardiac enlargement* Weakness of the first heart sound tic tac rhythm (embryocardia) and systolic murmurs have also been noted as evidence of myocarditis

Cardiac Shock

Extensive myocardial damage may result in a sharp diminution in cardiac output and produce the clinical picture of shock. The clinical syndrome of cardiac shock usually appears in the second week of the disease and is sometimes heralded by striking pallor, vomiting and abdominal pain. A grayish cyanosis, coldness of the extremities, complete apathy, collapse of the peripheral veins and a sharp fall in blood pressure are prominent features. Tachycardia and a small thready pulse are usual in shock but in the presence of complete heart block the pulse rate may be slow or relatively normal. Not infrequently the clinical picture of shock may result from peripheral circulatory failure rather than from cardiac damage.

Congestive Heart Failure. A moderate degree of congestive heart failure is usually associated with but overshadowed by the evidences of cardiac shock. The characteristic clinical picture of left- and right-sided failure with signs and symptoms of pulmonary congestion and of peripheral edema and venous engorgement, occurs very uncommonly. This is probably due to the fact that either the patient succumbs from cardiac shock if the damage to the heart is sufficiently severe or the myocardial changes regress if the patient survives. But I have seen a six year old boy who died with the typical clinical picture of congestive heart failure three weeks after the onset of an attack of diphtheria which was undiagnosed and untreated until his admission to the hospital just before death. His electrocardiogram showed severe changes in the QRS complex including low voltage notching, slurring W shape in lead I and a deep Q_4. The T waves were low and semi-inverted. The electrocardiographic appearance was that of a recent myocardial infarction.

Other Circulatory Abnormalities

Occasionally *intracardiac thrombi* are formed, especially in cases with subendocardial myocardial hemorrhage and inflammation which extend to the endocardium. These thrombi may be the source of emboli which produce isolated or repeated infarctions of the brain or lungs. Hemiplegia, cough and hemoptysis with pulmonary signs, and gangrene of an extremity have been observed.[9, 31]

Patients with complete heart block rarely suffer from epileptiform convulsions, syncope or other symptoms of the *Adams-Stokes syndrome*. Attacks of *angina pectoris* occur rarely. Late in the convalescent period, about the fourth to sixth week, patients may present a persistent tachycardia or a tachycardia induced by slight effort or at the end of the day. A *bacterial (diphtheritic) endocarditis* due to the Klebs-Loeffler bacillus occurs rarely.

DIAGNOSIS

The presence of acute myocarditis in a patient with diphtheria is indicated first by severe electrocardiographic abnormalities, especially complete heart block or bundle branch block. Clinically, a weakening or splitting of the first sound at the apex, gallop rhythm and cardiac enlargement usually denote an acute myocarditis. A severe myocarditis is revealed by the development of cardiac shock or congestive heart failure, usually in the second or third week of the disease.

PROGNOSIS

Acute myocarditis is a serious complication of diphtheria, accounting for most of the deaths in this disease after the first week. According to Place[3] and others[16, 4] the mortality rate varies between 50 and 60 per cent being almost 100 per cent in children between the ages of one and two, 50 per cent between two and ten, and 25 per cent among adults. In fatal cases death occurs usually in the first two weeks of the disease but occasionally later.

A poor prognosis is indicated by electrocardiographic evidence of heart block or bundle branch block and by certain clinical manifestations, such as a sudden reduction in heart rate with resulting bradycardia, persistent and marked tachycardia in the second or third week of the disease, gallop rhythm and especially the development of cardiac shock with or without congestive heart failure.

That diphtheritic myocarditis may lead to permanent fibrosis which predisposes to cardiac enlargement and congestive heart failure much later in life has been suggested but remains unproven.[27] On the other hand certain conduction disturbances developing during the active myocarditis may persist for many months or years or even permanently (p 388). Thompson, Golden and White[8] examined 100 persons who had had severe or moderately severe diphtheria from fifteen to twenty years previously; in none was there evidence of atrioventricular or intraventricular

block They concluded that there is no proof that diphtheria contributes to the later development of heart block

TREATMENT

The treatment of diphtheritic myocarditis is that of the underlying diphtheria The early and adequate use of diphtheria antitoxin and penicillin is most important Bed rest should be longer than in the uncomplicated case of diphtheria The treatment of shock is similar to that discussed under myocardial infarction (p 562)

SCARLET FEVER

Confusion as to the occurrence of heart disease during scarlet fever has arisen from a failure to distinguish three forms of cardiac involvement

1 Bacterial (hemolytic streptococcal) endocarditis pericarditis or myocarditis

2 Rheumatic heart disease (endo- myo-, pericarditis)

3 Benign (non bacterial) carditis due to scarlet fever per se

Bacterial or Suppurative Cardiac Disease

Rarely there is an acute bacterial endocarditis or a suppurative pericarditis secondary to hemolytic streptococcal bacteremia The latter arises from suppurative complications such as a purulent arthritis osteomyelitis or more often a sinus thrombosis following otitis media and mastoiditis In addition to endocarditis or pericarditis there may be foci of necrosis in the myocardium or abscesses of miliary or larger size Embolic gangrene of an extremity associated with scarlet fever[39] is suggestive of a complicating acute streptococcal endocarditis

Scarlet Fever and Rheumatic Heart Disease

This relationship was discussed above (p 808) where it was concluded that scarlet fever like other hemolytic streptococcal infections could precipitate or reactivate rheumatic fever with subsequent rheumatic heart disease When chronic cardiovascular heart disease follows scarlet fever the pathologic lesions are identical with those of rheumatic heart disease

It is well known that scarlet fever may be followed shortly by arthritis which in turn may be complicated by endocarditis and chronic heart disease It is essential to distinguish two forms of non suppurative arthritis associated with scarlet fever First there is a true scarlatinal synovitis or arthritis such as occurs with other infections which is unrelated to rheumatic fever and is never followed by heart disease Second there may appear a true rheumatic polyarthritis usually in subjects with preexisting rheumatic heart disease in whom rheumatic infection is reactivated by the scarlet fever In general, benign scarlatinal arthritis occurs earlier usually between the fourth and tenth days of the disease rheumatic arthritis usually appears in the third or fourth week of the disease The benign arthritis, like other forms of infectious arthritis frequently involves the joints of the fingers and hands while these joints are uncommonly affected in rheumatic fever

SCARLATINAL (BENIGN) CARDITIS

This refers to non specific electrocardiographic clinical and pathologic changes similar to those observed in many other infectious diseases Such cardiac complications were noted in 106 (6 per cent) of 1770 cases studied by Rosenbaum[37] A definite verrucous endocarditis with permanent valvular damage has been reported rarely[40] but the rheumatic or bacterial origin of the verrucae must be considered Similarly, occasional instances of pericarditis attributed directly to scarlet fever were probably due to an activation of rheumatic fever or to a complicating streptococcal bacteremia Scarlet fever does not appear to produce a chronic form of heart disease independent of rheumatic or bacterial (suppurative) complications

Pathology

As a rule there are no significant myocardial lesions or only mild degenerative changes such as cloudy swelling of the muscle fibers Occasionally there are mild focal or diffuse interstitial cellular infiltrations of lymphocytes and plasma cells and less often of neutrophilic or eosinophilic leukocytes But some observers have claimed that the myocardial lesions of scarlet fever are more severe and occur frequently[3, 35] Great care is necessary not to misinterpret the myocardial lesions of diphtheria for the latter disease may occur coincidentally in about one fifth of the cases of scarlet fever and may be unrecognized clinically

Clinical Features

The so-called scarlet fever heart has been diagnosed near the end of the first week of the disease or during convalescence[35] on the

Cardiac Shock

Extensive myocardial damage may result in a sharp diminution in cardiac output and produce the clinical picture of shock. The clinical syndrome of cardiac shock usually appears in the second week of the disease and is sometimes heralded by striking pallor, vomiting and abdominal pain. A grayish cyanosis, coldness of the extremities, complete apathy, collapse of the peripheral veins and a sharp fall in blood pressure are prominent features. Tachycardia and a small, thready pulse are usual in shock, but in the presence of complete heart block the pulse rate may be slow or relatively normal. Not infrequently the clinical picture of shock may result from peripheral circulatory failure rather than from cardiac damage.

Congestive Heart Failure. A moderate degree of congestive heart failure is usually associated with but overshadowed by the evidences of cardiac shock. The characteristic clinical picture of left and right sided failure with signs and symptoms of pulmonary congestion and of peripheral edema and venous engorgement occur very uncommonly. This is probably due to the fact that either the patient succumbs from cardiac shock if the damage to the heart is sufficiently severe, or the myocardial changes regress if the patient survives. But I have seen a six year old boy who died with the typical clinical picture of congestive heart failure three weeks after the onset of an attack of diphtheria which was undiagnosed and untreated until his admission to the hospital just before death. His electrocardiogram showed severe changes in the QRS complex including low voltage, notching, slurring, W shape in lead I, and a deep Q_4. The T waves were low and semi-inverted. The electrocardiographic appearance was that of a recent myocardial infarction.

Other Circulatory Abnormalities

Occasionally *intracardiac thrombi* are formed, especially in cases with subendocardial myocardial hemorrhage and inflammation which extend to the endocardium. These thrombi may be the source of emboli which produce isolated or repeated infarctions of the brain or lungs. Hemiplegia, cough and hemoptysis with pulmonary signs, and gangrene of an extremity have been observed.[9, 10]

Patients with complete heart block rarely suffer from epileptiform convulsions, syncope or other symptoms of the *Adams Stokes syndrome*. Attacks of *angina pectoris* occur rarely. Late in the convalescent period, about the fourth to sixth week, patients may present a persistent tachycardia, or a tachycardia induced by slight effort or at the end of the day. A *bacterial (diphtheritic) endocarditis* due to the Klebs-Loeffler bacillus occurs rarely.

DIAGNOSIS

The presence of acute myocarditis in a patient with diphtheria is indicated first by severe electrocardiographic abnormalities, especially complete heart block or bundle branch block. Clinically, a weakening or splitting of the first sound at the apex, gallop rhythm and cardiac enlargement usually denote an acute myocarditis. A severe myocarditis is revealed by the development of cardiac shock or congestive heart failure, usually in the second or third week of the disease.

PROGNOSIS

Acute myocarditis is a serious complication of diphtheria, accounting for most of the deaths in this disease after the first week. According to Place[3] and others[14, 31] the mortality rate varies between 50 and 60 per cent, being almost 100 per cent in children between the ages of one and two, 50 per cent between two and ten, and 25 per cent among adults. In fatal cases death occurs usually in the first two weeks of the disease but occasionally later.

A poor prognosis is indicated by electrocardiographic evidence of heart block or bundle branch block and by certain clinical manifestations, such as a sudden reduction in heart rate with resulting bradycardia, persistent and marked tachycardia in the second or third week of the disease, gallop rhythm and especially the development of cardiac shock with or without congestive heart failure.

That diphtheritic myocarditis may lead to permanent fibrosis which predisposes to cardiac enlargement and congestive heart failure much later in life has been suggested but remains unproven.[7] On the other hand certain conduction disturbances developing during the active myocarditis may persist for many months or years or even permanently (p. 388). Thompson, Golden and White[9] examined 100 persons who had had severe or moderately severe diphtheria from fifteen to twenty years previously; in none was there evidence of atrioventricular or intraventricular

ally, as a rule in elderly patients and those with underlying heart disease The electrocardiographic changes occur chiefly after defervescence, but also before and during the crisis

Size of the Heart

The size of the heart was studied by Levy[49] by means of successive roentgenograms during the course of the disease He reported a significant enlargement in 61 9 per cent of 71 cases It is often difficult to exclude the factor of abdominal distention with elevation of the diaphragm in modifying the position and apparent size of the cardiac silhouette Associated cardiac failure and sodium water retention in the course of lobar pneumonia may account for definite enlargement of the heart in some cases

Circulatory Measurements

The *blood pressure* remains fairly constant but usually falls sharply if acute circulatory failure develops[5]

The *venous pressure* is usually normal but may be elevated especially in persons with preexistent heart disease and congestive heart failure[47]

The *circulation time* is usually normal but was prolonged in about 10 per cent of 75 cases studied by Hitzig et al[47] and in about 25 per cent of those observed by Sigler et al[44] The prolonged circulation times were encountered more often in those who succumbed than in those who recovered and in those beyond the age of 45 than in those below that age

The *circulating blood volume* was found to be normal in cases without circulatory failure[47]

The *cardiac output* was found to be increased during the febrile stage below normal after the crisis and back to normal only after one to three weeks[48]

Congestive Heart Failure and Acute Circulatory Failure

Acute circulatory failure (shock) occurs most often in very toxic cases of lobar pneumonia especially those associated with bacteremia and consolidation of multiple lobes It usually occurs at the height of the disease just before the crisis occasionally earlier and less frequently after the crisis The clinical picture is that of apathy or restlessness and disorientation weak rapid pulse cold extremities grayish cyanosis collapsed peripheral veins and a terminal drop in blood pressure in fatal cases Although the occurrence of shock in pneumonia is of ominous significance recovery is not rare

Congestive heart failure is less common than shock, it usually occurs only in elderly patients and those with preexistent organic heart disease Left sided heart failure is difficult to recognize in the presence of pneumonia but the diagnosis may be aided by finding a prolonged circulation time Pulmonary edema may occur in severe and fatal cases of pneumonia due to toxic damage and increased permeability of the pulmonary capillaries In such instances of pulmonary edema not due to left sided heart failure the circulation time is normal[47] Right sided heart failure is revealed by venous congestion increased venous pressure and moderate hepatic enlargement but peripheral edema is usually absent or occult

Treatment of Circulatory Complications

The most important measures are the early and adequate use of chemotherapy and antibiotics to control the underlying infection Theoretical considerations and clinical results[49] suggest that digitalis should not be administered in uncomplicated cases of lobar pneumonia However it should be given if there is definite evidence of congestive heart failure with or without atrial fibrillation

Atypical Pneumonia

In a series of 321 cases of atypical pneumonia 3 7 per cent revealed changes in the RST segments flattening or inversion of T waves and prolongation of the P R interval or of the QRS complex in the electrocardiogram[51] The changes have been interpreted as evidence of myocardial involvement, in some instances they are identical with those described under acute pericarditis

INFLUENZA

The influenza bacillus causes occasional cases of *bacterial endocarditis* Rarely it may produce a fibrinous or purulent *pericarditis*

Myocardial changes are uncommon and mild They consist of cloudy swelling of the muscle fibers and focal or diffuse collections of round cells and histiocytes[61] Rarely there are more severe destructive changes of muscle fibers[62]

Cardiovascular disturbances are uncommon Acute circulatory failure may occur in toxic cases and rarely congestive heart failure[59] During convalescence weakness precordial pain, palpitation and dyspnea are common

Electrocardiographic Changes A prolongation of the P-R interval is not uncommon and occasionally there is more severe partial heart block [62] Complete heart block has also been reported This may be associated with Adams Stokes syndrome and may disappear after a few days [illegible]

Sinus bradycardia is common during convalescence Extrasystoles, sinoatrial block, wandering pacemaker, nodal rhythm, tall notched P waves and abnormalities of the T wave and S T interval have also been observed occasionally [60] Occasional death from acute coronary thrombosis has been noted in young adults following an attack of influenza

TYPHOID FEVER

A bacterial endocarditis or pericarditis due to Eberth's bacillus is extremely rare Myocardial lesions are infrequent mild and non specific

Pathology of the Myocardium

Recent studies have disclosed merely cloudy swelling of the muscle fibers, a mild degenerative change seen in many infections Very infrequently there is an interstitial myocarditis with an infiltration of round cells and polymorphonuclear leukocytes

Electrocardiographic Abnormalities

Electrocardiographic abnormalities occur in the majority of cases of typhoid fever either during the acute illness or during convalescence [illegible] [illegible] [67] The commonest changes are *flat, diphasic or inverted T waves* in two or more leads These abnormalities usually appear in the third or fourth week of the illness and return to normal one to three weeks after the onset of convalescence In 23 of 35 patients with T wave abnormalities Rachmilewitz and Braun[67] observed [illegible] rapid normalization of the electrocardiogram following the administration of niacin

A prolongation of the P R interval has been noted by some observers, especially during convalescence, but this was found only once in Mainzer's[65] series of 106 cases Occasionally complete heart block has been recorded [64]

Relative bradycardia is characteristic of the febrile stage True bradycardia and sinus arrhythmia are common during convalescence, but tachycardia may appear in the third to fifth week of the illness as an evidence of myocarditis, effort syndrome or of complications such as intestinal hemorrhage or perforation

Clinical Circulatory Disturbances

Acute circulatory failure (shock) occurs occasionally as a result of toxemia, dehydration or hemorrhage I have seen a boy, aged 15, admitted on the fifth day of his illness with evidence of extreme dehydration and shock The heart rate was 140, the pulse thready, the heart sounds weak and tic tac in quality The blood pressure was too low to measure accurately He recovered after transfusions

Congestive heart failure [illegible] extremely rare except in cases of preexisting heart disease In a woman of 25 whom I observed, tachycardia gallop rhythm, cardiac enlargement and hepatomegaly were noted five weeks after the onset of typhoid fever The electrocardiogram revealed inversion of the T wave in leads I, II and IV These changes disappeared only after three months, while the cardiac abnormalities did not disappear until four months after they were first noted

MENINGOCOCCUS INFECTIONS

The meningococcus may produce an *acute or subacute bacterial endocarditis* with or without meningitis

Pericarditis also may result from a meningococcemia and is usually associated with meningitis But in the case reported by Orgain and Poston [illegible] meningococcus pericarditis with a large effusion and tamponade of the heart occurred without a history of preceding meningococcemia or meningitis Herrick[70] observed pericarditis 12 times among 280 cases of meningococcus meningitis, 6 were fibrinous and 6 were associated with purulent or seropurulent effusions of 30 to 640 cc Conklin[68] reported a case in which there was a turbid effusion of 1500 cc Recovery may occur spontaneously or with the aid of pericardial paracentesis, sulfonamides and penicillin

Myocarditis was observed post mortem in 111 of 256 cases of meningococcemia [69] There are microscopic foci of interstitial and perivascular cellular infiltrations Occasionally there are microscopic or macroscopic abscesses with destruction of muscle fibers [72] [73] Intracellular and extracellular gram negative diplococci have been demonstrated

Isolated electrocardiographic [illegible]hanges have been noted In one case of prolonged meningococcemia without meningitis which I observed there was a transient prolongation of the P R interval to 0 24 second Distinct R T eleva

tions should suggest the presence of pericarditis

UNDULANT FEVER

Infections with brucella organisms rarely involve the heart a *bacterial endocarditis* being the most frequent cardiac complication (p 876) This occurred in 1 per cent of 300 cases studied by Hardy [77]

Pericarditis with effusion also occurs rarely and was noted twice by Hughes[78] and once in association with endocarditis by Hardy [77]

The myocardium may disclose an infiltration of small and large round cells and moderate cloudy swelling and granular degeneration of the myocardial fibers [75]

Electrocardiographic abnormalities found by Rubegni[79] included elevations or depressions of the RS T interval and low isoelectric or inverted T waves Usually the electrocardiographic changes revert rapidly to normal but I have seen inverted T waves persist for two months Atrial fibrillation has been noted [74] Acute circulatory failure occurs occasionally [76]

TUBERCULOSIS

Tuberculosis may be associated with extensive pulmonary changes causing increased pulmonary vascular resistance pulmonary hypertension and chronic cor pulmonale (Chapter 39)

Tuberculosis may involve the heart directly most often causing a tuberculous pericarditis with effusion (p 602) with or without compression of the heart (p 609)

Tuberculosis of the myocardium is rare although more than 200 cases have been reported [85] Custer and Charr[81] discovered an incidence of 0 44 per cent in about 15 000 cases of tuberculosis The myocardium is most often involved by an extension of contiguous pericardial lesions but occasionally by infection from the blood stream Three types of lesions have been described the miliary the large nodular and the diffusely infiltrating [83] The latter may cause widespread destruction as in the case of Bellet et al ,[illegible] in which it extended from the pericardium through the ventricular myocardium to reach the endocardium The large nodular or the infiltrating lesions may rupture into the cardiac cavity and cause a disseminated tuberculosis The infiltrating type may involve the atria and cause atrial fibrillation The large nodular lesions are usually found in the atria and may form tumor like nodules termed tuberculoma [illegible] They may be asymptomatic or cause obstruction to blood flow

Myocardial tuberculosis is usually asymptomatic Involvement of the atria may result occasionally in atrial premature beats atrial flutter or fibrillation [88] These arrhythmias in a patient with tuberculosis especially tuberculous pericarditis should suggest atrial involvement [8] Paroxysmal ventricular tachycardia has been recorded as occurring with myocardial tuberculosis [87] Congestive heart failure was attributed to extensive myocardial scarring secondary to tuberculous myocarditis in one of Wilbur s[89] cases

Endocardial tuberculosis is the rarest form of cardiac tuberculosis The endocardium may be involved by extension of pericardial or myocardial lesions or as part of a disseminated miliary tuberculosis Rarely isolated tuberculous valvular endocarditis has been reported [84]

ACTINOMYCOSIS

Actinomycosis rarely affects the heart As a rule the pericardium is affected by extension of neighboring lesions in the lungs, mediastinum or other thoracic structures [6] Very rarely the myocardium is invaded by way of the general blood stream or coronary arteries and occasionally by extension of pericardial actinomycosis Bacterial endocarditis due to Actinomyces bovis has been reported the valvular lesion being the only lesion in the heart

The pericardium reveals necrotizing suppurative and sclerotic lesions [90] There is usually a seropurulent yellowish cloudy fluid which is occasionally hemorrhagic The pericardial layers become thickened and adherent The fibrocaseous material extends to the myocardium and even to the endocardium producing necrosis and abscesses and masses of various sizes These masses may obstruct a valvular orifice,[91] or may break into the cardiac cavities or coronary veins and cause a dissemination of actinomycosis

Despite amazingly extensive lesions there may be no clinical symptoms referable to the heart As a rule the cardiac symptoms when present are overshadowed by those referable to the primary disease Involvement of the heart may be suspected in a patient with actinomycosis if there are evidences of pericarditis, arrhythmias or congestive heart fail-

ure In Uhr's[93] case the entire clinical picture of bacterial endocarditis was due to the valvular lesion

VIRUS INFECTIONS

Measles

Significant electrocardiographic changes were reported in 20 of 106 patients with measles T wave abnormalities and prolonged atrioventricular conduction was observed [105]

Infectious Hepatitis

Electrocardiographic changes consisting of T wave depressions were found in 9 of 11 cases studied by Dehn et al [96] Christiansen and Warburg[97] described a depression of heart rate and negative or isoelectric T waves in leads II and III Foci of myocardial necrosis and diffuse serous inflammation have been described [104a]

Infectious Mononucleosis

Clinical electrocardiographic and pathologic evidence of cardiac involvement in infectious mononucleosis has been noted by Houck [107] The electrocardiogram disclosed low voltage of the QRS and T waves in 4 to 100 cases and in 2 of these the T wave was inverted [101] In one patient there was a pericardial rub and in another a pericardial effusion Abnormal electrocardiograms were observed in 23 per cent of 223 patients with infectious mononucleosis [118] In necropsied cases sparse collections of mononuclear cells and lymphocytes have been noted about blood vessels or elsewhere in interstitial tissue [98]

Influenza A

Two cases of non bacterial myocarditis in one of which death resulted from heart failure were recorded by Finland et al [103] Acute congestive heart failure was reported by Borden [95] There may be necrosis of muscle fibers with extensive cellular infiltrations

Epidemic Parotitis (Mumps)

T wave changes and a prolongation of the P R interval were described by Wendkos and Noll [120] Rosenberg[113] observed electrocardiographic abnormalities in 15 per cent of 104 cases usually during the fifth to tenth day of the illness There were inversion of T waves, elevation of the ST in CF_4, biphasic or inverted P waves prolongation of the P R interval and 1 case each of partial and complete heart block Bengtsson and Ohrndal[94] observed electrocardiographic changes in 4 4 per cent of 564 cases of mumps These consisted of S T segment depressions low or negative T waves and atrioventricular block In a case reported by Felknor and Pullen[102] there was clinical evidence of congestive heart failure including gallop rhythm, tachycardia enlargement of the liver and râles at the bases of the lungs

Acute Anterior Poliomyelitis

Myocarditis has been found in 40 to 90 per cent of necropsied cases of poliomyelitis [117, 119] Electrocardiographic changes were found in 14 per cent of 467 patients [104] and in 84 of 181 patients in another series [109] They occur early and may persist several weeks Prolongation of the P-R interval ST segment deviations flat or inverted T waves and prolonged Q T interval are the abnormalities encountered [illegible] [110, 111] Hypertension may develop with bulbar poliomyelitis Pulmonary edema may be due to cerebral disease or left heart failure Bulbar poliomyelitis is commonly associated with a syndrome of cardiovascular collapse due to involvement of the medulla and an interstitial myocarditis [106] Absence of this syndrome in cases of spinal paralysis despite the presence of myocarditis, indicates that the clinical picture is due chiefly or exclusively to disease of the medulla The syndrome occurs within one or two days after the onset of bulbar paralysis, and is characterized by high temperature, anxiety, tachycardia and shock Pulmonary edema is a common terminal feature The inhalation or insufflation of 100 per cent oxygen may correct arterial anoxemia and shock and reverse the downhill clinical course [99a] Pathologically microscopic perivascular and interstitial cellular infiltration of lymphocytes, plasma cells and especially neutrophilic polymorphonuclear leukocytes and edema are occasionally observed [116, 99, 100, 112, 108] Isolation of the poliomyelitis virus from the heart in fatal cases of poliomyelitis has been reported [108]

Other Viral Diseases

Virus myocarditis has also been reported in connection with Coxsackie B virus [illegible] varicella psittacosis, dengue epidemic encephalitis and yellow fever [114] In three cases of encephalitis with electrocardiographic changes indicating myocardial damage, the disease was attributed to viruses and was interpreted as an entity similar to encephalo myocarditis observed in animals [115]

RICKETTSIAL DISEASES

Typhus Fever

Gore and Saphir[121] found pathologic evidence of myocarditis in 23 of 48 fatal cases of epidemic typhus and in 9 to 19 cases of Rocky Mountain spotted fever Herzog and Rodriguez[1 2] described (1) vascular changes (2) perivascular and subendocardial interstitial nodules and (3) diffuse interstitial inflammatory changes in 97 per cent of 103 hearts in an epidemic of typhus fever in Chile Capillary and precapillary vessels undergo endothelial proliferation occasional necrosis inflammation of the vessel wall occasional mural thrombosis and a pericapillaritis

Acute circulatory failure (shock) may occur in the middle of the second week or earlier in toxic cases[1 4] Gallop rhythm is occasionally heard but frank congestive heart failure is rare

Electrocardiogram Low isoelectric diphasic or inverted T waves were observed in 72 per cent of 85 cases and a prolongation of the P R interval in 48 per cent[1 8] In one case there was a right bundle branch block and at post mortem examination the heart presented multiple small infarcts due to necrotizing thromboarteritis of the small vessels In patients recovering from typhus fever the electrocardiographic abnormalities disappear and there is no chronic heart disease

Scrub Typhus (Tsutsugamushi Fever)

Pathologic evidence of myocarditis was found by Gore and Saphir[121] in all of 227 cases of scrub typhus Endothelial proliferation and perivascular infiltrations of round cells and necrosis of muscle fibers are the commonest findings[1 4] Minor electrocardiographic abnormalities include ST segment depression or elevation and low T waves[1 2] In 5 or 6 patients with cardiac decompensation Hollander[1 3] found low amplitude of the QRS complexes

TRICHINOSIS

Trichinosis is not infrequently associated with pathologic and electrocardiographic evidence of myocarditis[125]

Pathology There are interstitial and perivascular collections of eosinophilic and neutrophilic leukocytes lymphocytes and occasional mononuclear and plasma cells associated with focal necrosis of the muscle fibers[130]

The Trichinella spiralis was observed in the myocardium in the case of Zenker[137] and in one of Terry and Work[134] In Spink's[135] case the larvae were found after digestion of the heart muscle with artificial gastric juice although not demonstrable on histologic examination As a rule however the larvae are not observed in the heart It is believed on experimental grounds that the myocardial changes are caused by the presence of the trichinella larvae but that they do not become encysted in the heart and either die early or migrate elsewhere[129 131] Therefore they are not observed if death occurs after the first week or two The myocarditis may represent a fixed tissue reaction to antigenic factors of T spiralis

Clinical evidence of myocarditis is usually absent Occasionally there is acute circulatory failure (shock) I have twice noted gallop rhythm In these two cases there were other evidences of congestive heart failure including dyspnea venous engorgement and peripheral edema Terry and Work[134] reported a verified case of trichinosis myocarditis which was mistaken for rheumatic fever because of the combination of arthritis fever epistaxis and a prolonged P R interval in the electrocardiogram

Electrocardiographic changes were observed in 2 of 44 cases of Beecher and Amidon[128] in 6 of 18 by Spink[135] in one third of the cases studied by Cushing[1 7] and in 21 per cent of 114 cases observed by Solarz[136] Flattening or inversion of the T waves occurs in two or more limb leads especially lead II or leads I and II and in the precordial leads Occasionally upward convexity of the RS T segment and cove plane type of T inversion simulate the changes seen in acute myocardial infarction[127 132] A prolongation of the P R interval low voltage of the QRS and intraventricular block are noted occasionally The electrocardiographic changes appear in the second week of the disease and disappear within a month or two but a prolongation of the QRS may persist[134]

Marked improvement in fever and clinical course of severe trichinosis with myocardial involvement has followed adrenocorticoid therapy[128 133]

ECHINOCOCCUS INFECTIONS

Cardiac involvement by echinococcus (hydatid) cysts occurs rarely and in about 0 5 to 1 per cent of all echinococcus disease Dévé[139]

analyzed 137 cases of cardiac echinococcus disease, in 83 per cent of which the primary echinococcus infestation was limited to the heart while in the remainder the cardiac cyst coexisted with one or more primary cysts in other organs, particularly the liver Any chamber of the heart may be involved with cysts, which vary in size from that of a cherry to that of an orange A review of echinococcus cyst of the left side of the heart was presented by Peters and associates [144]

In the absence of complications there are no symptoms, the cysts being found accidentally at postmortem examination Some patients suffer from palpitation, arrhythmias, attacks of dyspnea or precordial oppression Local effects of large cardiac cysts include peculiar murmurs , enlargement of the cardiac silhouette or bizarre shadows in the cardiac contours on roentgenologic examination Involvement of the interventricular septum has caused intermittent heart block with Adams Stokes syndrome [141] Pericarditis, polyserositis and constrictive pericarditis may occur, an instance of the latter having been cured by surgery

Single or recurrent rupture of a cyst into the cardiac cavity may cause (a) sudden death from anaphylactic shock or obstruction of a valvular orifice, (b) anaphylactoid reactions with anxiety vomiting and shock (c) embolism of cysts with obstruction of the vessels to the brain lungs abdominal viscera or extremities [145] Recovery may be complicated by hemiplegia gangrene or renal shutdown Rupture of the cysts into the pericardium occurs occasionally with inflammatory reaction and adherent pericardium

Diagnosis may be suggested by the combination of (a) echinococcus cyst elsewhere, blood eosinophilia and positive skin or serologic tests for echinococcus, together with (b) suggestive roentgen ray evidence of calcified cysts in the heart, bizarre shadows in the cardiac silhouette, peculiar cardiac murmurs or a sudden anaphylactic shock like syndrome with or without embolization Diagnosis is important because of the possibility of surgical treatment An echinococcus embolism of the axillary artery was removed by Kohler [142] In several cases cardiac echinococcus disease was diagnosed during life [139] In one case the diagnosis was made roentgenographically and treated successfully by operation [143]

TRYPANOSOMIASIS (CHAGAS' DISEASE)

This is a common South American disease caused by the Trypanosoma cruzi and transmitted by a bedbug vector, the Panstrongylus magistus [146] It occurs as an acute generalized disease in which the myocardium is almost always involved, and as a chronic disease with predominant cardiac manifestations [147] In the acute form there are diffuse myocardial lesions with extensive destruction of muscle fibers associated with a mononuclear interstitial myocarditis In the chronic form there is a predominant interstitial myocarditis with infiltration of lymphocytes plasma cells mononuclears and macrophages and diffuse fibrosis All parts of the heart are involved

The acute form of the disease is dominated by generalized evidences of toxemia and disseminated lesions, but sudden death may result from cardiac involvement The chronic form is characterized by insidious onset, profound weakness, palpitation and precordial pain, dyspnea on effort, cardiac enlargement and all the objective evidences of progressive congestive heart failure The clinical picture may simulate coronary artery disease [150] Syncope occurs commonly and may be due to complete heart block Sudden death occurs frequently A special characteristic of the disease is the frequency of all forms of arrhythmias and conduction disturbances [148, 151] These include marked bradycardia, partial and complete heart block premature contractions atrial flutter and fibrillation and right bundle branch block [149] The QRS complexes are of low voltage Rosenbaum and Alvarez[152] in Buenos Aires observed electrocardiographic abnormalities in 113 (86 9 per cent) of 130 cases of the chronic form of Chagas' disease Right bundle branch block occurred in 5 , per cent ventricular extrasystoles in 53 9 per cent, primary T wave changes in 42 4 per cent P wave abnormalities in 23 per cent and left ventricular enlargement in 22 1 per cent

CARDIAC DISEASE DUE TO OTHER INFECTIONS, INTOXICATIONS, DRUGS OR PHYSICAL AGENTS

Electrocardiographic or pathologic evidence of myocardial involvement has been described in a variety of other infection among them focal infections,[153] bronchiectasis and a number of bacterial infections besides those specifically discussed Pericarditis in

cluding constrictive pericarditis due to Pasteurella tularensis has been noted[169] (p 609) Electrocardiographic changes and evidence of myocardial pericardial and endocardial involvement have been reported in Reiter's disease [173, 171, 165] Myocarditis pericarditis or endocarditis has also been noted occasionally in infections with other higher bacteria yeasts or fungi such as coccidioidomycosis [167] blastomycosis torulosis toxoplasmosis [172] histoplasmosis[17, 174] and sarcosporidia [150] Schistosomiasis (bilharziasis) secondarily causes cor pulmonale by producing an extensive obliterating pulmonary endarteritis (p 982) Rarely an amebic pericarditis complicates an amebic abscess of the left side of the liver [156] Myocardial lesions are occasionally observed in malaria as a result of plugging of the coronary capillaries by erythrocytes involved by malarial parasites [170]

Myocardial lesions have been attributed to the metabolic toxins associated with uremia (p 994) and those associated with extensive burns [156] serum sickness [199] and cutaneous lesions [134] Myocardial infarction has been reported during or shortly after serum sickness a wasp sting administration of tetanus antitoxin penicillin and fever therapy [176] Considerable interest has been aroused by the finding of severe interstitial myocarditis following the experimental or clinical administration of sulfonamides [191, 180] A case of eosinophilic and giant cell granulomatous myocarditis associated with exfoliative dermatitis was attributed to penicillin hypersensitivity [179]

Phosphorus poisoning may produce intense fatty degeneration of the heart and electrocardiographic abnormalities [181] but the clinical picture is dominated by concomitant hepatic damage *Carbon monoxide poisoning* will be discussed (p 1093) Cardiac abnormalities due to overdosage with digitalis (p 265) and quinidine (p 370) have also been discussed Myocardial necrosis and calcification have been observed following poisoning with bichloride of *mercury* Acute interstitial myocarditis has been described in a case of exfoliative dermatitis following arsphenamine administration [177] *Emetine* causes inversion of the T waves in two or more leads occasional changes in the QRS complex dyspnea tachycardia apical systolic murmurs and even gallop rhythm [180, 170] De Cossio[18] described T wave inversions in the precordial leads in all patients and Q T prolongation in 90 per cent of those receiving emetine appearing usually one week after administration of the drug is begun The electrocardiogram may resemble or indicate that of myocardial infarction with respect to RS T elevations and T wave inversions [158a] [illegible] Fatal myocarditis due to emetine has been reported [156]

Deep ST depressions or T wave inversions were noted in electrocardiograms of patients receiving tetraethylthiuram disulfide (Antabuse) therapy for alcoholism at the height of an alcohol test reaction [183] This was interpreted to denote latent coronary insufficiency or myocardial anoxia and was occasionally associated with a fall in blood pressure and a shock like picture

Myocardial lesions have also been noted following deep roentgen ray therapy to organs adjacent to the heart [186]

Chapter 37

THE HEART IN HYPERTENSION AND RENAL DISEASE

THE HEART IN HYPERTENSION

HYPERTENSION AND HYPERTENSIVE HEART DISEASE

Hypertensive heart disease is generally regarded as the commonest form of cardiac affection. Nevertheless the exact kinship between hypertension and heart disease is obscure and the delineation of hypertensive heart disease as a pure etiologic entity, independent of other forms of heart disease, is ill defined.

The causal relationship of hypertension to heart disease is based first of all on the frequency with which the two conditions are associated.[53] In a series of over 30 000 autopsies with 4700 cardiovascular deaths about 45 per cent of the latter were due to hypertensive heart disease.[33] The course of hypertension also supports its relationship to heart disease, for at least 60 to 75 per cent of hypertensive patients ultimately succumb from cardiac complications, especially heart failure.[11, 53, 149, 198] Finally it is believed that the physiologic disturbances associated with hypertension are such as to impose a serious strain on the heart (p 927). In summary the concept of a form of heart disease due to hypertension, per se, is based on (1) the very high incidence of hypertension in cases of heart disease, (2) the predominant frequency of ultimate cardiac disease in hypertensive patients, and (3) physiologic evidence that hypertension increases the work and otherwise strains or impairs cardiac function.

Hypertensive and Coronary (Atherosclerotic) Heart Disease

The exact causal relationship between hypertension and heart disease is obscured by two types of data.

(1) There is a lack of correlation in most cases between the severity and duration of hypertension and the development of cardiac complications.

(2) Hypertension is associated with a high incidence of coronary atherosclerosis. On the one hand Clawson,[3] in a necropsy study of about 1000 cases of coronary atherosclerotic heart disease, found that hypertension had been present in about 70 per cent. Conversely coronary sclerosis has been found in 90 per cent of hearts of persons dying with hypertension.[■] The relative importance of coronary atherosclerosis and hypertension in producing clinical heart disease is suggested by the clinicopathologic observations of Averbuck.[7] In two similar groups of hypertensive cases which came to autopsy, significant coronary atherosclerosis was found in 85 per cent of those with clinical heart disease and in only 10 per cent of those without heart disease.

Careful clinical and pathologic study of the problem over many years has impressed me with the predominant importance of coronary atherosclerosis in determining the manifestations of so-called hypertensive heart disease. This concept does not exclude any causal relationship between hypertension and the coronary atherosclerosis or the possibility of some common mechanism. Nor does it exclude the mechanical or other effects of hypertension on the heart which increase its susceptibility to injury by means of a deficient coronary blood supply.

Occasionally, and particularly in the experience of coroners, sudden death in hypertensive individuals is associated with pronounced cardiac hypertrophy and heart weight exceeding 400 gm, without significant coronary disease. In such cases the cardiac disease and sudden death are attributed exclusively to hypertension, in the absence of any other discoverable cause. In cases of malignant hypertension heart failure develops frequently in the last stages while coronary atherosclerosis is usually not severe. The heart failure may be

attributed to the strain of the hypertension and the consequent pronounced cardiac hypertrophy, but renal impairment in the excretion of sodium and water may also be an important causative factor

Systolic and Diastolic Hypertension

The clinical features and complications which characterize the disease hypertension or essential hypertension appear to be related to an elevated diastolic blood pressure rather than an elevated systolic blood pressure As a rule the systolic blood pressure *also is elevated when there is diastolic hypertension* but systolic hypertension may occur without elevation of the diastolic pressure In older individuals especially beyond the age of 60 the systolic pressure and the pulse pressure quite commonly increase although the diastolic pressure remains relatively unaltered It is believed that this rise in systolic pressure is related to atherosclerosis of the aorta and diminished elasticity of this large vessel Although a rise in the systolic pressure is usually associated with an increase in mean pressure and therefore in the work of the heart alone it appears to be of little significance in the development of clinical heart disease or of renal or cerebral impairment

NORMAL BLOOD PRESSURE AND HIGH BLOOD PRESSURE (HYPERTENSION)

There is no universal agreement as to the dividing line between normal and high blood pressure On the basis of various measurements of blood pressure in normal individuals follow up studies of military personnel and mortality data of life insurance companies I have always regarded a persistent elevation of the diastolic blood pressure above 90 mm Hg as representing diastolic hypertension However in individuals past the age of 50 diastolic blood pressures up to 95 or even 100 mm Hg were considered as probably normal Corresponding to these diastolic pressures a systolic pressure of 150 mm Hg or above was regarded as representing systolic hypertension in individuals below the age of 50 Beyond that age systolic pressure of 160 to 170 mm Hg were commonly regarded as normal More recently studies by Master and his associates[1,4] Hamilton Pickering and associates[80] and others have indicated that there is a progressive rise of diastolic as well as systolic pressure with age and that the range of normal blood pressure[7] is higher than the figures just stated Actually the blood pressures found by these observers represent the *frequency distribution of* blood pressure levels among men and women at various ages obtained under the particular conditions of their observations[179] Whether the blood pressures of the majority of individuals of a given sex and in a given age range thus obtained represent *normal* blood pressures remains to be determined

The determination of the arterial blood pressure and the evaluation of normal blood *pressure versus hypertension are* beset by at least three difficulties

1 The Accuracy of the Determined Blood Pressure

This need not be a significant problem for the indirect method of blood pressure determination using auscultation and the sphygmomanometer is quite satisfactory and accurate when performed with care There is reasonable agreement between direct intra arterial measurements and those obtained by the indirect method[81,316] The indirect readings average about 4 mm lower than the direct for the systolic pressure and 9 mm higher for the diastolic pressure The closest correlation between the two methods with respect to diastolic pressure is said to be obtained when the cessation of sounds rather than the sudden diminution in intensity is taken as the criterion[81] but this view has been disputed by Roberts and associates[184] Error may be introduced in the measurements of the blood pressure of obese individuals with large arms When the standard cuff width of about 13 cm is used the auscultatory blood pressure tends to be too high in persons with obese arms and too low in those with thin arms[179]

2 Casual and Basal Blood Pressures

Significant variations in blood pressure may occur at different times of the day and from day to day owing to emotional and other factors unrelated to organic disease Pressures determined without regard to the time of day or environmental factors and without special preparation of the patient are termed *casual blood pressures* If several such readings are taken repeatedly after brief intervals of a few minutes there may be variations of slight or considerable degree When variations are large the blood pressure is termed labile blood pressure If hypertensive levels are reached in some of the measurements the subject is said to have *labile hypertension* Some physicians

make repeated determinations of casual blood pressures at intervals of several minutes and use the lowest blood pressure. Others may make a single casual determination. Blood pressures determined as soon as the patient awakens and before he gets out of bed are usually lower than at any other time in the day and are termed *basal blood pressures*. These are less variable than casual blood pressure determinations. In hypertensive patients particularly, both the casual and the basal blood pressure readings may fall to a variable extent after a period of a week or more of complete bed rest.

3 Criteria of Normal Blood Pressure Versus Hypertension

It is difficult to compare the data of different investigators as a basis for setting up criteria for normal and elevated blood pressure. There may be a significant error in statistical data based on blood pressures determined casually with varied techniques by a host of different observers who are unaware that such isolated measurements will be used for determining "normal" standards. In addition the material used is not comparable. In some studies the samples tended to exclude subjects with blood pressures above an arbitrary level, for example, applicants for certain types of standard insurance. Other samples were so chosen that subjects with definitely abnormal blood pressures may have been included. The stated upper limits of normal blood pressure have varied from approximately 140 mm Hg systolic and 90 mm Hg diastolic[18, 185] to 200 systolic and 110 mm Hg diastolic,[3, 14, 35] the latter pressures in older subjects.

Assuming that there is a progressive rise in blood pressure with age and that more than 35 per cent of individuals between the ages of 60 and 64 have a diastolic blood pressure above 100 mm Hg may this not signify that more than 35 per cent of individuals in this age range in this country and in Great Britain suffer from at least mild or moderate hypertension rather than that they are experiencing a normal increase in blood pressure due to the aging process? Attention is called to a possible analogy to the increased incidence of hypercholesterolemia and coronary heart disease with aging in the same countries, and the question whether this denotes normalcy or a pathologic process. It will be of interest to discover whether the described rise in blood pressure with age occurs in countries in which hypertension is a less common disease.

The distinction between hypertension and normal blood pressure possesses significance insofar as the former is associated with a higher incidence of clinical symptoms and complicating disease and with a diminished life expectancy. A given blood pressure range may not be regarded as normal for a given age or sex, regardless of its frequency, if it is associated with a higher incidence of illness and mortality than lower blood pressure levels in the same age group. There is suggestive evidence that in any age group the incidence of cardiac, renal and cerebral complications and the mortality rate are higher when the diastolic pressure exceeds 90 mm Hg and the systolic is simultaneously above 140 mm Hg than when the blood pressures are below these levels.[185, 49] Army officers with even moderate degrees of transient hypertension developed sustained hypertension more frequently than those who had never had an elevated blood pressure, and showed a higher rate of retirement for disability and a higher death rate from cardiovascular renal disease.[120] There is greater need for studies correlating various ranges of blood pressure with the subsequent development of these complications and with life expectancy than for studies of the mere incidence of various blood pressure at different age levels. Too much stress should not be laid on the practical importance of an exact dividing line between normal and elevated blood pressure. Slight degrees of hypertension may actually have little more than statistical significance with respect to mortality and vascular complications. For the most part these complications and a shortened life expectancy are observed in individuals whose diastolic pressure exceeds 110 and especially 120 or 130 mm Hg. There is general agreement that pressures above these levels represent hypertension. The borderline levels of diastolic blood pressure concerning which there is disagreement may be important only insofar as they may be harbingers of still higher and more significant levels of blood pressure in later life.

ETIOLOGY OF HYPERTENSIVE HEART DISEASE

The etiology of hypertensive heart disease is obscured by uncertainty as to the genesis of the underlying hypertension. A detailed dis

cussion of hypertension, per se, is beyond the scope of this book. Only a brief résumé is given in order to obtain a better orientation towards its relationship to hypertensive heart disease.

Essential Hypertension and Secondary Hypertension

Hypertension is associated with or due to a variety of conditions, notably

(1) Renal diseases (acute and chronic glomerulonephritis, chronic pyelonephritis, polycystic kidneys, renal tumors, periarteritis nodosa, renal vascular anomalies and occlusions, toxic nephroses),

(2) Endocrine diseases (Cushing's syndrome, pheochromocytoma),

(3) Vascular disease (coarctation of the aorta, acute porphyria),

(4) Cerebral lesions (brain tumor, bulbar poliomyelitis).

Hypertension associated with these primary diseases is sometimes termed secondary hypertension. In the largest group of hypertensive cases no apparent underlying disease can be discovered. These are therefore termed "primary" or essential hypertension.

THEORIES OF HYPERTENSION

The pathogenesis of hypertension in the large group of cases termed essential hypertension is unknown. Such observations as appear pertinent have related the hypertension to disturbances of (1) the endocrine organs, (2) the kidney or (3) the central nervous system. In addition, humoral pressor agents generated by metabolic or other disturbances have been considered as possible etiologic factors. It has also been postulated that the arterioles may become abnormally sensitive to normally circulating pressor agents. Finally, it is possible that there are different kinds of hypertension within the category known as essential, and that more than one of the above factors may be concerned in individual cases of hypertension.

Endocrine Theory

Tumors of the adrenal medulla (p. 1025) cause paroxysmal or persistent hypertension but they do not account for the vast majority of cases of this essential hypertension. Nevertheless Palmer[151] still believes that norepinephrine may be responsible for essential hypertension. More significant is the hypertension associated with hyperfunction of the adrenal cortex as exemplified by Cushing's syndrome (p. 1024). Toxemia of pregnancy with its associated hypertension may be related to adrenal cortical steroids which are found in the placenta. Conversely, there is pronounced hypotension in Addison's disease in which there is a deficiency of the adrenal cortex. In cases of Addison's disease the continued administration of the synthetic adrenal cortical hormone desoxycorticosterone (DCA) together with sodium chloride may produce hypertension[166] (p. 1024). The same procedure in hypertensive patients leads to further elevation of the blood pressure.[159, 164] DCA has also been found to have an immediate pressor effect when injected intravenously in hypertensive individuals.[74] In animals, the adrenals appear to be necessary to the production or maintenance of experimental hypertension by renal ischemia,[145] and DCA has been reported to produce hypertension and atherosclerosis in rats.[199] Selye[201] has postulated that hypertensive vascular disease, as well as other diseases, results from adrenocortical secretion in response to various non-specific "stresses" (alarm reaction). Genest et al.[68] suggested that hypertension could result from a state of mild and chronic hyperaldosteronism. But although as a rule the adrenals are necessary for hypertension, animals have been made hypertensive even after adrenalectomy.[116] Even more significantly, marked hypertension has persisted in some patients even after bilateral adrenalectomy.

These observations may indicate merely that the endocrine glands are responsible for one small group of cases of hypertension, or that the adrenal cortex in particular may be one element in a complex cycle of events leading to human hypertension. Concepts attributing to the adrenal cortex and/or to the pituitary hypothalamic centers a major role in hypertension have been formulated by Selye[90] and by Heinbecker.[95]

Sodium and Hypertension. The sodium ion is in some way related to the development of certain forms of experimental hypertension[9, 77] and possibly also human hypertension.[164] However, the sodium ion is not directly responsible for hypertension. The relationship of sodium to hypertension was most strikingly indicated by the beneficial effect of a very low sodium diet in the treatment of many patients with essential hypertension (p. 935). There is some evidence that there is a low incidence of hypertension in races with a low sodium intake

in their diet No hypertension was observed in any individuals of a group of adults whose spontaneous sodium intake was low This suggested a hypothesis that a minimal level of sodium intake must be exceeded for the development of hypertension although the sodium in itself is not sufficient for its development [39] Hypertensive individuals behave differently from normals in their response to rigorous sodium restriction[18] and to acute salt loads [5] Hypertension has been produced in the rat by substituting hypertonic chloride solutions for drinking water,[188] and a high correlation has been found between an elevation in blood pressure and the concentration of sodium chloride fed to male albino rats [132]

Restriction of dietary potassium in hypertensive patients also has been noted to result in small but significant decreases in blood pressure despite sodium retention [26]

Renal Genesis of Hypertension

1 Association with Intrinsic Primary Renal Disease The association of hypertension with a variety of intrinsic diseases of the kidney has long been known In these cases the bilateral renal disease precedes the hypertension and is generally regarded as the cause of the hypertension but the mechanism is uncertain

2 Experimental Production of Hypertension by Renal Ischemia However, a renal origin for essential hypertension as well was given renewed impetus when Goldblatt and his associates[73] induced pronounced and persistent hypertension without renal excretory insufficiency in dogs by bilateral constriction of the renal arteries Subsequently renal hypertension was induced by Page[146] by investing the kidney with cellophane which formed a fibrocollagenous compressing hull The experiments of Goldblatt and his associates led to the concept that human essential hypertension, like the experimental form might be the result of renal ischemia But, except for occasional instances of hypertension the Goldblatt mechanism is no longer regarded as a basic factor in the pathogenesis of essential hypertension

3 Unilateral Renal Arterial and Urologic Disease Further support of the concept of a renal genesis of hypertension is found in the striking instances of hypertension following unilateral renal arterial occlusion e g by embolism,[53] thrombosis,[76] atheromatous plaque[10] or external compression,[104] in cures of such cases of hypertension by unilateral nephrectomy, and in cases of unilateral urologic disease and hypertension in which the hypertension was cured by removal of the diseased kidney [20 87 176 101]

4 Renal Pressor Substances Finally, the demonstration of pressor substances related to the ischemic kidney in the experimental animal, and the purported similarity of the hypertension induced by such pressor substance to experimental renal hypertension have also been advanced as evidence for the renal genesis of hypertension[147] (v infra) There is also evidence that the normal and not the ischemic kidney excretes something which may be responsible for hypertension [?] Grollman and associates[85] showed that hypertension may occur in the absence of both kidneys, provided excretion is effected by peritoneal lavage Their observations and those of Handler and Bernheim[8] suggest that the kidney normally produces a substance which prevents the occurrence of hypertension Hypertension may follow absence or diminution of this renal antipressor substance The possibility has also been considered that hypertension occurs when a normal pressor substance produced in the kidney or elsewhere is abnormally retained because of renal dysfunction [?] But there is usually no renal impairment in essential hypertension, except in very advanced stages of the disease

5 Renal Arteriolosclerosis in Essential Hypertension Renal arteriolosclerosis is almost universally present in autopsied cases of essential hypertension [15 57] Whereas Fishberg[57] interpreted these findings as secondary to hypertension Moritz and Oldt[134] concluded that they were evidence of a primary diminution in renal blood flow and therefore supported the renal pathogenesis of essential hypertension In a series of 500 renal biopsies taken in the course of sympathectomy for hypertension Castleman and Smithwick[30] found that there was no vascular disease or only insignificant lesions in about 25 per cent and Heptinstall[?] in a similar study found only slight vascular changes in approximately 60 per cent of 50 renal biopsies They concluded that hypertension therefore preceded the development of renal arteriolosclerosis Goldblatt[7] has objected that the small specimens taken do not necessarily reflect the vascular status of the entire kidney

A more detailed discussion of the arguments favoring the renal mechanism of hypertension may be found in Goldblatt's[72] review and of

the opposing viewpoint in a review by Smith, Goldring and Chasis [96] Despite uncertainties as to the exact mechanism relating the kidney and hypertension, *the weight of evidence strongly suggests that the kidney may be an important link in the pathogenesis of hypertension*

Neurogenic and Humoral Factors in Hypertension

Since it has been long known that sympathetic vasoconstriction of the splanchnic vessels can elevate the blood pressure conspicuously it was thought that the arteriolar constriction of human hypertension was due to this neurogenic mechanism This viewpoint has been supported by the observation that a substantial fall in blood pressure follows sympathectomy in humans with hypertension In man increased intracranial pressure is associated with elevation of blood pressure and hypertension may occur in bulbar poliomyelitis and other diseases of the brain Psychic factors have been related to hypertension by their effect on the central nervous system as well as by stimulating the secretion of norepinephrine

On the other hand there are many studies which seem to cast doubt on or minimize the importance of the sympathetic nervous system in the pathogenesis of essential hypertension The fall in blood pressure following sympathectomy in clinical hypertension is often absent or insignificant or transient Despite extensive sympathectomy the blood pressure is rarely restored to normal A moderate fall in pressure after sympathectomy might denote merely the elimination of the normal vasoconstrictor element of the blood pressure without modification of the abnormal and excessive arteriolar tonus responsible for the hypertension There is as yet insufficient evidence that the central or sympathetic nervous system plays a primary role in the production of essential hypertension

In experimental renal hypertension a neurogenic factor has been excluded because (1) total sympathectomy does not prevent or abolish the hypertension induced by constriction of the renal artery [4] (2) transplantation of an ischemic denervated kidney to the neck of a different bilaterally nephrectomized dog induces hypertension [4] or hypertension may be induced by constriction of the renal artery after the kidney has been transplanted These experiments indicate that a humoral agent is responsible for the hypertension

More direct support for a humoral mechanism of hypertension is provided by the finding of a number of substances which are believed to account for experimental renal hypertension [8 8] The following schema has been evolved [147 7 43]

1 Renin [7] is an enzymatic substance formed in normal and hypertensive kidneys which enters the blood stream through the renal vein and acts upon

2 Hypertensinogen (renin activator), an alpha globulin produced in the liver and found in the plasma to produce

3 Hypertensin[139] (angiotonin[140]), a polypeptide which is a powerful pressor and vasoconstrictor This can be inactivated by

4 Hypertensinase, an enzyme produced, among other organs by normal kidneys and found in the blood

Other pressor substances obtained from kidney have been suggested as possible agents in the mechanism of hypertension, including the vasoexcitor material (VEM) of Shorr et al [20] (p 303) and pressor amines reported to result from defective deamination of amino acids in the anoxic kidney [16] Schroeder and Olsen[137] discovered an amine like pressor substance in the blood of patients with hypertension which they termed *pherentasin* It is uncommon in the blood of normotensive subjects A host of other pressor substances have been described but there is no consistent association with hypertension None is invariably present in the blood of hypertensive patients, and they are found in some normal individuals An antibody to renin (antirenin), capable of neutralizing the pressor effect of an intravenous injection of renin, has been described [229] A possible relation of hepatic metabolism or hepatic detoxification of sex hormones is suggested by the finding of a remarkably low frequency of hypertension and cardiac hypertrophy at autopsy in women who were found to have subchronic hepatitis at autopsy [278]

A causal relationship between these humoral agents and experimental renal hypertension is probable, their significance for human hypertension is hypothetical

OTHER ETIOLOGIC FACTORS

Age

Hypertension is uncommon before the age of 20 Thereafter it is encountered in 20 to 25 per cent of the general population and in

to 60 per cent of those beyond the age of 50[125] Hypertension before the age of 20 occurs chiefly with coarctation of the aorta, acute or chronic glomerulonephritis and rarely with endocrine tumors or unilateral renal disease

Sex

Hypertension is slightly more common in the female but hypertensive (and atherosclerotic) heart disease is much more frequent in the male Data on these points are not in agreement

Race and Environment

An increased incidence of hypertension is often related to the accelerated tempo of modern industrialized civilizations Perhaps the purported increase in hypertension in western civilization is due to dietary differences which disturb metabolism, rather than to increased environmental stress Negroes in Africa rarely suffer from hypertension,[44] but in the United States hypertension is more frequent and more severe in Negroes than in whites [11] Similar observations have been made with respect to Chinese who emigrate to the United States Cohen[35] concluded that hypertension was rare in the Indians in the southwestern portion of the United States There were only 14 instances of hypertension among 1140 admissions There are many pitfalls in attempting to draw conclusions of reported differences in incidence of hypertension among various regional and racial groups [11]

Heredity

There is suggestive evidence of a familial tendency to hypertension [175, 80, 185, 176] This evidence consists of records of hypertension in *many members of a family of the occurrence* of hypertension in twins[211] and the tendency to higher pressures in relatives of patients with hypertension as compared with relatives of individuals with normal blood pressures [211, 80] Thomas[27] found that among medical students with at least one parent who had hypertension or coronary heart disease there was a significant number with a high resting blood pressure and heart rate and with hyperreactivity to the cold pressor test Hypertension was found to be three times as frequent among siblings of hypertensive individuals as among siblings of normotensives [224] Hypertension is said to be inherited as a dominant characteristic [11, 211] Statistical evaluation of small series of cases is difficult because of the frequency of hypertension in the general population, or because of disagreement as to standards of normal and elevated blood pressure

Constitution

Hypertension has been related to body build and constitution [185] It is commoner in the obese, and occurs with some predilection for the short, low necked, stocky individual There are certainly many exceptions The hypertensive individual is characterized as a hyperreactor with exaggerated response to cold, epinephrine, etc

Temperament and Emotion

Psychologic disturbances have been postulated as initiating factors in hypertension Transient, and occasionally permanent hypertension has been found to follow repeated powerful emotional experiences involving fear, anxiety and hostility, e g , in the course of battle Palmer[181] regards hypertension as a "chronic emergency response in congenitally susceptible individuals due to the strain of adjustment to the environment " A characteristic hypertensive personality[18] and distinctive psychiatric pattern[8, 17] have been described [181] Subnormal assertiveness, dependence, suppressed hostility and obsessive-compulsive traits are commonly noted in hypertensive patients,[79] but similar traits have been described in other organic diseases supposedly due to psychic factors Undoubtedly many of the *symptoms* associated with essential hypertension are of psychic origin However, there is little scientific evidence to indicate that psychic disturbances are the prime cause of *hypertension* Experiments indicating that the blood pressure rises or the renal plasma flow diminishes when certain *emotional stresses* are introduced into the conversation or experimental situation[51, 60] do not have direct bearing on the problem of the pathogenesis of hypertension

PATHOLOGIC PHYSIOLOGY

Circulatory Dynamics

The *cardiac output* is normal in uncomplicated hypertension [22] Since the blood pressure is elevated, the *peripheral arterial resistance* must be *increased* to approximately the same degree [11] The viscosity of the blood is altered insignificantly

The increased peripheral resistance, due to widespread constriction of the arterioles and minute arteries, is the fundamental vascular alteration in essential hypertension The arterial pressure rises because the volume flow

of blood (cardiac output) in the arterial tree is unchanged while the capacity of the arterial tree is reduced by vasoconstriction

The cause of the increased peripheral resistance and the responsible mechanism are unknown The responses to sympathectomy hypotensive drugs and greatly restricted sodium intake suggest that various mechanisms may be causative in different hypertensive individuals Arteriolar constriction responsible for the increased peripheral resistance is due primarily and chiefly to increased tone but intrinsic structural changes (widespread intimal thickening and medial hypertrophy) may contribute to the arteriolar narrowing

That the heart is capable of maintaining its normal output despite the increased resistance to outflow is due to compensatory cardiac dilatation and hypertrophy (p 91) If humoral substances are concerned in the pathogenesis of hypertension these substances may aid in maintaining the normal cardiac output against increased peripheral resistance by increasing myocardial efficiency

The *work of the heart in hypertension* can be calculated though imperfectly by multiplying the cardiac output and the mean arterial pressure[193] The kinetic energy of ejection is ordinarily a negligible factor but it may be more important in hypertension because of the increased velocity of ejection of blood[38] Since the cardiac output is normal the work of the heart is increased approximately in proportion to the elevation of arterial pressure

The *circulation time* is normal in the absence of heart failure

The *venous pressure* is normal as is the right atrial pressure measured directly by intracardiac catheterization

The *circulating blood volume* is normal in the absence of heart failure

Mechanism of Cardiac Disease and Cardiac Failure in Hypertension

Cardiac disease and failure in hypertension may be due to

(1) Increased work of the heart leading to cardiac dilatation and hypertrophy The blood supply does not keep pace with the increase in muscle mass and there is relative anoxia This disparity is exaggerated with the development of coronary atherosclerosis

(2) Hypertension accelerates and intensifies the development of coronary atherosclerosis (p 429) The development of cardiac failure may be due predominantly to coronary insufficiency

(3) With advancing hypertension impairment of renal blood flow and renal excretory function become significant factors A deficiency in the renal excretion of sodium and water would intensify any tendency to congestive heart failure

PATHOLOGY

The essential cardiac abnormality is hypertrophy of the left ventricle[100] In patients who succumb from non-cardiac causes dilatation is minimal (so-called concentric hypertrophy) This is probably due to the gradual evolution of the hypertension which permits effective hypertrophy to develop without apparent dilatation The hypertrophy involves first the outflow tract (p 102) or anterior half of the left ventricle and later also the inflow tract

In cases of hypertension with heart failure dilatation and hypertrophy may both be pronounced Although the left ventricle is predominantly affected the right chambers may also be dilated and hypertrophied Studies of heart weights of individual cardiac chambers in hypertension indicate that the right ventricle hypertrophies only with the advent of heart failure[101]

Coronary atherosclerosis with or without severe narrowing and with or without occlusion and infarction is commonly present Many of the pathologic findings in so-called hypertensive heart disease are due to atherosclerosis of the coronary arteries (p 429) Ischemic necrosis occurs in malignant hypertension

CLINICAL FEATURES AND COURSE

Hypertension imposes a load on the heart which for many years may be compensated by left ventricular hypertrophy Eventually in more than half the cases this compensatory mechanism is inadequate and congestive heart failure appears Accordingly hypertensive heart disease is often classified into two categories (1) the compensated stage and (2) the decompensated stage

Compensated Stage of Hypertensive Heart Disease

There are no symptoms referable to the heart unless there is advanced coronary atherosclerosis Angina pectoris or an acute attack of coronary occlusion and myocardial infarction may occur There may be symptoms

on the clinical picture which is described on page 1024

Classification of Hypertension According to Severity

One of the most widely used sets of criteria of the severity of hypertension is that of Keith Wagener and associates [111] who classified a series of 219 cases according to the severity of the changes in the optic fundus as follows

Grade I Mild narrowing or sclerosis of the retinal arteries The arteries are narrowed relative to the caliber of the veins Normally the arteriovenous diameter ratio is about 4 to 5

Grade II Moderate to marked sclerosis with exaggerated light reflex and compression of veins at arteriovenous crossings

Grade III Angiospastic retinitis, with edema cotton wool exudates and hemorrhages in the retina superimposed on sclerotic and spastic arteries The ratio of the diameter of artery to vein is progressively decreased At some points arterioles have disappeared and may not reach the periphery of the retina

Grade IV Papilledema or choking of the disk (edema and elevation) in addition to the vascular exudative and hemorrhagic lesions described in Grade III

These grades of increasing severity of retinal lesions correspond in a general way to progressively higher diastolic pressures and increased incidence of symptoms and complications

Based on another extensive series of cases Smithwick[209] devised a more complex system of classification, giving a numerical value to various unfavorable factors These factors were graded I to IV according to severity The following groupings were listed

Grade I Fundus Grade I according to the above Keith Wagener classification No cardiac, renal or cerebral complications

Grade II Fundus Grades II, III (or IV), but no cerebral cardiac or renal complications If any of these complication are present, the patient is still classified as grade II if the fundus shows only zero or Grade I lesions

Grade III Diastolic pressure below 140 with cerebral, cardiac or renal complications, but not the severe complications listed under Grade IV Fundus Grades II or III (or IV)

Grade IV Resting diastolic blood pressure 140 mm Hg or more If the diastolic pressure is below 140, then the hypertension is still classified Grade IV if there is a history of a cerebrovascular accident with a residual or there is frank congestive heart failure or the phenolsulfonphthalein test shows less than 15 per cent excretion in 15 minutes Usually Grades III or IV fundus

Other classifications of hypertension according to severity have been evolved Many of these distinguish (I) mild (II) moderate (III) severe hypertension, and (IV) malignant or accelerated phase of hypertension *(I) Mild hypertension* is characterized by systolic blood pressures below 200 and diastolic blood pressures below 110 mm Hg or by intermittent elevation in blood pressure (labile hypertension) *(II) Moderate hypertension* is characterized by systolic pressures of 200 to 230 and diastolic pressures of 110 to 120 mm Hg Symptoms may or may not be present There is good renal function *(III) Severe hypertension* is characterized by systolic blood pressures between 230 and 280 and diastolic blood pressures between 120 and 140 mm Hg which are relatively fixed As a rule, in these cases there are both symptoms and evidences of complications with respect to the cardiac renal or cerebral vascular systems *(IV) Malignant hypertension* has been defined by its accelerated progression and various clinical manifestations but the essential criterion is the presence of papilledema of the fundus in addition to exudates, hemorrhages and vascular narrowing As a rule the diastolic blood pressure is 130 mm Hg or more The neuroretinal edema, including papilledema, has been related to the intense degree of elevation of the diastolic pressure with consequent elevation of intracranial pressure[183] and pathologic spasm with focal edema [29] Furthermore, reversal of malignant to benign hypertension is usually produced by measures which lower the diastolic pressure below a critical level [171] However, very high diastolic blood pressures may occur without neuroretinitis (papilledema) [221] Conversely, neuroretinitis has been noted after the disappearance of hypertension [160] There is usually a brief stage in which malignant hypertension is associated with little or no renal impairment There is a later stage of compensated renal insufficiency and finally, before long a stage with azotemia or uremia Cardiac failure is common in malignant hypertension

Investigation of the hypertensive patient should include not only a complete history and physical examination blood pressure measurements and examination of the fundus but also roentgenologic examination of the chest for the size and configuration of the heart an electrocardiogram and such additional tests as may be necessary to determine cardiac function including the presence or absence of heart failure It is also important to establish the presence or absence of underlying renal disease and especially the state of renal function by examination of the urine a concentration test the 15 minute phenolsulfonphthalein excretion test and the determination of blood urea nitrogen or non protein nitrogen

DIAGNOSIS OF HYPERTENSIVE *HEART DISEASE*

The diagnosis of hypertensive heart disease in the compensated stage is based on the combination of persistent diastolic hypertension and evidence of left ventricular hypertrophy (roentgenologic and electrocardiographic)

The combination of diastolic hypertension and left ventricular hypertrophy together with evidence of (a) angina pectoris (b) coronary occlusion and myocardial infarction (c) congestive heart failure and/or (d) electrocardiographic signs of intraventricular conduction disturbances should justify a diagnosis of hypertensive and coronary (atherosclerotic) heart disease if aortic stenosis is excluded

PROGNOSIS

Variable Outlook According to Different Observers

The prognosis in untreated hypertension has assumed increasing importance as new measures have been introduced for its treatment Keith Wagener and Barker[111] reported on the mortality rates for various groups of hypertensive patients based on their classification according to changes in the optic fundus after a follow up period of five to ten years The mortality rates were 40 per cent in Grade I 65 per cent in Grade II 92 per cent in Grade III and 99 4 per cent in Grade IV after the above interval Using the same criteria for classification Palmer and his associates[1] reported mortality rates in 430 cases of essential hypertension after eight years to be 22 per cent in Grade I 47 per cent in Grade II 78 per cent in Grade III and 94 per cent in Grade IV Except for Grade IV the outlook was somewhat better than that reported by Keith et al[111] Many of the reports evaluating new therapeutic measures for hypertension compare results obtained with the control mortality rates reported by Keith and his associates Such comparisons are unduly favorable to the therapeutic agent because continued studies of the natural life history of hypertension indicate that the outlook is better than that reported by Keith and his associates except possibly in Grade IV representing the malignant or accelerated phase of hypertension

There is still need for further study of the natural life history of essential hypertension because of the tremendous variation in severity and course of different cases of clinical *hypertension and because of the wide range of* mortality rates reported by various observers who have followed large series of unoperated patients For example Perera[1 8] reported a 17 per cent mortality in a 12 year average follow up period of 250 cases Bechgaard[13] a 28 per cent mortality in a 4 to 11 year follow up of 1038 cases Hammarstrom and Bechgaard[55] a 51 per cent mortality in a 2 to 10 year follow up of 435 cases Palmer et al[14] a 61 per cent mortality in an 8 year average follow up of 430 cases whereas Keith Wagener and Barker[111] reported a still higher mortality in the 5 to 9 year follow up of their 219 cases Undoubtedly these variations in mortality rate are evidences of differences in type and severity of the cases of hypertension in the various series reported

It is becoming increasingly apparent that the life history of uncomplicated hypertension is usually very long[146 161 132 37] Perera[161] followed a group of 100 patients from the onset of their hypertension to death and found the average duration was 19 years when the onset occurred at an average age of 32 years The range of duration was between 3 and 34 years The average duration of life was 7 years after the onset of angina pectoris 5 years after the onset of albuminuria myocardial infarction or congestive heart failure 3 years after the onset of a cerebral vascular accident and 1 year after the onset of azotemia In 40 patients in whom the cause of death was determined death was due to congestive heart failure without myocardial infarction in 19 to myocardial infarction in 7 to a cerebral vascular accident in 17 and to uremia in 6 It should be empha

sized that even these results may not give as optimistic a picture as is warranted first because these data were based on patients who had already succumbed, whereas others followed in the same series may still be living, secondly, because hypertensive patients with the most favorable course and without symptoms or complications are not likely to come to the clinic or to specialists in hypertension

Outlook and Complications in Malignant Hypertension

The group classified as accelerated or malignant hypertension is a particularly important one because the criteria can be well defined and because the prognosis in this group is fairly well established Therefore the effectiveness of a given form of therapy can be best assessed in this group of cases Schottstaedt and Sokolow[191] in a study of 104 cases of malignant hypertension found survival time after discovery of the papilledema to be 13 months in patients with good kidney function at the time of diagnosis In 10 of these cases renal impairment developed in an average of 4 4 months In 91 patients with malignant hypertension, treated only symptomatically, uremia was especially frequent and only 3 survived for 30 months Smith and associates[207] in 376 cases of essential hypertension which were investigated at postmortem examination, found on the basis of the Keith Wagener criteria that uremia was the cause of death in only 3 per cent of Grade I in 2 per cent of Grade II in 15 6 per cent of Grade III and in 59 per cent of Grade IV which represents malignant hypertension In addition, congestive heart failure almost always complicates malignant hypertension before the end of its course The relatively rapid course and unfavorable outcome in malignant hypertension and the early and frequent development of uremia in malignant hypertension are elements which enable the use of this group of cases as a control for the evaluation of therapeutic measures

Height of Blood Pressure and Prognosis

The height of the blood pressure in general is correlated with the expectation of life according to insurance statistics Thus May[127] reported that in policy holders with blood pressures below 140 mm Hg the ratio of actual to expected mortality was 103 per cent, between 140 and 170 mm Hg the ratio was 134 per cent, in those with systolic pressures over 170 mm 220 per cent and in those over 200 mm 828 per cent The height of the diastolic blood pressure had an important influence on the mortality rate in the series of 151 hypertensive patients followed by Leishman[114] On the other hand recent studies are less definite regarding the question of prognosis and the height of blood pressure in hypertension But it appears that there is a significant rise in complications and mortality when the diastolic blood pressure exceeds 130 mm Hg and especially when it exceeds 140 mm Hg There are, however, occasional instances in which blood pressures of this range or higher are well tolerated for many years, particularly in women When, as is usually the case diastolic blood pressures of 140 mm Hg or higher are associated with the papilledema of malignant hypertension, the outlook is very unfavorable[20]

Prognosis of Hypertensive Heart Disease and Complicating Coronary Atherosclerosis

About 60 to 75 per cent of patients with hypertension succumb from cardiac complications, about 15 to 20 per cent from cerebral thrombosis, 5 to 10 per cent from uremia, and the remainder from dissecting aneurysm of the aorta or intercurrent diseases such as carcinoma, pulmonary embolism or infection[11, 44] When the heart is involved in hypertension the outlook is often determined by complicating coronary atherosclerosis, myocardial infarction and heart failure The development of congestive heart failure is a serious complication of hypertension, but the outlook is much better since the institution of strict dietary sodium restriction and the widespread use of mercurials Furthermore, heart failure often regresses following treatment of hypertension by diet, sympathectomy or hypotensive drugs The patient with hypertensive heart disease who was reported by Strade[216] to have lived for 32 years after the first incident of heart failure is an example of the most favorable possibility with good treatment The outlook becomes quite unfavorable when hypertension with heart failure is complicated by renal insufficiency This combination is observed notably in two circumstances (1) Malignant hypertension is complicated by congestive heart failure in a very high percentage of cases (2) Late in the history of treatment of congestive heart failure there is often an in

sidious or rapid development of renal insufficiency Whether this merely represents a terminal or terminating incident in the course of hypertensive heart disease with failure or whether it is the result of treatment of the heart failure per se is uncertain

Effect of Treatment on Prognosis[186a]

The most impressive evidence of the promising effectiveness of newer methods of treatment is the improved outlook in cases of so-called malignant or accelerated hypertension The amelioration or disappearance of the retinal abnormalities especially the papilledema the cardinal feature of malignant hypertension is a commonplace observation after treatment with very low sodium diet sympathectomy or the newer hypotensive drugs (p 936) Schottstaedt and Sokolow[191] pointed out that the disappearance of the papilledema in these cases indicates a decrease in the tempo of malignant hypertension and a reversal to benign hypertension However they stressed that vigorous treatment must be instituted in cases of malignant hypertension *before* renal function is impaired and before irreparable cardiac or cerebral complications have developed Smithwick[209] reported a mortality rate of 56 per cent among patients with malignant hypertension who underwent sympathectomy compared with a control figure of 100 per cent in the follow up period of 5 to 9 years Schroeder[195] reported that there was only a 9 per cent mortality in a period of 13 to 34 months among 212 patients with severe and malignant hypertension under treatment with hypotensive drugs On the other hand the mortality rate was 60 9 per cent in patients discontinuing treatment Among 106 patients with malignant hypertension studied during a three year period 28 discontinued treatment and 25 of these died within a month all of hypertension and its complications [196] The course of 10 with uremia was unaffected Of the 68 who continued treatment 14 died (21%) but only 3 as a result of complications of hypertension Thus 79 per cent of those who continued treatment were alive at least 15 to 36 months and most of these returned to full activity [196] The figure of 9 per cent mortality in 13 to 34 months may be compared with the figures of Schottstaedt and Sokolow[191] indicating that two thirds of patients with malignant hypertension die within 9 months

TREATMENT

CARDIAC MANIFESTATIONS

The treatment of heart failure of angina pectoris and of acute coronary occlusion is discussed in Chapters 11 18 and 21 respectively

CONTROL OF HYPERTENSION

General Considerations

Logical treatment of essential hypertension is handicapped by a lack of knowledge as to the etiology and pathogenesis of this disease If it is regarded as a generalized vascular disease rather than as a mere elevation of the blood pressure then little is known except that it consists in an increased constriction of the arterioles and the consequences thereof We do not know whether this arteriolar narrowing is due chiefly or exclusively to sympathetic vasomotor constriction or to intrinsic spasm initiated by humoral or metabolic agents or to an exaggerated arteriolar response to normally circulating constrictor substances Secondary structural changes may intensify the narrowing

We do not know whether or to what extent the elevation of blood pressure per se is responsible for the symptoms and complications of essential hypertension It is highly probable that the cardiac and cerebral complications which are the most frequent causes of death are due chiefly to atherosclerosis and that the elevated blood pressure is only a secondary contributory factor Furthermore many of the symptoms occurring in uncomplicated essential hypertension do not differ from those frequently seen in normotensive individuals with emotional disturbances On the other hand the elevated blood pressure per se appears to be a *significant if not the major* factor in the symptomatology and complications associated with that form of essential hypertension which is termed the accelerated or malignant phase [169] Despite occasional exceptions and moderate variations in the critical level of diastolic blood pressure associated with malignant hypertension clinical experience strongly indicates that the development of the fundus of malignant hypertension is associated with diastolic blood pressures of 140 mm Hg or more and that concomitantly with this elevation of pressure and fundus changes there develops a high incidence of

malignant nephrosclerosis with necrosis of arterioles uremia and the characteristic occipital headaches of recumbency and visual disturbances due to retinal hemorrhages and exudates

With these considerations in mind, the physician should decide whether he is treating or should treat an elevated blood pressure or a disease called essential hypertension In the group of cases termed malignant hypertension the reduction in blood pressure per se is an important therapeutic objective and the various specific blood pressure lowering agents or techniques are therefore indicated In all other groups of essential hypertension there is uncertainty as to the contribution of the elevated blood pressure to symptoms and complications and therefore there is a less definite foundation for the use of antihypertensive measures The use of measures to reduce the blood pressure in such cases may still be rationalized by the evidence that these elevations in blood pressure accelerate the development of coronary or cerebral atherosclerosis or add to the mechanical work of the heart It may be possible also that by lowering the blood pressure in the more benign group of hypertensive patients the malignant or accelerated phase will be prevented

It has already been indicated (see Prognosis) that an imperfect knowledge of the natural course of essential hypertension hampers a proper evaluation of those measures which claim to benefit the course of hypertension by reducing the blood pressure This uncertainty should be weighed when the physician recommends medical or surgical measures involving risk, expense annoyance and unpleasant side actions

Correction of Underlying Causative Disease

Remediable causes of hypertension should be sought Surgical removal of a pheochromocytoma or of a pituitary or adrenal cortical tumor correction of coarctation of the aorta (p 779) and relief of urinary obstruction may reduce or abolish hypertension When no adrenal tumor is found in a patient with hypertension due to Cushing s syndrome, the hypertension may be relieved by excision of one adrenal gland and about three quarters of the other [35] Unilateral nephrectomy occasionally offers a brilliant cure of hypertension, but the clinical history and the findings by pyelography or aortography should offer a strong probability that the unilateral disease is responsible for the hypertension before nephrectomy is undertaken [101] The function of the impaired kidney should be minimal or absent whereas the function of the remaining kidney should be relatively good and there should be no abnormal retention of nitrogenous material in the blood stream In 1918 Smith [illegible] found reports of 47 well documented cases in which a significant reduction in blood pressure was achieved among 242 instances of unilateral nephrectomy Schaffer and Markowitz[139] reported that more than one third of patients of all ages with hypertension and unilateral renal disease are rendered normotensive by nephrectomy, more than one third are unimproved and the remainder greatly improved

General Treatment

Adequate rest, relaxation and sleep are essential Occasional bed rest for a week or two may be valuable when the blood pressure rises to critical levels If there is severe headache elevation of the head of the bed with 12 inch blocks may be desirable during bed rest There should be no restriction of exercise recreation or other activities in the absence of complications Some physicians empirically prescribe moderate sodium restriction although only extremely low sodium diets effectively reduce blood pressure

Psychotherapy, including reassurance and readjustment of the patient's attitude and way of life, is valuable Some physicians who are "psychoanalytically oriented or who have a psychoanalytic bias would like to have the material under this heading dominate the section on treatment of essential hypertension However, despite the purported relationship between the stress of modern living and hypertension despite the psychopathologic personality said to be associated with hypertension and despite the fact that many of the symptoms of patients with hypertension are regarded as 'psychoneurotic" there is no scientific basis for attributing essential hypertension to psychic factors nor is there any valid evidence that hypertension can be alleviated or cured by psychotherapy On the other hand these comments should not be misinterpreted to mean that the patient with hypertension should not receive the benefits of psychotherapy when such treatment is indicated Psychoneurotic manifestations may be alleviated by psychotherapy in the hypertensive patient as in the normotensive Similarly, *mild sedatives,* such as the barbitu

rates bromides or chloral hydrate, are the drugs most widely used in hypertensive patients Perhaps this statement will require alteration as the newer hypotensive drugs begin to dominate therapy The sedative drugs like psychotherapy are indicated for the clinical symptoms and not for the reduction of hypertension per se But the Rauwolfia preparations may achieve a reduction in both emotional and vascular tension

Weight Reduction is desirable for the obese and is often associated with a fall in blood pressure [80] but in some studies the results are unpredictable inconstant and rarely impressive [1,2] Palmer[181] stressed the relation of obesity to hypertension and hypertensive vascular disease and recommended a low calorie diet which excludes all visible fat Despite the unproven relationship of obesity to hypertension the occasional beneficial influence of weight reduction on elevated blood pressure and the generally unfavorable effect of obesity on life expectancy [II] justify the recommendation of weight reduction in the obese hypertensive patient In evaluating the relationship of obesity and weight reduction to hypertension the physician should bear in mind the error introduced in the measurement of blood pressure in the obese[172] (p 921) The possible value of low calorie low fat (and presumably low cholesterol) diets to the hypertensive patient may be related to their alleged action in the prevention or retardation of the atherosclerotic complications associated with hypertension In addition weight reduction may be desirable because it may increase the cardiac reserve in hypertensive patients with early congestive heart failure

Specific Antihypertensive Measures

A number of specific measures are effective in reducing the blood pressure and modifying or alleviating some of the clinical manifestations in patients with essential hypertension These include (1) the rice diet and other very low sodium diets (2) the antipressor or hypotensive drugs (3) sympathectomy and possibly (4) bilateral adrenalectomy

RICE DIET AND OTHER LOW SODIUM DIETS[11]

The possible relationship of the sodium ion to hypertension has been discussed (p 923) Low sodium diets were recommended for the treatment of hypertension over 45 years ago[8] and recently regained temporary popularity The diets should contain preferably less than 200 mg but not more than 500 mg of sodium daily as described in the chapter on the treatment of heart failure (p 239) Adherence to the diet should be checked by determinations of urinary sodium which should total less than 500 mg in 24 hours Evidence has been adduced to show the value of extreme sodium restriction in the reduction of high blood pressure [II, 18]

Kempner[113] recommended the so-called rice diet (300 gm of rice 20 gm of protein but no animal protein 5 gm fat 150 mg sodium carbohydrates in the form of fruits or fruit juices to make 2000 calories 1 liter of fluid daily vitamin supplements) On this regimen Kempner observed a significant reduction in blood pressure in the majority of hypertensive patients as well as a decrease in the size of the heart a disappearance of electrocardiographic abnormalities and improvement or disappearance of retinal abnormalities

Recently Newborg and Kempner[143] reported on a follow up of 177 hypertensive patients with papilledema (malignant hypertension) 120 of whom were treated with the rice diet for 1 to 117 months There was a striking improvement in symptoms and signs of malignant hypertension with complete disappearance of papilledema in 92 of 100 patients who were able to adhere to the initial course of treatment There was an impressive increase in survival time during an average five year follow up period among those who adhered strictly to the dietary regimen e g of those who had followed the rice diet for at least a year and were continuing treatment 86 per cent were still alive compared with 19 per cent of survivals among those who discontinued the diet after the initial period of treatment The survival rate was significantly higher (70%) among those with good renal function than among those with impaired renal function (31%) as determined by the 2 hour phenolsulfonphthalein test

The essential findings of Kempner[114] and associates were confirmed by carefully controlled studies made by Watkin Froeb and associates[231] and by Corcoran and associates [37] who found significant reductions in blood pressure in 20 to 30 per cent of patients or more[1] on the rice fruit diet I have had similar experiences with patients who had adhered closely to the diet A period of 4 to [illegible] weeks on diets with adequately restricted sodium intake

may be necessary before there is a significant lowering of blood pressure

It has now been amply demonstrated that the merit of the Kempner rice-fruit diet depends on its very low sodium content [13, 44, 87, 94] Low sodium diets of more palatable and varied composition are as effective as the rice fruit diet in the reduction of high blood pressure On the other hand, the addition of small amounts of sodium to the rice fruit diet, causing the sodium content to exceed 500 mg or 1 gram reverses the fall in blood pressure which had been achieved by the rice diet The addition to the rice diet of protein fat and vegetables which were very low in sodium did not prevent the fall in blood pressure in individuals who were responsive to the rice diet [94]

The rice diet is an impractical method for the treatment of hypertension and is rapidly losing ground with the advent of the newer hypotensive drugs *Except for a few patients* in private practice or who are hospitalized, and except for those who are part of a group project supervised by an enthusiastic therapeutist it is impossible to maintain any large number of patients consistently and continuously on the rice diet This is due to its relative impalatability, its lack of variety and the omission of proteins and fat as well as salt These deficiencies have been partly met by very low sodium diets which are well balanced with respect to protein, fat and carbohydrates and which permit a variety of foods and spices other than salt But it is almost as difficult to maintain patients for long periods of time on such low sodium diets as are necessary to effect a reduction in hypertension

To reduce further the impalatability of extremely low sodium diets cation exchange resins have been proposed,[71] just as they have been used to improve low sodium diets in the treatment of congestive heart failure (p 244) With the aid of these resins, diets containing 1 to 1 25 gm of sodium (2 5 to 3 gm of sodium chloride) may be used instead of the levels of 200 to 500 mg which are ordinarily necessary Occasionally cation-exchange resin therapy in combination with low *sodium intake is followed* by dramatic improvement in patients whose hypertension had not responded satisfactorily to sympathectomy However the impalatability, bulk, expense and other unpleasant features associated with resin therapy have negated its advantages

The rigorously low sodium diet does not appear to be indicated in the mild or moderate form of hypertension On the other hand in the more severe types of hypertension, notably the malignant phase of hypertension the rice diet or equally restricted low sodium diets may be chosen for patients who will adhere strictly to the regimen and who will not or cannot tolerate the more powerful antipressor drugs and who prefer to try some form of medical therapy before considering sympathectomy In the presence of azotemia very low sodium diets may intensify renal insufficiency and may induce uremia[18] or the low sodium syndrome (p 275) Low sodium diets are beneficial in the patients with hypertension complicated by *congestive heart failure The rice* diet is a low fat, low cholesterol (as well as low *sodium*) diet and posses es whatever merit there may be in such a diet for the alleviation or retardation of the atherosclerotic complications of *hypertension* The low sodium diet may be preferable or safer than the strong hypotensive drugs in patients with cerebral coronary or renal insufficiency in whom there may be a risk of sudden reduction in blood pressure Finally, it is possible that low sodium treatment of hypertension has a *theoretical* advantage over the use of hypotensive drug and sympathectomy in that it may more directly affect the intrinsic arteriolar resistance which appears to be the basic abnormality in essential *hypertension* [177, 131]

DRUG TREATMENT OF HYPERTENSION

The drugs most widely used in recent years to reduce the blood pressure in hypertension are (1) Rauwolfia serpentina (2) Veratrum viride or album and their extracts or alkaloids (3) hydralazine (Apresoline), (4) the various autonomic ganglion blocking agent including the hexamethonium compounds pentolinium (Ansolysen) chlorisondamine (Ecolid) and mecamylamine (inversine) Essentially they act to reduce the blood pressure by diminishing the sympathetic vasoconstrictor tone of the arterioles Inhibition or release of sympathetic vasoconstrictor tone may not *represent* a correction of the basic pathologic state It may merely serve to reduce or eliminate normal vasoconstrictor tone and vasoconstrictor reflexes while the pathologic factor responsible for intrinsic arteriole constriction is unaffected The rationale of using these drugs is based on a presumed benefit from the reduction of arteriolar resistance and blood

pressure per se regardless of whether or not this reduction is accomplished by correction of the primary cause or basic mechanism

If hypotensive drugs are prescribed it is usually desirable to instruct the patient that he may experience possible unpleasant side actions until the dosage is adjusted over a period of weeks and how he may handle these side actions A member of the patient s immediate family or the patient himself is sometimes instructed in the technique of measuring the blood pressure and should be informed as to the variability in blood pressure readings and should be cautioned not to overemphasize minor elevations Multiple blood pressure determinations may be desirable during the course of the day with the patient in the standing as well as the recumbent or sitting positions When using drugs capable of inducing severe postural hypotension the patient s blood pressure should be carefully checked in the standing position or he should stand unsupported for one minute to determine whether he becomes faint or dizzy, before taking the next dose

The physician should start with the mildest hypotensive drugs and resort to stronger ones only when the former prove ineffective or when a considerable hypotensive effect is urgently required Similarly he should administer small doses and increase the dose gradually Sharp sudden reductions in blood pressure should be avoided because of the danger that hypotensive episodes may be complicated by coronary insufficiency and thrombosis by cerebral vascular insufficiency and thrombosis or by renal ischemia and shutdown The physician should be aware that blood pressure readings taken in his office may be significantly higher than those taken by the patient at home and that the latter may present [redacted] more useful guide to drug dosage

Choice of Drug

The decision to employ [redacted] hypotensive drug and the choice of drugs depend in large measure on the evaluation of the severity and type of hypertension and the presence or absence of complications as discussed above (p 930)

In practice the choice of hypotensive drugs for the treatment of hypertension may be discussed with respect to four groups of cases (1) the mild cases of benign hypertension (2) the moderate or severe cases of benign hypertension (3) the malignant or accelerated phase of hypertension and (4) various forms of hypertension associated with significant cardiac cerebral or renal complications

1 *Mild Benign Hypertension* In this type of patient with a systolic blood pressure under 200 and a diastolic pressure of 110 or less there is usually no indication for the use of hypotensive drugs Continued observation is desirable and conservative treatment consisting of reassurance mild sedatives and weight reduction if indicated One is less likely to administer hypotensive drugs if the hypertensive patient [redacted] female beyond the age of 45 than if a male or below the age of 45 In the latter groups the course of hypertension may become more serious and efforts to reduce the blood pressure are designed to prevent the development of higher levels of hypertension or more severe types If the patient is asymptomatic the physician has a problem in deciding whether to discuss the elevated blood pressure at all Since often some comment must be made in order to insure continued observation of the patient it is important to explain the nature of the elevated blood pressure and why active hypotensive treatment is not indicated if this is the physician s conclusion When non specific symptoms are present probably unrelated to the elevated blood pressure [redacted] such it [redacted] important to treat these symptoms by reassurance sedation and more formal psychotherapy if necessary In cases of mild hypertension with symptoms the preparations of Rauwolfia serpentina (p 939) have come to be widely used because they offer the benefits of mild sedation and at the same time are capable of reducing the blood pressure in a fair percentage of cases

2 *Moderate and Severe Benign Hypertension* In this group of patients with moderately or markedly elevated blood pressure but without the fundus changes which characterize malignant hypertension the systolic blood pressure is above 200 and may range to 2,0 or higher The diastolic pressure is above 110 and may be above 120 in the more severe cases For purposes of presentation we are omitting from this group patients with significant myocardial cerebral or renal complications The initial drug of choice in this group of cases would be a preparation of Rauwolfia serpentina because it is associated with the lowest incidence of side effects Dosage and method of administering the drug are discussed in detail below (p 940) If the Rauwolfia prepa

ration is ineffective or inadequately effective after several weeks a preparation of veratrum is added Subsequently a preparation of hydralazine may also be added if necessary, or it may be substituted for the veratrum if the latter was not tolerated As a rule I prefer not to begin with the ganglion blocking drugs, pentolinium Ecolid or Inversine in cases of hypertension not in the malignant or accelerated phase but I often employ them in combination with reserpine in patients with a fixed diastolic pressure of 130 mm Hg or more and in patients with Grade III fundus regardless of the degree of hypertension The administration of the ganglion blocking drugs is more complicated requires more careful observation and is associated with greater risk than the drugs which have been mentioned On the other hand if these other drugs alone or in combination are ineffective if the hypertension is severe or if the progress of the disease suggests the imminence of malignant hypertension or some serious complication, I employ one of the ganglion blocking agents preferably mecamylamine (Inversine) These drugs may be used alone or in combination with Rauwolfia or hydralazine (p 946)

3 Malignant Phase of Hypertension Despite the aversion of some investigators to the use of this term I am convinced that it has a useful and even valuable purpose But it is important that there be general agreement as to definition and criteria (p 930) In this group there is an urgent need for prompt reduction in blood pressure Hypotensive drugs are now first choice over the use of low sodium or rice diets or sympathectomy Hypotensive *drugs must be administered before there is* severe azotemia or uremia The primary hypotensive drugs for this condition are the ganglion blocking agents pentolinium Ecolid or Inversine As a rule they have been combined with Rauwolfia or hydralazine, which are designed to potentiate their effect to enable smaller doses of the ganglion blocking drugs to be used and to neutralize some of the side actions of these drugs The combination of a ganglion blocking drug with hydralazine or with Rauwolfia or with both may be undertaken from the beginning, or a maximal result may be obtained with either drug and the other drug added subsequently

If hypotensive drugs cannot be tolerated or are ineffective, the patient with malignant hypertension should be placed on a diet containing 200 mg of sodium or less preferably in combination with a Rauwolfia preparation alone or with Rauwolfia and veratrum in maximally tolerated doses If these measures are likewise ineffective, sympathectomy should be undertaken If the sympathectomy is likewise unsuccessful one should attempt to repeat the various hypotensive drug programs indicated because of the possibility that they will be effective after sympathectomy even though they were ineffective prior to that operation The possible application of bilateral adrenalectomy with and without sympathectomy is still under study With the use of the hypotensive agents, it appears that patients with malignant hypertension who ordinarily have a mortality between 85 and 100 per cent within 18 months to 3 years have had a mortality rate of about 45 to 55 per cent during a similar period The results are even more impressive when one considers only those patients with malignant hypertension in whom renal insufficiency is not advanced or is minimal

Many investigators do not favor the use of hypotensive drugs in patients with renal insufficiency, and this would appear to apply to many cases of malignant hypertension Although the course of malignant hypertension is rapid, there is a phase in which papilledema and high diastolic pressure are present but renal function is still relatively normal or at least compensated so that there is little or no azotemia During this phase of the disease and sometimes even when there is slight azotemia it is possible to reverse or retard the process by the use of these agents [104] In more severe cases *of hypertension with advanced renal insufficiency* it is probable that no form of therapy will be very useful and one must be satisfied with the administration of low protein diets and symptomatic treatment

4 Benign Forms of Hypertension with Complications. This concerns chiefly the cases of mild, moderate or severe benign hypertension with angina pectoris or coronary thrombosis with cerebral infarction or insufficiency due to atherosclerosis or cases complicated by uremia Most of the patients with hypertension terminating in uremia are in the category of the malignant phase In many instances in which cerebral or cardiac complications are present, these are due to atherosclerosis and not to the hypertension per se When the complication dominates the clinical picture

reserpine and those of serotonin, a vasoconstrictor substance isolated from the blood and brain and found chiefly in the small intestine, platelets and brain[24, 237] Reserpine, like serotonin, potentiates the sedative action of barbiturates and alcohol and is blocked by lysergic acid diethylamide (LSD) The administration of large doses of reserpine, as with serotonin, results in the prompt excretion of 5 hydroxy indole acetic acid (5 HIAA)

Indications Rauwolfia is utilized chiefly in the mild or moderate forms of hypertension and particularly in the labile hypertension of the so-called diencephalic type It is also widely used in combination with other drugs, particularly with the ganglion blocking agents Its stimulation of the bowel helps to combat the constipation caused by the latter It reduces the dose necessary for effective therapy and smoothes out the sharp fluctuations in blood pressure often caused by ganglion-blocking drugs Rauwolfia has been most useful in benign hypertension when administered in combination with veratrum and/or hydralazine It neutralizes the tachycardia and may prevent the headache caused by the latter The intramuscular or intravenous administration of reserpine has been used also to control hypertensive crises[102]

Dose and Administration The initial dose is 0.5 mg daily of reserpine (Serpasil) divided into one to four doses in the course of the day As a rule I start with 0.25 mg after the morning meal and again after the evening meal and continue for at least three to four weeks If there are unpleasant side actions (infra), then the dose is diminished to 0.1 mg twice daily If there is no effect I increase the dose in an effort to obtain a hypotensive action, but not more than 1 mg is given daily as a rule If increasing the dose produces unpleasant side actions without the desired effect, then the dose is somewhat diminished to eliminate the side actions and other drugs such as veratrum or hydralazine or eventually both, are combined with it (p 946) Since a satisfactory response may require four to six weeks, drastic changes in dosage and the addition of other drugs should be deferred until that interval has elapsed When used for the treatment of hypertensive emergencies reserpine is administered parenterally, but it is not as effective as veratrum or the ganglion blocking agents An initial dose of 2.5 or 5 mg is given intramuscularly or intravenously[79a] Thereafter 2.5 to 5 mg, occasionally up to 10 mg may be administered at 6 to 12 hour intervals but dosage is altered as required to obtain the desired blood pressure After a latent period of 1 to 4 hours a maximum reduction in blood pressure is attained 2 to 5 hours after administration[103] For more rapid effects veratrum hexamethonium or pentolinium should be employed

Results As the sole hypotensive drug Rauwolfia is usually effective only in mild or moderate cases of hypertension A moderate hypotensive effect is achieved in about half of the cases of benign hypertension and normal blood pressure may be restored in one third In addition it overcomes tachycardia when this is present Whether or not it reduces the blood pressure, it frequently relieves nervousness and anxiety, irritability, palpitation and headache According to some observers the hypotensive effect of reserpine is no greater than that to be expected from the use of a mild sedative and the establishment of patient rapport[141]

Side Actions The Rauwolfia preparations have virtually no serious toxicity and relatively infrequent and minor unpleasant side actions The commonest annoying side action is nasal congestion and stuffiness Antihistamine drugs appear to help this occasionally but have failed in most instances in my experience Sometimes this side action disappears with continued therapy Diarrhea or irritability of the bowel has been an annoying symptom in a few cases but generally this can be controlled by reducing the dosage It is not likely to occur when Rauwolfia is used in combination with ganglion blocking agents Similarly drowsiness, fatigability, increased appetite and weight gain, mental depression, apathy and occasionally unpleasant dreams or nightmares have been encountered but usually with large doses Rarely jitteriness or anxiety and, in men, decrease in libido without impotence have been noted Suicidal and paranoid tendencies have been noted rarely in patients on reserpine therapy A Parkinson like syndrome has been observed Perera described the occurrence of fluid retention with extensive edema and evidence of heart failure, following Rauwolfia therapy in occasional patients

Veratrum Compounds[130, 93, 137] *Preparations* These are drugs obtained from the roots of Veratrum album and Veratrum viride and are

composed largely of alkaloid esters yielding alkamines The preparation Vertavis is the crude root Vergitryl and Veriloid are purified mixed alkaloids of Veratrum viride, available in 1, 2 and 3 mg tablets Pure crystalline alkaloids protoveratrine A and B obtained from Veratrum album are marketed as Provell Maleate in 0 5 mg cross scored tablets and as Veralba in tablets of 0 2 and 0 5 mg Cryptenamine is an alkaloid fraction of Veratrum viride supplied commercially as Unitensin in 2 mg tablets [24]

Action The veratrum drugs reduce the blood pressure of hypertensive individuals by reflex depression of the carotid sinus and consequent inhibition of its effector vasoconstrictor nerves They produce cardiac slowing by a reflex mediated through the vagal cardio-inhibitory nerve The vasomotor center in the medulla as well as the carotid sinus may be involved in these reflexes The receptor sites of action for these drugs may be in the left ventricle coronary and pulmonary arteries The decline in blood pressure is associated with a reduction in the peripheral resistance which is evenly distributed through the vascular system and with a moderate decline in cardiac output [22] Veratrum compounds stimulate the emetic center (nodose ganglion) in doses which are fairly close to those producing the hypotensive effect

Indications The veratrum drugs were formerly used alone for their hypotensive effect but increasing tolerance and the small range between the hypotensive and emetic dosage minimized their usefulness At the present time they are indicated chiefly in combination with Rauwolfia or with Rauwolfia hydralazine for the treatment of mild or moderately severe cases of benign hypertension However their usage has diminished sharply The bradycardiac effect has been useful in hypertensive patients with tachycardia and in neutralizing the tachycardia of hydralazine Veratrum has been especially recommended for emergency use by intravenous administration in acute hypertensive crises (hypertensive encephalopathy) [120] and in hypertensive patients with acute heart failure

Dose and Administration The veratrum drugs may be administered orally intramuscularly or intravenously As a rule one begins with one tablet of any of the mentioned preparations (0 5 mg of Provell Maleate c~ ... or Unitensin 2 mg after each meal and again on retiring) In order to avoid gastrointestinal symptoms some investigators have tried to give the drug after an early breakfast four hours before the evening meal and on retiring The doses increase gradually one tablet per day at 3 or 4 day intervals until the desired hypotensive effect is achieved or unpleasant side actions occur As a rule 1 5 to 3 mg daily of the protoveratrine alkaloids (Provell Maleate or Veralba) or 8 to 14 mg of cryptenamine (Unitensin) is an adequate dose when the drug is tolerated Smaller doses may suffice and nausea may be less troublesome when combined with preparations of Rauwolfia The dosage must be carefully regulated by continuous trial in order to obtain the desired effect without disabling side actions

When used for *emergency treatment of acute hypertensive crisis* in essential hypertension glomerulonephritis or toxemias of pregnancy the drug is usually given intravenously Two mg of Veralba or Unitensin is dissolved in 200 cc of a solution of 5 per cent glucose in water or physiologic saline and administered by slow continuous drip beginning at the rate of 3 to 6 cc in 10 minutes The blood pressure is determined at frequent intervals When the desired reduction in blood pressure is obtained the rate of flow is slowed and regulated to maintain the effect Similarly protoveratrine has been given intravenously in an initial dose of 1 5 to 1 9 micrograms per kilogram of body weight with subsequent doses of 20 micrograms at 10 minute intervals until a satisfactory hypotensive result is obtained Intermittent intravenous injections may be given slowly in doses of 0 04 to 0 1 mg over a period of 5 to 20 minutes with frequent determination of blood pressure This may be repeated at 30 minute to 4 hour intervals with slight increments if necessary to obtain the desired hypotensive effect Veriloid has been administered intravenously at the rate of 0 6 to 1 1 microgram per kilogram of body weight per minute with reduction of blood pressure in all of 25 patients [314] A maximal response is usually attained within 30 minutes and the drug s action persists for 1 to 3 hours Acute excessive hypotensive effects may be treated by an intramuscular injection of phenylephrine (5 mg) and severe bradycardia may be overcome by the intravenous or intramuscular injection of 0 4 mg of atro...

reserpine and those of serotonin, a vasoconstrictor substance isolated from the blood and brain and found chiefly in the small intestine, platelets and brain[26, 237a] Reserpine, like serotonin, potentiates the sedative action of barbiturates and alcohol and is blocked by lysergic acid diethylamide (LSD) The administration of large doses of reserpine, as with serotonin results in the prompt excretion of 5 hydroxy indole acetic acid (5-HIAA)

Indications Rauwolfia is utilized chiefly in the mild or moderate forms of hypertension and particularly in the labile hypertension of the so-called diencephalic type It is also widely used in combination with other drugs particularly with the ganglion blocking agents Its stimulation of the bowel helps to combat the constipation caused by the latter It reduces the dose necessary for effective therapy and smoothes out the sharp fluctuations in blood pressure often caused by ganglion-blocking drugs Rauwolfia has been most useful in benign hypertension when administered in combination with veratrum and/or hydralazine It neutralizes the tachycardia and may prevent the headache caused by the latter The intramuscular or intravenous administration of reserpine has been used also to control hypertensive crises[103, 84]

Dose and Administration The initial dose is 0 5 mg daily of reserpine (Serpasil) divided into one to four doses in the course of the day As a rule I start with 0 25 mg after the morning meal and again after the evening meal and continue for at least three to four weeks If there are unpleasant side actions (infra), then the dose is diminished to 0 1 mg twice daily If there is no effect, I increase the dose in an effort to obtain a hypotensive action but not more than 1 mg is given daily as a rule If increasing the dose produces unpleasant side actions without the desired effect then the dose is somewhat diminished to eliminate the side actions and other drugs such as veratrum or hydralazine or eventually both are combined with it (p 948) Since a satisfactory response may require four to six weeks, drastic changes in dosage and the addition of other drugs should be deferred until that interval has elapsed When used for the treatment of hypertensive emergencies reserpine is administered parenterally but it is not as effective as veratrum or the ganglion blocking agents An initial dose of 2 5 or 5 mg is given intramuscularly or intravenously[79] There after 2 5 to 5 mg, occasionally up to 10 mg may be administered at 6 to 12 hour intervals but dosage is altered as required to obtain the desired blood pressure After a latent period of 1 to 4 hours a maximum reduction in blood pressure is attained 2 to 5 hours after administration[103] For more rapid effects veratrum hexamethonium or pentolinium should be employed

Results As the sole hypotensive drug Rauwolfia is usually effective only in mild or moderate cases of hypertension A moderate hypotensive effect is achieved in about half of the cases of benign hypertension, and normal blood pressure may be restored in one third In addition it overcomes tachycardia when this is present Whether or not it reduces the blood pressure, it frequently relieves nervousness and anxiety, irritability, palpitation and headache According to some observers the hypotensive effect of reserpine is no greater than that to be expected from the use of a mild sedative and the establishment of patient rapport[161]

Side Actions The Rauwolfia preparations have virtually no serious toxicity and relatively infrequent and minor unpleasant side actions The commonest annoying side action is nasal congestion and stuffiness Antihistamine drugs appear to help this occasionally but have failed in most instances in my experience Sometimes this side action disappears with continued therapy Diarrhea or irritability of the bowel has been an annoying symptom in a few cases, but generally this can be controlled by reducing the dosage It is not likely to occur when Rauwolfia is used in combination with ganglion blocking agents Similarly drowsiness fatigability, increased appetite and weight gain, mental depression apathy and occasionally unpleasant dreams or nightmares have been encountered but usually with large doses Rarely jitteriness or anxiety and in men, decrease in libido without impotence have been noted Suicidal and paranoid tendencies have been noted rarely in patients on reserpine therapy A Parkinson-like syndrome has been observed Pereira[158] described the occurrence of fluid retention with extensive edema and evidence of heart failure, following Rauwolfia therapy in occasional patients

Veratrum Compounds[120, 98, 187] *Preparations* These are drugs obtained from the roots of Veratrum album and Veratrum viride and are

minimized by starting with very small doses of the drug, and usually subsides with continued treatment It is often alleviated by the administration of an antihistamine Tachycardia with palpitation also occurs relatively frequently A variety of other side actions has also been reported Among these dyspnea on exertion and anginal pain are particularly disturbing The anginal pain may resemble status anginosus Because of these side actions hydralazine should probably never be used in patients with hypertension complicated with angina pectoris or other clinical evidence of coronary heart disease

Apresoline may also cause dizziness faintness numbness or tingling of the extremities, malaise depression disorientation and anxiety Occasionally nausea and vomiting edema of the ankles and eyelids flushing nasal congestion lacrimation conjunctival injection skin rashes drug fever hiccups periosteal edema pain in the back of neck shoulders arms anemia pancytopenia and acute psychoses have been noted but most of these are relatively rare

After prolonged use of the drug particularly in high dosage (600 mg daily or more) rheumatoid arthritis with fever may appear And if the drug is continued, a syndrome resembling that of lupus erythematosus may develop[51, 167, 138, 96] In addition to incipient rheumatoid arthritis and fever there are pleural and pericardial manifestations skin rashes, microscopic hematuria occasional lymphadenopathy and splenomegaly, increased sedimentation rate altered distribution of serum proteins with an increase in gamma globulin leukopenia and L E cells Thus far it has appeared that a discontinuation of the drug has resulted in a satisfactory control of the syndrome The remission may be aided by the administration of corticotrophic hormones

Ganglion Blocking Agents (Hexamethonium[195, 203] Pentolinium[204] Ecolid[126, 40] Inversine)[65, 157] Hexamethonium compounds have had wide usage in the treatment of hypertension They are compounds with two quaternary ammonium groups connected by a 6 carbon chain *Hexamethonium chloride* was first administered chiefly by hypodermic or intramuscular injection in preparations containing 25 mg or 100 mg of the hexamethonium ion per cubic centimeter (e g Bistrium) The oral preparation is available as the bromide or chloride in scored tablets of 250 mg or 500 mg each (e g Methium, Esomid Hexameton) The hexamethonium preparations were largely replaced by *pentolinium tartrate* or pentamethylene pyrrolidium in which two terminal quaternary nitrogen atoms in pyrrolidine rings are connected by a chain containing 5 carbon atoms It is available commercially as Ansolysen in 20 mg, 40 mg and 100 mg scored tablets as well as in 10 cc vials containing 10 mg per cubic centimeter for subcutaneous or intramuscular use Still more recently similarly acting hypotensive drugs *chlorisondamine* (Ecolid)[174, 85, 1, 6] and *mecamylamine*[137] (Inversine) have been introduced Ecolid is a bis quaternary derivative of a dialkyl amino alkyl isoindoline At present Ecolid is available in 25 mg and 50 mg tablets for oral use Inversine a secondary amine (3 methylaminoisocamphane) is available in 2 5 5 0 and 10 mg tablets

Action These drugs are potent agents which suppress or inhibit both sympathetic and parasympathetic impulses by blockade of the ganglia of the autonomic nervous system Thus arteriolar constriction is diminished the peripheral resistance is reduced and the blood pressure is lowered Cerebral blood flow is diminished[35] Cardiac output may be initially increased but is then decreased Orthostatic reduction in blood pressure is especially marked and orthostatic hypotension may result from use of the drug The renal blood flow diminishes with fall in the mean arterial blood pressure despite a slight diminution in renal vascular resistance Cardiac rate is slowed and the force of cardiac contraction diminished Inhibition of parasympathetic impulses is responsible for many of the undesirable side actions (infra)

Although these drugs are essentially similar in their action they differ considerably in potency and duration of effect Pentolinium (Ansolysen) is said to be five times more active than hexamethonium in producing sympathetic ganglionic block whereas the less desirable parasympathetic ganglionic blocking effect is only one or two times that of hexamethonium Ecolid is likewise said to be five times as potent as hexamethonium The duration of action of pentolinium was found to be about 40 per cent longer than that of hexamethonium whereas the action of Ecolid is about five times as prolonged as that of hexamethonium Hexamethonium has a sig

nificant action usually for 2 to 4 hours, pentolinium for 8 to 12 hours or longer, reaching its peak in 2 to 4 hours, Ecolid acts for 16 to 24 hours and Inversine for 6 to 36 hours. As with hexamethonium, 20 per cent or less of the oral dose of pentolinium is absorbed after oral administration. Nevertheless pentolinium gave a more predictable hypotensive response, was more effective and better tolerated. In particular there was less constipation and interference with emptying of the urinary bladder with pentolinium. Occasionally uncontrollable sharp fluctuations in systolic blood pressure may occur with Ansolysen.

Ecolid possesses advantages over both pentolinium and hexamethonium because of better absorption and more prolonged action. The effects of Ecolid develop an hour or more after ingestion and reach a maximum in 6 to 8 hours, usually diminishing by 12 to 16 hours and disappearing after 24 hours. Because of the more prolonged action, fewer doses are needed than with either hexamethonium or pentolinium.

Inversine is superior to the other ganglion blocking drugs in that it is completely absorbed and is as effective orally as parenterally in equivalent doses. Its onset of action ranges between one half and two hours and its activity persists for 6 to 36 hours.[13]

Indications. The ganglionic blocking agents mentioned above are indicated in the treatment of severe forms of benign hypertension and especially in the malignant phase of hypertension. In the benign forms of hypertension, unless very severe, these agents should be used only after a trial of Rauwolfia preparations alone or in combination with veratrum and hydralazine has been found unsatisfactory. The ganglion blocking drugs are ineffective or contraindicated in the presence of uremia, but this should not be interpreted to preclude their use in cases of malignant hypertension with good renal function or with compensated renal insufficiency or minimal azotemia. These agents may be used in similar cases of hypertension which have not responded satisfactorily to the rice diet, extremely low sodium diets or sympathectomy. They may also be useful in the treatment of acute hypertensive crises, although protoveratrine has been generally preferred.

Dose and Administration. Hexamethonium has been administered intramuscularly or subcutaneously as the bromide or chloride salt, or given orally as the chloride.[93] It has now been largely replaced by the other ganglion blocking drugs.

Pentolinium (Ansolysen) replaced hexamethonium for oral use because of greater absorption, longer action, less tolerance and less constipation. The initial dose is 20 mg of Ansolysen three times daily. Smirk[93] has recommended that it be given on arising, between lunch and dinner, i.e., with the stomach empty, and before retiring, e.g., at 8 A.M., 3 P.M., and 10 P.M. But it has also been given after meals.[93] The dose is raised gradually every few days by increments of 20 mg if tolerated, until the systolic blood pressure of the patient in an upright position 2 to 3 hours after a dose of Ansolysen is 110 to 150 mm Hg. After a week, the patient may be receiving 100 mg three times daily, which is an effective hypotensive dose in many patients.[93] Some patients require only 40 to 60 mg or less three times daily, whereas other patients require 140 to 200 mg or more three times daily. In occasional instances the effective dose may go as high as 1 gm daily or more. Perry and Schroeder[165] reported an average daily dosage of 727 mg of pentolinium with 748 mg of hydralazine in 9 patients with malignant hypertension, and an average daily dose of 415 mg of pentolinium with 306 mg of hydralazine in 3 patients with severe benign hypertension.

It is important to individualize dosage according to the response and the occurrence of toxic symptoms. Furthermore it has been recommended that in patients over the age of 70 the initial dose be one third of that usually employed, and that it be half the usual initial dose in patients on a low sodium diet or who have previously had a sympathectomy. Dosage is controlled by frequent blood pressure determinations taken at home. The previous dose is cut in half if the standing systolic blood pressure is less than 120 mm Hg and omitted if less than 100 mm Hg or if there has been no bowel movement for 24 hours. The dose is similarly reduced or omitted if the patient experiences weakness, dizziness or faintness on standing upright for one minute just before each dose.

The dosage of *Ecolid* varies between 25 and 300 mg daily.[93, 126, 40] Initially the patient is given a 25 mg or a 50 mg tablet one hour before breakfast. This may act the entire day. However, if a second dose is needed, this is

given 1½ hours after the evening meal The second dose is determined by frequent measurements of the blood pressure at home The initial dosage of 25 mg is increased slowly by 25 mg increments until the desired effect is obtained Dryness of the mouth cycloplegia and constipation may be controlled by pilocarpine nitrate 5 mg three times daily, or by prostigmine bromide 15 mg one to three times daily A laxative may be necessary

Mecamylamine (Inversine) may be administered initially in 2 5 mg doses after the morning and evening meals and increased after a few days to 5 mg two or three times daily The dose is increased by 2 5 mg increments until a satisfactory hypotensive effect is obtained or side actions prohibit further increases Freis and Wilson[63] administered a mean daily dose of 30 mg (range 8 to 80 mg) to 35 patients with various grades of hypertension The mean reduction in basal blood pressure was 23 per cent systolic and 19 per cent diastolic in the supine position and 30 per cent systolic and 23 per cent diastolic in the erect position Because of increased morning reactivity to hypotensive drugs the morning dose should remain relatively small or be omitted and larger doses given after lunch dinner and at bedtime as required to obtain a smooth control of the blood pressure As with other ganglionic blocking drug therapy, the blood pressure should be taken with the patient standing and the dose should be omitted if there is dizziness or faintness on standing for one full minute Reserpine may be administered in combination with Inversine by giving 0 25 mg of reserpine morning and evening for several weeks and then only in the evening Inversine should probably not be used or used with caution to avoid intense and sudden hypotensive effects in hypertensive patients with severe coronary cerebral or renal insufficiency

The method of administering these ganglionic blocking agents with reserpine or hydralazine is discussed below

Results Ansolysen Ecolid and Inversine have not been used long enough at this writing to provide satisfactory follow up results But all three ganglionic blocking agents are capable of reducing the blood pressure in a great majority of cases of hypertension, including those with very severe benign hypertension and those with the malignant phase of the disease[196 203 83 137] Symptoms including severe headache are ameliorated Heart failure is controlled[112] In addition papilledema retinal exudates and hemorrhages when present, can be greatly diminished or eliminated the cardiac size reduced and electrocardiographic changes returned to normal

Follow up studies with hexamethonium have yielded very impressive results particularly in the treatment of malignant hypertension the natural course of which is best known and most unfavorable Schroeder[196] reported that in 212 cases of severe malignant hypertension that were adequately treated (with hexamethonium and hydralazine) and followed for a period of 13 to 34 months there was a 9 per cent mortality, whereas in similar patients discontinuing treatment the mortality was 60 9 per cent Furthermore the mortality rate due to known hypertensive complications was only 3 2 per cent in those who presented themselves without uremia and who continued treatment In those who discontinued treatment mortality from hypertensive complications was 55 per cent Of 68 patients with the malignant phase of hypertension 54 were alive after 13 to 34 months of treatment whereas 14 had died within a period of 1 to 18 months None of the 54 had malignant hypertension after treatment The mortality rate was only 3 per cent in those presenting without renal insufficiency, 11 per cent in those presenting with renal insufficiency and 100 per cent in those with previous uremia Similarly, Kaufman and Sokolow[110] in a 30 month follow up of patients with malignant hypertension who were treated with hexamethonium found that reversal of the malignant to the benign phase and survival beyond two years were possible in at least half of the patients who were treated while their renal function was still satisfactory These figures give striking support to the efficacy of treatment with these hypotensive drugs and also stress the importance of instituting treatment before uremia has developed

The early results with pentolinium give promise of at least equalling those with hexamethonium Gifford and associates[70] succeeded in reducing significantly the blood pressure of 23 of 24 patients with severe hypertension and satisfactory control was achieved for 1 to 7 months Among 27 patients with severe "fixed' hypertension with an average pretreatment blood pressureof

230/135 (range, 180/110 to 260/160 mm Hg) the blood pressure was reduced and stabilized at an average level of 170/110 (range, 130/95 to 210/130 mm Hg) following 2 to 6 months of treatment by Freis and associates[63] In a series of 31 cases treated with pentolinium tartrate there was a reduction of more than 20 mm Hg in the mean blood pressure in the standing position (median, 38 mm Hg) in 87 per cent and in the recumbent position in 67 per cent (median reduction 23 mm Hg)[2]

Similarly the early results with both Ecolid and Inversine indicate that these drugs are as effective as pentolinium in reducing hypertension and that their hypotensive action is smoother and more uniform throughout the day

Side Actions and Toxicity · One of the most important disturbances with hexamethonium resulted from the irregular and unpredictable absorption of the drug from the gastrointestinal tract with consequent cumulative effect This effect was particularly severe in the presence of constipation which is a regular side action of hexamethonium Occasionally the constipation has been so severe that ileus has resulted and has been fatal Excessive action after cumulation has resulted in sharp and sudden reductions in blood pressure with symptoms of postural hypotension or syncope and prolonged shock Other side effects include nasal stuffiness due to congestion blurring of vision due to loss of accommodation, dryness of the mouth and impaired sweating Anorexia urinary retention and impotence have also been annoying In patients under prolonged hexamethonium therapy, a fatal interstitial pneumonitis has been observed[45] perhaps more frequently in the Negro and in patients whose hypertension was poorly controlled by the drug

The side actions with pentolinium are essentially the same as with hexamethonium, except for lesser degrees of constipation, and similar side actions occur with Ecolid and Inversine However, constipation is much more severe with Inversine than with Ansolysen therapy Postural hypotension is particularly disturbing and may be characterized by weakness nausea, dizziness palpitation and tachycardia but especially by faintness or syncope Occasionally there is a sudden blackout and syncope without warning possibly resulting in injury The patient should be made aware that the peak action of Ansolysen is 2 to 4 hours after ingestion, and should be alert to assume the recumbent position if there are any warning signs I have observed prolonged hypotension and death from pentolinium Severe hypotension which does not respond to recumbency should be treated by intravenous Levophed[30] (p 563), until it is certain that the action of the pentolinium is completely dissipated (12 hours or more) Postural hypotension is also common with Ecolid and may be particularly troublesome in the early morning Blurring of vision associated with mydriasis, is especially disturbing because it may last all day Delayed gastric emptying with nausea or vomiting may occur initially Constipation, decreased force of micturition and dryness of the mouth have been noted but have been less troublesome than with the other ganglionic blocking agents

Side effects of Inversine include constipation, orthostatic dizziness and syncope, dryness of the mouth and occasional glossitis dilated pupils and blurred vision, decreased libido and potentia urinary retention, anorexia nausea vomiting, weakness, fatigue and sedation Fever, excessive heat infection, alcohol vigorous exercise and sodium depletion may be associated with excessive reaction to Inversine and other ganglion blocking drugs Pressor amines may be used to counteract hypotensive effects of Inversine but one should administer these cautiously Parasympathomimetic drugs such as neostigmine bromide, 15 mg, or pilocarpine nitrate 5 mg, may be used to overcome constipation, dryness of the mouth and some of the ocular symptoms

Combined Drug Therapy The use of combinations of the various hypotensive drugs discussed above has been mentioned repeatedly Some of these combinations may now be summarized When reserpine or hydralazine is combined with ganglion blocking agents it tends to reduce tolerance, diminish the required effective dose smooth out sharp fluctuations in blood pressure and neutralize or prevent some side actions[4]

Schroeder[195] has combined hexamethonium orally with hydralazine and termed this hyphex treatment After the oral hexamethonium dosage has been gradually increased to 500 mg every 4 hours or less if the desired blood pressure reduction has been obtained hydralazine is added in small doses (25 to 50

mg every 4 hours) with gradual increments until 150 mg per dose ■ given four times daily Thereafter the hydralazine is continued regardless of the blood pressure, but the hexamethonium may be increased up to 750 mg per dose or diminished according to need After the patient has been normotensive for about six months, the dose of one or the other drug ■ reduced gradually and then omitted When 1 mg of reserpine was added at night to hyphex therapy, the daily dosage of hexamethonium could be reduced in about one quarter of 75 patients

Freis[82] has recommended the simultaneous administration of Ansolysen with hydralazine and reserpine as well as neostigmine to neutralize constipating effects He gives these drugs in three dosage combinations which he terms hypotensen A B and C according to increasing strength of the dose These combinations all contain 0 ■ mg reserpine and 15 mg of neostigmine bromide but in addition A contains 20 mg of hydralazine and 60 mg of pentolinium B contains 50 mg of hydralazine and 100 mg of pentolinium whereas C contains 90 mg of hydralazine and 200 mg of pentolinium These combinations are put up in capsules The patient ■ started with one capsule of hypotensen A every 8 hours i e on arising in the morning in mid afternoon and at bedtime If after three days to a week there is no appreciable reduction in the blood pressure in the supine or erect positions hypotensen B is administered and at a later date if this is unsuccessful he is given hypotensen C Combinations of A B and C were also employed to adjust the dosage With these combinations Freis has claimed that there was little or no constipation minimal loss of visual accommodation dryness of the mouth or disabling postural hypotension But impotence remained a problem especially in older persons Similar results with pentolinium and hydralazine have been reported by Perry and Schroeder [163] More recently Doyle et al [47] and others ■ ■ have reported that the combination of reserpine with pentolinium is the best means of treating severe hypertension and this is the combination which I used most commonly until Inversine became available and replaced pentolinium

In mild and moderate cases of hypertension combinations have been used in which Rauwolfia serpentina preparations were the main stay If Rauwolfia therapy ■ not successful after a trial of 4 to 6 weeks ■ veratrum drug is added, one tablet being given three times daily after breakfast at 2 P M and at bedtime, i e at intervals of about 8 hours (one tablet of Provell or Veralba equals 0 5 mg) If after several days to a week there are no distressing side actions and if a satisfactory hypotensive effect has not yet been obtained the dose of veratrum may be increased to two three or four tablets three times daily until the desired effect is achieved without side actions Finally, if the veratrum and Rauwolfia combination is unsuccessful hydralazine (Apresoline) is gradually added beginning with 10 mg doses three or four times daily and increasing until the desired effect is obtained After a satisfactory hypotensive effect is obtained and drug therapy is continued for ■ matter of weeks or months it is possible to eliminate one or two of the drugs Wilkins and associates ■ reported that in about one third of 137 cases in which Rauwolfia and other drugs in combination were necessary to achieve ■ satisfactory reduction in blood pressure control was effected later by Rauwolfia alone Forty two of these patients still required both hydralazine and Rauwolfia and 16 required all three drugs Twenty-eight of the 137 had to have hexamethonium in addition to one or more of the other drugs Winsor ■ has reported that the combination of 0 4 mg of reserpine and 100 mg of Apresoline daily, in divided doses was most effective in benign hypertension Similarly Naegele and associates[14] found that the combination of Rauwolfia and hydralazine achieved an adequate reduction in blood pressure in most patients with mild or moderate blood pressure and frequently in those with severe hypertension Prior administration of Rauwolfia reduced the incidence and severity of palpitation tachycardia and headache commonly associated with hydralazine The latter was given in increasing doses up to 300 to 600 mg daily My own practice ■ to initiate treatment with reserpine and then to add Inversine to the reserpine in cases of severe benign hypertension or malignant hypertension Recently Eiber[52] reported satisfactory results with the combination of chlorpromazine and Rauwolfia in the treatment of hypertension Because of the hepatotoxicity of chlorpromazine and the availability of other effective drugs this combination appears undesirable for the treatment of hypertension

Other Drugs *Thiocyanate*[223] The argument as to the effectiveness and risk of toxicity of this drug has largely abated as it has been replaced by the newer hypotensive agents However, it is still used occasionally for the reduction of blood pressure in hypertension[5] and particularly for the control of hypertensive headaches[186] The oral daily dose is initiated with 0 3 gm but may be increased gradually by 0 15 gm per day up to 0 45 to 0 9 gm daily Blood levels of 8 to 12 mg per 100 cc should not be exceeded For relief of hypertensive headache it may be administered by intravenous injection of 20 cc of a solution containing 1 396 gm of sodium thiocyanate representing 1 gm of thiocyanate ion One may administer *sodium nitroprusside* orally to obtain the same effects as with thiocyanate The initial dose is 30 mg four times daily and this may be increased after a few days to 60 mg four times daily which usually gives a thiocyanate level of 8 to 12 mg For hypertensive crises sodium nitroprusside may be administered by constant intravenous infusion[195] A solution is made to give 100 micrograms per cubic centimeter and the infusion is started at the rate of about 100 to 300 micrograms (1 to 3 cc) per minute and modified according to the blood pressure and clinical response

Phenoxybenzamine hydrochloride (Dibenzyline)[151] This is a long acting adrenergic blocking agent which can produce marked postural hypotension as well as a reduction of blood pressure in the recumbent position[87, 8] However it has not proved satisfactory for the treatment of hypertension because of the difficulty in controlling the hypotensive effects because of tachycardia nasal congestion miosis, and especially because of the severity of weakness listlessness, dizziness, palpitation and other sequelae It is still indicated in the control of hypertension due to pheochromocytoma, in a dosage of 10 mg four times daily with gradual increases until the optimum effect is obtained It is usually stopped 36 to 72 hours before surgery, but may be utilized to control sudden rises in blood pressure during the course of the operation

Hydergine[11, 217] This drug contains equal parts of the hydrogenated alkaloids of ergotoxine, namely dihydroergocornine, dihydroergocristine and dihydroergokryptine These are powerful adrenergic blocking agents which have been recommended for clinical use in peripheral vascular disease and hypertension, especially in patients with cerebrovascular disease[215] Hydergine has not proved to be as useful in the treatment of hypertension as other agents mentioned above and has attained no popularity in this country[50] Lowering of blood pressure in hypertensive patients has been too inconstant and of relatively small degree

Pyrogens and specifically soluble bacterial pyrogen (Pyromen—Baxter), administered intravenously 5 or 6 days weekly in a sufficient dose to cause a temperature rise to 103 or 104° F , were reported to induce a reversal of the malignant phase of hypertension to prevent uremia and prolong life in these patients[150] Similar effects have been claimed for the ganglion blocking agents, rice diets and sympathectomy, which are more practical

SURGICAL TREATMENT OF HYPERTENSION

Sympathectomy

More or less extensive sympathectomies have been performed to eliminate or reduce the neural component responsible for increased splanchnic, arteriolar vasoconstriction in hypertension More probably these operations reduce arteriolar constriction by diminishing normal sympathetic tone without affecting the pathologically increased intrinsic arteriolar tone Peet performs a bilateral supradiaphragmatic splanchnicectomy and lower dorsal ganglionectomy in a single stage procedure[188] Smithwick[208] performs a bilateral lumbodorsal splanchnic sympathectomy, removing the great and lesser splanchnic nerves dividing their aortic branches, excising the sympathetic trunk and interrupting their rami communicantes from D6 to L2 The operation is performed through a posterior, transdiaphragmatic approach in two stages usually with a ten day interval between stages An even more extensive sympathectomy is carried out by Grimson[80, 82]

Beneficial and sometimes striking results have been reported in a majority of operated patients with these procedures[188, 100, 32, 210, 11] Reduction in blood pressure, disappearance of severe retinal abnormalities with improvement or return of vision, elimination of intractable headache and restoration of gainful occupation have been noted frequently or almost regularly A reduction in blood pressure has been reported in 21 to 66 per cent of various series of operated cases A prolongation of

life for patients in the serious malignant phase of hypertension has also been reported [157] It is interesting to note the frequent reversal or disappearance of cardiac abnormalities including cardiac enlargement electrocardiographic evidence of left ventricular hypertrophy as well as gallop rhythm, pulsus alternans and recurrent left ventricular failure [75, 157, 107] It is of interest also that the results obtained from the less extensive procedures of sympathectomy are almost as good as those obtained from the more extensive procedures which most advocates of sympathectomy favor for the highest percentage of favorable results

Smithwick and Thompson[110] compared the results of splanchnicectomy for essential hypertension in 1266 patients who had a thoracolumbar sympathectomy with the results in 467 patients who were suitable for operation but refused it The over all five year mortality was 19 per cent in the operated group and 54 per cent in the non operated The operative mortality varied from zero in group I to 11 per cent in the most severe group group IV At the end of five years the mortality in each of the groups was considerably lower in the operative series than in those refusing it The most striking difference was observed in group II with a 13 per cent mortality in the operated patients and 38 per cent in those who were not operated on and in group III in which the mortality was 20 per cent in the operated and 71 per cent in the non-operated In group IV corresponding most closely to the cases termed malignant hypertension the mortality was 59 per cent in the operated patients at the end of five years compared to a mortality of 90 per cent in the non operated Smithwick *and Thompson considered sym*pathectomy to be the treatment of choice for hypertension in the cases falling in groups II and III, although some of the patients in these groups required treatment by diet and drugs as well It is of interest that the most striking improvement was noted in those groups of patients in which it is most difficult to be sure of the natural course of the disease without operation There is considerable question whether the non operative cases classified in corresponding groups can be accepted as adequate controls Although the results in group IV are reported as being less dramatic they are more impressive to me because the reduction in mortality occurred in a group of patients in whom we are reasonably certain that an unfavorable course would have ensued

The operation has been criticized as being at most a palliative procedure of desperation of unproven advantage over medical therapy unphysiologic and without effect on the basic cause of hypertension [75] A significant persistent reduction in blood pressure is obtained in less than 50 per cent of those operated on [109] Disadvantages include an operative mortality of 1 to 5 per cent or more considerable postoperative morbidity a relatively long period of hospitalization and convalescence in the Smithwick procedure annoying postural hypotension for several months neuritic pain for months, frequent loss of ejaculation in the male but not impotence and uncomfortable sweating in areas supplied by the unoperated sympathetic fibers In addition one must stress the failure to obtain a satisfactory reduction in blood pressure in at least 30 and possibly 70 per cent of the operated cases and the fact that even when hypertension is initially controlled the reduction in blood pressure and other effects is maintained in probably not more than 20 per cent in a period of three years The operation is contraindicated in the presence of azotemia very recent myocardial infarction or cerebral accident and uncontrolled heart failure On the other hand alleviation of the hypertensive factor may eliminate the manifestations of heart failure as well as other clinical complications

The surgical indications vary with different physicians Sympathectomy has been largely abandoned as a treatment for hypertension in most clinics since the introduction of low sodium diets and especially the hypotensive *drugs For the most part sympathectomy* is now reserved for patients with severe and progressive manifestations especially those with the malignant form of hypertension who do not respond to medical therapy as outlined above

Taking cognizance of the powerful effects and frequent side actions of the recent hypotensive drugs especially the ganglion blocking agents Proger[175] has properly raised the question whether sympathectomy especially a simple superdiaphragmatic splanchnicectomy as advised by Peet may not be a more conservative method of treating hypertension than the lifelong use of the hypotensive drugs

However it is apparent that after having been employed for about twenty years, sympathectomy is rapidly falling into disuse This clearly indicates that the surgical procedure of sympathectomy despite its relatively low mortality is regarded as a formidable experience in comparison with available medical regimens and that the results obtained by the latter are regarded as being at least as satisfactory as those obtained with sympathectomy

Bilateral Adrenalectomy

Total and subtotal adrenalectomy, alone or combined with sympathectomy, have been utilized in the treatment of severe hypertension by several groups of investigators [41, 6, 73, 240, 105] The rationale for the procedure was based on the experimental and clinical observations relating the adrenal gland to hypertension (p 923) and upon the observations of Green et al [79] that bilateral adrenalectomy was followed by prolonged regression of vascular disturbances in a diabetic patient with malignant hypertension An operative mortality of about 25 per cent in the earlier cases has been considerably reduced to about 3 to 10 per cent Since Addison s disease is produced by the operation, 25 to 50 mg of cortisone or its equivalent in related steroids 3 to 6 gm of sodium chloride and approximately 2 mg of desoxycorticosterone acetate (Doca) must be given daily Bowers [2] performs a bilateral adrenalectomy in two stages two weeks to three months apart The operation was performed or attempted in 27 patients Six patients died in the immediate postoperative period A normal blood pressure was restored in 20 of the 21 survivors Symptomatic improvement of hypotensive symptoms was obtained in all the survivors Hypoadrenalism was present in all The reduction in blood pressure was maintained for as long as 22 months at the time of the report

Jeffers and associates[105] reported on adrenal resection and sympathectomy in 125 hypertensive patients, in 96 of whom an Adson type sympathectomy and either total or subtotal adrenalectomy were performed The mortality rate was 23 per cent for a four year period Death was due to strokes in more than one half of the cases and to coronary occlusion uremia and adrenal insufficiency in many others In those who survived, the reduction in blood pressure was interpreted as excellent in 44 per cent, fair in 24 per cent, and improvement was described in the fundus, size of the heart, electrocardiogram and especially in symptoms of congestive heart failure Headache and angina pectoris were relieved in 70 per cent

In the light of the comments regarding sympathectomy it is difficult to believe that this even more extensive surgical procedure will gain acceptance as a form of therapy I is uncertain whether the results are any better than those of sympathectomy alone And this procedure, as has been stated, is being rapidly replaced by medical forms of therapy It is generally stated that adrenalectomy is still an experimental procedure for hypertension and should only be used as such This operation may be indicated occasionally when a patient with malignant hypertension cannot be controlled by any medical means or sympathectomy It may also be indicated in forms of hypertension associated with Cushing's syndrome It is contraindicated in patients with poor renal function or azotemia, in patients who have suffered a coronary occlusion or cerebral vascular accident less than six months earlier and in patients more than 55 years of age [105]

THE HEART IN RELATION TO RENAL DISEASE

ACUTE GLOMERULONEPHRITIS

There are four important manifestations of acute glomerulonephritis which are of special interest to the cardiologist (1) hypertension, (2) cardiac enlargement, (3) electrocardiographic evidence of myocardial involvement and (4) congestive heart failure

Hypertension is a cardinal feature of acute diffuse glomerulonephritis and occurs at the onset of the disease The rise in blood pressure is almost always moderate and usually does not exceed 180/100 except with encephalopathy

Cardiac enlargement appears early probably within the first week or two [28, 119] The enlargement is relatively mild but may be considerable in the presence of pronounced congestive heart failure Serial roentgen ray examinations disclose a return to normal cardiac size with subsidence of the disease [41] Occasionally cardiac enlargement persists despite normal blood pressure [58] Hypertrophy

as well as dilatation of the left ventricle is observed at autopsy[268]

The cardiac enlargement has generally been attributed to the hypertension but it has been observed in the absence of significant hypertension and the degree of enlargement is usually out of proportion to the mild elevation in blood pressure and its brief duration Gore and Saphir [redacted] found evidence of a serous myocarditis with sparse cellular infiltration in 16 of 160 anatomically proven cases of acute and subacute glomerulonephritis They attributed both cardiac hypertrophy and failure to the myocarditis On the other hand I have observed pronounced cardiac enlargement and hypertrophy only in association with heart failure and it has appeared to me that it is the heart failure which, in accordance with Starling s law of the heart, is responsible for the enlargement

Electrocardiographic abnormalities occur frequently but they are mild and may not be observed except after repeated examinations Low or inverted T waves in lead I and in the precordial leads are the commonest changes [78, 245] Prolongation of the P R interval and of the Q T interval also occurs According to La Due and Ashman[277] right deviation of the Wilson gradient is a common abnormality and denotes relative ischemia of the left ventricle The electrocardiographic changes are not necessarily indicative of anatomic myocardial damage but may be due to such factors as hypertension cardiac enlargement and electrolyte and acid base disturbances The electrocardiographic abnormalities usually disappear within two to four weeks

Congestive heart failure is the most important most serious and most frequent complication of acute glomerulonephritis[260, 307, 291, 250, 289] It has been reported to occur in 20 to 50 per cent of the latter A diagnosis of cardiac failure was established in 22 of 88 cases recently reported by Murphy and Murphy[289] Heart failure has been attributed to the strain of the hypertension[276, 289] and to myocardial damage as indicated by electrocardiographic and anatomic changes But the elevation in blood pressure appears too slight and brief and the electrocardiographic and anatomic changes too minor to be significant and there is often no correlation between the degree of hypertension and the presence or severity of heart failure[291, 307, 255] The heart failure appears to me to be due to a relative deficiency in the renal excretion of sodium and water[256] It appears most frequently when oliguria is severe and is usually induced by overenthusiastic parenteral administration of sodium containing fluids to combat vomiting and promote diuresis Although acute glomerulonephritis is regarded as primarily or predominantly a glomerular disease tubular function in this condition is disturbed to a variable degree and tubular disturbance may be as severe as in the so-called lower nephron nephrosis (p 952) The clinical picture may be indistinguishable from the latter and the dangers of sodium and fluid administration are just as great in the presence of severe oliguria This explanation does not exclude the possibility that hypertension and myocardial edema— serous myocarditis —are secondary accessory factors in the accentuation of myocardial disability[285]

Heart failure may be characterized by a sudden onset of dyspnea and orthopnea often progressing to acute pulmonary edema But frequently it appears more gradually Tachycardia muffled cardiac tones an apical systolic murmur gallop rhythm and râles at the bases of the lungs are common with left ventricular failure But heart failure may develop more insidiously and may involve the systemic as well as the pulmonary circulation Pleural effusion is common and is part of the general anasarca There is evidence that renal edema fluid does not differ essentially in composition from that of cardiac edema and may have a similar pathogenesis[305] A high venous pressure was found regularly by several observers[276, 255] but the circulation time was normal The blood volume is usually increased[75] Davies[55] found the cardiac output normal in 5 patients with acute glomerulonephritis studied by cardiac catheterization The explanation for the normal circulation time in the presence of ' congestive heart failure in nephritis is uncertain It suggests that some associated factor is neutralizing the circulatory slowing usually associated with heart failure or that there was no cardiac failure but only an abnormal retention of sodium and water However the circulation time may be prolonged when heart failure complicates acute glomerulonephritis as I have observed on several occasions and as reported by Kopelman[274] The edema of nephritis like that of heart failure may not be caused by an intrinsic disturbance in capillary permeability, but by an elevated

hydrostatic pressure, sodium and water retention and sometimes also a diminution in osmotic pressure due to low plasma proteins

Treatment

The treatment of acute glomerulonephritis should be primarily directed to the prevention or abolition of heart failure, which is always present or a potential danger Sodium intake should be completely avoided if there is severe oliguria and should not exceed 200 mg daily until normal urinary output and concentration are restored The parenteral administration of fluids is hazardous until that stage is reached During the acute phase an allowance of 500 to 1000 cc of fruit juice orally, is permissible as the total diet In the presence of severe oliguria or anuria fluid intake must be stringently restricted Thereafter one may shift to the rice-fruit-fruit-juice regimen as advocated by Kempner until renal function is restored In the presence of heart failure, digitalis in a rapidly excreted form should be given (e Cedilanid Digoxin) Mercurial diuretics should not be administered Acute left ventricular failure with pulmonary edema should be treated by morphine oxygen intravenous digitalization, application of tourniquets and if necessary, phlebotomy

TOXEMIA OF PREGNANCY (PREECLAMPSIA AND ECLAMPSIA)

The findings in the heart and circulation in toxemia of pregnancy resemble very much those described for acute glomerulonephritis [301] Edema, indicated by too rapid weight gain in the last three months of pregnancy, hypertension proteinuria and sometimes oliguria are the essential clinical features of preeclampsia, and eclampsia denotes that convulsions and/or coma are also present Sodium and water retention account for many of the cerebral, visual, renal and gastrointestinal symptoms Cardiac failure especially pulmonary edema, is due to excessive sodium water retention, but hypertension may be a contributory or major causative factor Studies with radioisotopes have indicated a progressive increase in the sodium space and in total exchangeable sodium during the course of pregnancy, but this increase is quantitatively greater in those who develop preeclampsia [67]

Treatment

Limited caloric intake and especially restriction of sodium to less than 1 gm daily in the last three months of pregnancy are indicated at the earliest signs of too rapid gain in weight or rising blood pressure Mercurial diuretics, with or without ammonium chloride may be administered, but their effectiveness in causing a diuresis is usually less striking than in the usual forms of congestive heart failure If the patient is in acute pulmonary edema morphine, oxygen, intravenous digitalization and possibly phlebotomy may be necessary If the patient is observed in a hypertensive crisis (hypertensive encephalopathy) with severe headache, vomiting cerebral amaurosis, aphasia or focal paresis with or without convulsions a hypotensive drug should be given intravenously, , veratrum as indicated on page 941 The patient should be in a quiet room and given adequate sedation, if necessary Convulsions should be controlled by 6 to 12 cc of 50 per cent magnesium sulfate injections intramuscularly or by a slow intravenous drip of 250 cc of 2 per cent magnesium sulfate, and by parenteral injections of sedatives (e g , 0 25 Sodium Amytal subcutaneously or the slow intravenous administration of 0 5 gm Pentothal sodium or Sodium Amytal) But sedatives should of course be avoided if the patient is comatose

If conservative treatment controls the "toxemic" manifestations, delivery should be induced at the earliest possible time compatible with the safety of the mother and child Termination of pregnancy is the single most reliable therapeutic measure in "toxemia" Immediate termination of pregnancy becomes particularly mandatory if symptoms of preeclampsia are very severe and not satisfactorily controlled if eclampsia develops, or if there are complications such as abruptio placentae

In many cases of so-called "toxemia of pregnancy" there is actually an underlying or preexistent essential hypertension or chronic glomerulonephritis Hypertension and proteinuria may become intensified during the course of pregnancy, or preeclampsia or eclampsia may be superimposed The hypertensive crises and cerebral edema of eclampsia may be indistinguishable from the hypertensive encephalopathy of essential hypertension

LOWER NEPHRON NEPHROSIS

Under the heading of lower nephron nephrosis [30, 282] are included renal diseases characterized by tubular degeneration and necrosis with subsequent regeneration fre-

quent pigment deposits in the tubules and interstitial inflammation but no visible glomerular alterations. Other terms for this condition include crush syndrome,[51, 52] acute anuria,[29, 47] acute tubular necrosis,[59] and shock kidney.[304] The tubular injury causes excretory failure with loss of tubular regulation and indiscriminate or virtually complete reabsorption of the glomerular filtrate.[95, 300] The disease may be caused by a wide variety of agents which induce prolonged shock, renal ischemia and anoxia or allergic and toxic damage to the tubules.[292, 304] Some of the best known causes are (1) extensive burns[34] or wound shock, especially the crush syndrome;[261, 258] (2) hemoglobinuric nephrosis due to mismatched blood; (3) sulfonamides;[283] (4) carbon tetrachloride inhalation;[290, 2, 5, 64, 295] (5) blackwater fever and other factors responsible for intravascular hemolysis of erythrocytes; (6) hyperthermia and various poisons and any condition which causes an acute prolonged reduction in cardiac output and shock,[59, 304] and consequent ischemia and anoxia of the renal tubules.

From the cardiovascular viewpoint the important features are the acute development of extreme oliguria or anuria and hypertension and the invariable danger and frequent occurrence of congestive heart failure. Cardiac dilatation, gallop rhythm, pulmonary congestion and hydrothorax, subcutaneous edema and ascites are common. Death is often due to acute pulmonary edema. Almost invariably the development of heart failure is precipitated by the parenteral administration of fluids in an effort to alleviate vomiting, promote diuresis, correct acidosis or maintain fluid or electrolyte balance. Intracellular breakdown contributes extensively to the excess of extracellular volume. Both of these factors are important because there is no urinary output at all or only an insignificant amount. Similar clinical evidence of left ventricular failure may be precipitated by parenteral sodium-containing fluids in patients with toxemia of pregnancy[373] whose urinary output is very small.

Treatment[19, 249, 267, 300, 7, 238]

Treatment should consist of no more than 500–750 cc. of fluids by mouth if tolerated. Or other forms of sodium free carbohydrate and fat diets such as Borst's butter and sugar diet[244] designed to minimize protein catabolism and maintain caloric intake, may be employed. The parenteral administration of fluids is interdicted until there is a good urinary output and improving renal concentration with a falling blood urea. Intravenous administration of fluids, even in limited amounts intended to compensate for insensible perspiration and vomited fluids, may be dangerous because of previous excessive fluid or sodium intake and because of shifts of fluid from the intracellular to the extracellular compartment. Peritoneal irrigation,[308, 290] artificial kidney[7, 287, 73] or similar therapies[93, 54, 69, 367] may be considered during the period of anuria and extreme azotemia. As a rule these are unnecessary except in the presence of significant hyperkalemia[97] or to control serious fluid retention. Johnston et al.[369a] claimed beneficial effects in cases of acute renal failure caused by ischemia from the intramuscular administration of the vasodilator drug papaverine (32 mg. every 2 hours for 48 hours).

When diuresis occurs, fluid intake may be increased cautiously, but the intake of sodium or of protein foods must be restricted until it is apparent that urea clearance and electrolyte excretion are adequate and blood urea nitrogen is diminishing. In the presence of oliguria or anuria digitalis should be given cautiously even when heart failure is present. Cedilanid by injection or Digoxin orally is preferred because of rapid elimination, but the usual dosage should be diminished to allow for deficient excretion. Mercurial diuretics are interdicted.

In some instances, if the patient is seen early during the stage of shock and if there is a low blood volume, the cautious administration of blood, plasma or saline is indicated. When oliguria is the result of dehydration caused by excessive vomiting or diarrhea or diabetic acidosis, the urine is almost always concentrated before renal tubular failure has occurred and there is usually little risk in the vigorous replacement of fluid and electrolytes. The urinary output should increase promptly. On the other hand, when oliguria is already present following prolonged shock and the urine is dilute and of low specific gravity (except when grossly bloody), there is great danger of overhydration in administering blood or fluids in an effort to overcome shock.

As a rule lower nephron nephrosis is a spontaneously reversible condition in which diuresis begins several days to two weeks after onset

and clinical improvement follows, provided that the patient does not succumb from heart failure pulmonary edema or hyperkalemia as a result of improper treatment Several months may be necessary for complete recovery of renal function Occasionally renal recovery is incomplete

CHRONIC NEPHRITIS AND UREMIA

Cardiac manifestations are uncommon until the stage of advanced renal insufficiency and uremia [93] Hypertension is less prominent than in cases of essential hypertension but occasionally the blood pressure and clinical features are indistinguishable from those of the malignant phase of essential hypertension is often a terminal manifestation, it may appear many weeks before the end, may undergo remission and recurrence and may even heal [271] Extreme retention of potassium may cause ventricular standstill or fibrillation and death [93]

The heart in uremia may show not only pericarditis but also foci of fatty degeneration and vacuolization of muscle fibers, which have been likewise attributed to metabolic toxins [[illegible]] Lüscher[281] described a case in which there was severe interstitial hemorrhagic myocarditis

Roentgen ray films of the chest show no abnormality or the left ventricular enlargement associated with hypertension Occasionally there are striking pulmonary changes

Fig 144 Azotemic edema of lungs *A* Glomerulonephritis with azotemia and pulmonary edema "Butterfly" type of pulmonary congestion and edema Symmetrical densities fan out from hila like wings of a butterfly Heart enlarged
B Clearing of lung fields and reduction of cardiac silhouette in same patient after treatment

Coronary atherosclerosis is less frequent than in essential hypertension probably because most patients with chronic glomerulonephritis succumb before the age of 40 In the cases of nephritis with hypercholesterolemia the coronary atherosclerotic process is said to be precocious

Heart failure is uncommon except toward the end of the disease It results from deficient excretion of sodium and water the intravenous administration of excessive quantities of fluids and occasionally from associated hypertension coronary atherosclerosis and anemia

In the presence of *uremia*, a sterile pericarditis occurs, possibly due to retained metabolites [99] (p 601) While the pericarditis characterized by bilateral clouding of the central and lower median lung fields which may appear and disappear in a few days (azotemic edema of the lungs) [2 3] (*Fig 144*) They are due to pulmonary edema caused by left ventricular failure

Electrocardiographic changes occur often in uremia There are frequently evidences of left ventricular hypertrophy and of myocardial damage in the cases associated with severe hypertension and coronary atherosclerosis More distinctive are [[illegible] 302]

(1) T wave inversions with or without ST elevations due to diffuse pericarditis [271]

(2) Prolongation of the Q-T interval due to hypocalcemia,

(3) Tall narrow T waves in limb and chest

leads with early hyperpotassemia bizarre slurring notching and widening of the QRS complexes[270] and bradycardia with or without intraaterial and atrioventricular block with more advanced potassium intoxication and finally cardiac arrest[221] ■ Electrocardiographic changes of hypopotassemia (p 1031) may occur in chronic renal insufficiency[103] as a result of vomiting diarrhea and insufficient food and therefore low potassium intake[296] (prolonged Q T interval wide T wave depression of ST segment)

Chapter 38

PULMONARY EMBOLISM AND ACUTE COR PULMONALE

RELATION OF PULMONARY EMBOLISM TO HEART DISEASE

The occurrence of pulmonary embolism following operation is well known but it is less generally recognized that it appears with greater frequency among medical patients,[4,5] especially those with heart disease[6,7] Thus of 370 autopsied cases of pulmonary embolism and infarction Hampton and Castleman[8] found that 40 per cent represented a post operative complication, but 30 per cent were cardiac medical cases and another 30 per cent non-cardiac medical cases

Pulmonary embolism is of special interest to the cardiologist in the following relationships

1 **Congestive Heart Failure** Pulmonary embolism may precipitate congestive heart failure in the cardiac patient especially the rheumatic cardiac who was previously well compensated It is a frequent cause for intensification of congestive heart failure and very commonly it is responsible for refractoriness of heart failure to all therapeutic agents Finally, it may be responsible for sudden death or it may represent the final blow in a chronic progressive unfavorable clinical course of patients in heart failure

2 **Acute Myocardial Infarction** (p 541) Pulmonary embolism is a common complication and is an important cause of death in the fatal cases of acute myocardial infarction Not infrequently pulmonary embolism presents a problem of differential diagnosis from acute myocardial infarction especially in patients with previous coronary occlusion Pulmonary embolism may itself be responsible for acute myocardial necrosis in the absence of acute coronary occlusion especially in the presence of preexistent coronary narrowing or occlusion

3 **Rheumatic Heart Disease** Pulmonary embolism has presented a problem in patients with rheumatic heart disease, and specifically mitral stenosis who are being considered for mitral commissurotomy Frequently they develop fever, without apparent cause which is interpreted as evidence of active rheumatic fever This is responsible for prolonged delay in performance of the operation or for rejection of the patient as unsuitable The actual cause of such fever is usually *recurrent pulmonary embolism* or occasionally patchy bronchopneumonia in the congested lung Although there is pathologic evidence suggesting the frequent presence of "active" rheumatic inflammation in the adult patient with rheumatic mitral stenosis this cannot be related to overt clinical manifestations of rheumatic activity Rheumatic fever is rarely responsible for acute febrile disease in the adult patient (over 25) with mitral stenosis and heart failure

4 **Unexplained Fever in the Cardiac Patient** Pulmonary embolism is the commonest cause of unexplained fever in the adult patient in congestive heart failure or in the cardiac patient who is subjected to bed rest for any reason In the adult with compensated rheumatic heart disease or congenital heart disease, bacterial endocarditis is the commonest cause of unexplained fever lasting more than a week In the child with a previous history of rheumatic fever rheumatic activation is the commonest cause of protracted fever but usually there will be other signs besides the fever

5 **Chronic Cor Pulmonale** The occasional development of chronic cor pulmonale due to recurrent pulmonary embolism will be discussed (p 981)

6 **Acute Cor Pulmonale** This includes cases of sudden pulmonary vascular obstruction due to massive or extensive pulmonary emboli Acute cor pulmonale and pulmonary em

bolism are not interchangeable terms, for only massive or extensive embolization is usually capable of producing cardiac disease

ETIOLOGY OF PULMONARY EMBOLISM

Pulmonary emboli result from dislodgment of antemortem blood clots arising in a thrombus of the systemic veins or right chambers of the heart As a rule the embolism is of the bland (non infected) variety Complete bed rest with immobilization of the body is the most important factor associated with venous thrombosis and consequent pulmonary embolism Cardiac disease, especially when complicated by heart failure malignant disease, especially of the pancreas, hematologic disease especially polycythemia obesity, age above 50 and varicose veins are among the predisposing factors[48, 8] Pulmonary embolism occurs after operations especially in the pelvic organs in females after prostatectomy in the male after parturition and after immobilization for fractures or for cerebrovascular accidents[8]

Pulmonary embolism is commonly precipitated by factors which raise the venous pressure and thus dislodge a venous thrombus e g, straining at stool getting out of bed or getting in and out of a wheelchair[70, 64]

PATHOLOGY

Pulmonary embolism may result from venous thrombi associated with pain, redness and swelling classified as *thrombophlebitis*,[2] or from venous thrombi which are virtually asymptomatic and classified as *phlebothrombosis*[1, 38, 34]

The source of the pulmonary embolus is a thrombus, almost always in the veins of the lower extremities but occasionally in the right atrium in patients with heart failure and atrial fibrillation, and more rarely in the right ventricle in cases of massive septal infection, idiopathic cardiac hypertrophy and heart failure, or endocardial fibrosis or fibroelastosis There is some difference in reported data as to whether the greatest frequency of the thrombi is in the deep femoral veins of the thighs[54] or in the deep veins of the calf muscles[59, 26] The causative thrombi may also be situated in the iliac veins, in the superficial femoral veins the plantar veins,[61] the periprostatic veins or rarely in other veins of the abdomen, the head, neck, upper extremities or trunk Venous thrombi in the lower extremities are frequently bilateral

For a discussion of the pathogenesis of venous thrombosis see Welch[74] Hampton and Wharton[31] and Ochsner et al[4] [?] Slowing of the blood stream (venous stasis),[63, 54] injury to the vascular endothelium[60] and alterations in the physical or clinical properties of the blood which promote coagulation are the most important causative mechanisms

The pulmonary emboli themselves may block the main pulmonary artery, sometimes extending to the conus of the right ventricle and partially occluding the pulmonary valvular orifice (functional pulmonary stenosis) There may be a riding embolus at the bifurcation of the pulmonary artery But most often the emboli are multiple, occlude smaller branches of the pulmonary arteries and are of different ages[5] Pulmonary infarction does not occur when very large or very small vessels are occluded Infarction is most likely to result if a medium sized or large pulmonary arterial branch is occluded if there is preexistent pulmonary stasis and if the patient survives at least for a day or two[33, 10]

Pulmonary embolism may cause right ventricular dilatation in acute cases[44, 33] right ventricular hypertrophy in chronic cases (p 981) Myocardial necrosis of the left ventricle, especially the subendocardial regions may result from anoxia, shock or possibly pulmonary coronary reflexes which cause coronary insufficiency and myocardial ischemia[35]

PATHOLOGIC PHYSIOLOGY

There is experimental evidence that serious circulatory disturbances occur only after 60 per cent of the pulmonary circulatory cross-sectional area is cut off and that death usually follows more than 85 per cent obstruction[6, 46, 24] With lesser degrees of obstruction insufficient to cause death or reduce the systemic arterial pressures, there is an increase in pulmonary vascular resistance compensated by a stronger right ventricular contraction and a rise in right ventricular and pulmonary arterial pressure[6, 19]

Circulatory and cardiac disturbances which follow large pulmonary emboli may be due to (1) mechanical interference with cardiac output and (2) myocardial ischemia or hypoxemia The myocardial ischemia or hypoxemia may be the result of (a) a sudden and severe reduc

tion in cardiac output and aortic pressure (shock) (b) arterial hypoxemia due to pulmonary asphyxia (c) reflex vasoconstriction of the coronary arteries mediated by the vagus nerves (pulmonocoronary reflex) [61, 4, 66] or (d) impaired coronary drainage by way of the Thebesian vessels due to the rise in pressure in the right cardiac chambers [73] The possibility of a pulmonocoronary reflex has been raised particularly because of the occurrence of shock and sudden death in cases in which there were only relatively small emboli There is experimental evidence favoring[61, 69] and refuting[63, 37] this hypothesis The occasional serious consequences of small pulmonary emboli have also been explained by local reflex vasoconstriction of the uninvolved pulmonary vessels However there is considerable uncertainty as to the importance of vasomotor effects in the pulmonary vessels [14, 73]

CLINICAL FEATURES

The clinical features of pulmonary embolism are so varied and often so non specific that the diagnosis must be ventured when any of a host of possible unexplained symptoms occur in a patient in heart failure especially if he has been subjected to bed rest

1 *Shock or sudden death* with or without preceding air hunger anxiety restlessness chest pain mental symptoms ocular palsies or convulsions may be due to a sharp reduction in cardiac output

2 *Acute right ventricular strain* is usually obscured by the manifestations of diminished cardiac output but may be disclosed by electrocardiographic signs (infra) and occasionally by a prominent pulsation in the second and third interspaces to the left of the sternum accentuation of the second pulmonic sound and a loud pulmonic systolic murmur

3 *Dyspnea tachypnea* and *cyanosis* may result from impaired pulmonary ventilation and possible reflexes of undetermined nature

4 *Pulmonary and Pleural Symptoms and Signs Due to Pulmonary Infarction* These may include chest pain especially on inspiration cough bloody expectoration fever leukocytosis physical and roentgenologic signs suggesting pneumonia pulmonary neoplasm[85] or pleural effusion [73] The pleural fluid is often sanguineous The chest pain the cough and the hemoptysis may one or all be absent in many cases of pulmonary infarction Jaundice may occur in cases of pulmonary infarction and severe chronic right sided congestive heart failure

5 *Fever and Other Non specific and Unexplained Symptoms* In many or most cases of pulmonary emboli the symptoms consist only in unexplained fever often in recurrent episodes unresponsive to antibiotics and associated in cardiac patients with the development or intensification of congestive heart failure Unexplained anxiety episodes of unexplained tachycardia with or without precordial oppression anxiety or transient dyspnea or episodes of tachypnea may be the only manifestations of pulmonary embolism A paroxysm of atrial fibrillation may be initiated by pulmonary embolism Occasionally there is transient weakness faintness or syncope or an unexplained fall in blood pressure Some pulmonary emboli are virtually asymptomatic

ELECTROCARDIOGRAPHIC SIGNS OF PULMONARY EMBOLISM

In 5 of their 7 cases of acute cor pulmonale in which electrocardiograms were taken early McGinn and White[66] observed abnormalities which were fairly similar and which were interpreted as being characteristic of the condition The chief abnormalities were

1 A deep S_1

2 Prominent Q_3 and inversion of T_3 as in myocardial infarction of the posterior wall

3 Depression of ST segment in lead II and often in lead I and a staircase ascent of ST_2

4 T_2 was diphasic or inverted

5 Occasionally there was a right deviation of the electrical axis but never a left deviation during the acute episode The abnormalities disappeared in a few days

Subsequent studies have confirmed these findings with certain variations and amplifications [65, 31, 73, 47, 38, 37, 40] In particular the electrocardiographic changes observed with pulmonary embolism appear to be those associated with clockwise rotation and a vertical electrical axis as well as possible right ventricular dilatation The abnormalities are found in only 10 to 20 per cent of cases of pulmonary emboli [67] chiefly because electrocardiograms are not taken early enough or because the emboli are too small to cause a strain on the right ventricle In cases of pulmonary artery obstruction produced in the course of pneumonectomy in humans the electrocardiograms showed a shift of the

A B

Fig. 146 *A* Pulmonary infarction left upper lobe
B Clearing of infarct with residual horizontal linear scars or focal atelectasis

electrical axis to the right and a deep S_1 in the majority of instances The changes appeared immediately and disappeared in 24 hours[8] Durant Ginsburg and Roesler[16] noted right bundle branch block with broad shallow S_1 and S_2 in the first two hours after pulmonary embolism (Fig 145) Occasionally P_2 is tall and sharp[78] Frequently the electrocardiogram of pulmonary embolism is modified by preexisting abnormalities due to myocardial disease A significant Q wave is less commonly present in aV_F in pulmonary embolism than in posterior ventricular infarction but occurs often enough to be unreliable as a distinguishing feature[56 17] A delayed R or R' may be present in aV_R S waves may be present in leads II III and aV_F

Multiple chest leads usually reveal the most persistent changes for they may not disappear for three to six weeks Wood[79] described an inversion of the T wave from V_1 to V_3 or V_4 Occasionally he observed a transient right bundle branch block (Fig 145) In addition a shift of the transitional zone to the left i e to V_4 or V_5 (clockwise rotation) has been noted in precordial leads

Clinical experimental and electrocardiographic observations strongly suggest that the electrocardiographic changes are due primarily or exclusively to acute right ventricular strain following massive pulmonary embolism[44 43 55] The possibility that myocardial anoxia is a contributing factor is suggested by the Q_3-T_3 changes resembling those of posterior wall infarction and by the pathologic findings of myocardial necrosis in cases of massive pulmonary embolism[3 15 11] However the identical electrocardiographic abnormalities have been observed in cases without myocardial necrosis

THE VECTORCARDIOGRAM IN ACUTE COR PULMONALE

A distinctive vectorcardiographic pattern has been described in cases of acute cor pulmonale and differentiated from that of posterior (diaphragmatic) ventricular infarction[37a] There was a slightly increased magnitude and duration of the initial vectors of the QRS loop There was clockwise rotation of the loop in the frontal plane and a large terminal appendage directed to the right and posteriorly occasionally superiorly The vector cardiogram of posterior infarction was distinguished chiefly by the greater increase in magnitude and duration of the superiorly directed initial vectors and by the absence of superiorly oriented terminal vectors

ROENTGENOLOGY

The roentgenologic signs directly attributed to acute cor pulmonale either are not striking or have been insufficiently studied The hilar shadows and pulmonary vascular shadows may be wider than normal The left middle salient may be prominent owing to dilatation of the pulmonary artery

Roentgenologic study[64 31 46] may suggest the presence of pulmonary infarction resulting from pulmonary embolism The shadows of pulmonary infarcts may not appear until 24 hours or several days after the occurrence of the pulmonary embolism An early sign of pulmonary infarction according to Wharton and Pierson[76] is the clouding of the base of the lung obscuring the costophrenic sinus on the affected side Infarcts are often multiple and occur chiefly in the lower lobes[67] Infarcts appear as areas of plate like atelectasis The shadows of infarcts may have the classic triangular or truncated shape (Fig 146) but more often they are round oval or irregular[31] Often they are indistinguishable from pneumonic infiltrations or from severe pulmonary congestion due to heart failure According to the studies of Hampton and Castleman[31] infarcts occur most often at the junction of two pleural surfaces and therefore the roentgen ray shadows are observed at the base of the lungs near the costophrenic sulcus at the junction of adjoining lobes and near the mediastinum (Fig 124 p 661) Pleural effusions are frequent and may conceal the shadow of the infarct itself There may be a shadow at one base with ultimate elevation of the diaphragm on that side due to partial atelectasis Rarely there is localized rarefaction indicative of necrosis or abscess Pleural thickening localized fibrosis or linear shadows may represent scars of old infarcts According to Westermark[75] and others[63] pulmonary embolism without infarction may cause transient clearing (avascularity) of the normal shadow of pulmonary tissue distal to the embolism

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of acute cor pulmonale involves (a) the diagnosis of pulmonary em

bolism plus (b) the diagnosis of right ventricular strain

Pulmonary embolism should be considered whenever there is a sudden onset of collapse, precordial oppression or chest pain, dyspnea, tachypnea or cyanosis, especially in patients who have been confined to bed for one to three weeks by cardiac disease, by an operation, fracture delivery or a medical illness Often, however, there may be only a clinical picture of shock or sudden weakness with little or no cyanosis chest pain or dyspnea Unexplained elevations in temperature and tachycardia in the second week postoperatively are often indicative of pulmonary embolism In cases of heart failure unexplained fever, lack of response to therapy or pleural effusions which are exudates or hemorrhagic should suggest the possibility of pulmonary embolism Tenderness of the calf muscles or thighs a positive Homans sign,[33] thickening and infiltration of the deep calf muscles[49] swelling of the leg or thigh and prominence of the superficial veins confirm the diagnosis Often however, there are neither symptoms nor signs of venous thrombosis In such cases venography with the aid of contrast media may disclose evidence of venous occlusion[4, 44, 16]

If death does not occur within 24 hours, the diagnosis may be further suggested or confirmed within the next few days by the development of cough and hemoptysis, localized pain on deep breathing local signs of pulmonary congestion or consolidation, a pleural rub physical signs of pleural effusion, or by roentgenologic evidences of pulmonary infarction But none of these may be present if infarction does not result from the pulmonary embolus The occurrence postoperatively or even in healthy ambulant patients[29, 33, 80] of a peculiar pneumonia or pleurisy should suggest pulmonary embolism as one of the conditions to be considered in differential diagnosis

The electrocardiogram may disclose distinctive features in about 10 to 20 per cent of pulmonary emboli but in a much higher percentage of massive emboli if the record is taken on the day of the attack (p 961)

Once a diagnosis of pulmonary embolism is made, the additional diagnosis of *acute cor pulmonale* depends on the finding of clinical evidence of pulmonary hypertension (e g, accentuation of P_2, percutory signs of a dilated pulmonary artery), roentgenologic evidence of pulmonary, right ventricular and perhaps right atrial dilatation, electrocardiographic evidence of right ventricular strain and clinical evidences of acute congestive right ventricular failure (e g, engorged cervical veins)

A problem in the differential diagnosis between coronary thrombosis and pulmonary embolism is most likely to arise when the latter is associated with chest pain The chest pain is frequently worse on inspiration in pulmonary embolism, rarely so in myocardial infarction except when complicated by early pericarditis On the other hand, the pain of myocardial infarction frequently radiates to the arms and forearms or is accompanied by weakness or numbness in the wrists unlike the pain of pulmonary embolism

The electrocardiogram of pulmonary embolism is distinguished from that of posterior ventricular infarction which it may simulate by the presence of a deep S_1 inversion of the T waves in V_1 V_2, shift of the transitional zone of QRS to the left in precordial leads and a late R in aV_R, and by the rapid reversion of these changes to normal Serial determinations of serum glutamic oxalacetic transaminase (S GOT) may aid in differentiating pulmonary embolism from myocardial infarction In many instances there is no rise in S GOT in cases of pulmonary embolism In other cases in which the S GOT is increased the level is usually not as high as in cases of acute myocardial infarction and the peak concentration occurs between the third and sixth day in pulmonary embolism, at about 24 hours after acute myocardial infarction[32a] (p 510)

PROGNOSIS OF ACUTE COR PULMONALE

The outlook after a massive pulmonary embolus is extremely unfavorable When the embolus is of sufficient size to cause shock or acute right ventricular dilatation death occurs in the majority of cases Of 100 clinical cases of pulmonary embolism reported by Takats, Beck and Fenn,[84] 87 died and 13 survived Similarly Hampton and Wharton[..] report the survival of 10 per cent of patients with pulmonary embolism following gynecologic operations Pulmonary embolism is regarded as being responsible for about 6 to 10 per cent of all postoperative deaths[3, 4, ...]

Pulmonary emboli of secondary or smaller branches are usually survived but are often of ominous significance They are frequently precursors of recurrent emboli ation which

may be terminated by a final massive embolus of the main pulmonary artery or its primary divisions In 21 4 per cent of 897 cases of pulmonary embolism studied by Barker et al [3] the first attack was fatal But of 343 fatal cases of embolism the fatal embolism was preceded by one or more non fatal emboli in 36 2 per cent These observers noted that if a patient has a non fatal postoperative pulmonary embolus he has slightly less than one chance in five of subsequent fatal pulmonary embolism and about three chances in ten of subsequent embolism fatal or non fatal The clinical signs and symptoms of small pulmonary emboli usually subside in a week or two but the clinical course may be prolonged by pleural effusion or suppuration of an infarct

Even pulmonary emboli of the primary pulmonary arteries may not cause death but may undergo organization and recanalization Such large emboli or multiple smaller emboli may occasionally produce pulmonary hypertension right ventricular hypertrophy and failure (*chronic pulmonary heart disease or chronic* cor pulmonale) (Chapter 39)

TREATMENT OF PULMONARY EMBOLISM

PROPHYLAXIS

Avoidance of Venous Thrombosis

The treatment of massive pulmonary embolism and its cardiac and circulation sequelae properly begins with prophylaxis against the development and dissemination of venous *thrombi* [I] *In medical cases it seems desirable* to avoid prolonged periods of bed rest unless *essential and to avoid immobilization of the* body *or extremities if bed rest is necessary Fortunately the dangers of bed rest especially* pulmonary embolism have recently been *publicized Since cardiac failure appears to be* a frequent predisposing cause among medical *cases adequate treatment of this condition is* important

In surgical cases care should be exercised in the handling of tissues and injury or com*pression of veins draining the lower extremities* should be avoided The position of the patient *on the operating table should cause no un*necessary interference with the venous return *Abdominal strappings or binders should not* be so tight that they prevent deep breathing *Postoperatively, abdominal distention should* be avoided or treated promptly Motion of the body should be encouraged *and regular fre*quent exercises of the legs and respiratory exercises should be ordered Adequate hydration prompt control of infection and avoidance of chilling are also believed to be valuable prophylactic measures [5] Reduction of the period of rest in bed (early ambulation not merely early sitting in a chair) may be of major importance in avoiding venous thrombosis [26] The Trendelenburg position has been recommended to avoid venous thrombosis but Frykholm[73] has opposed its use and advocated elevation of the head of the bed for one to two hours daily in order to distend the collapsed veins in the lower extremities and to compel active movements of the adductor muscles of the thigh Elastic bandages or stockings have been employed in the prophylaxis of post operative thromboembolism [71, 77]

The routine use of anticoagulants[41] has been recommended following operations injuries or other conditions requiring complete bed rest The use of anticoagulants in patients with acute myocardial *infarction* and *congestive* heart failure has been discussed (p 572 and p 287 *respectively*)

Recognition and Treatment of Venous Thrombosis

Daily examination of the legs for induration *or local tenderness over the deep veins for* pain on dorsiflexion of the foot with the leg ex*tended (Homans sign*[33]*) and for edema and* dilatation of the superficial veins and careful *measurement of the circumference of the legs* to discover swelling should be performed whenever *there is a* probability of venous thrombosis Sudden sharp chest pain *faintness hemoptysis fever tachycardia dyspnea or other manifestations of pulmonary em*bolism are usually the first indications of an underlying phlebothrombosis which is then discovered by *local examination*

The treatment of venous thrombosis (phlebothrombosis) to avoid initial or recurrent pulmonary embolism consists essentially of two measures (1) anticoagulant therapy or (2) thrombectomy and venous ligation

Although there has been a strong trend in favor of anticoagulants in the treatment (as well as prevention) of venous thrombosis and as a prophylaxis against pulmonary embolism venous ligation still has its adherents [72, 1, 7] In a recent review of 748 cases of phlebitis Byrne[7] reported a mortality rate of 2 1 per

cent in 369 cases treated by bilateral femoral vein ligation or occasionally by division of the inferior vena cava, a mortality rate of 29 per cent in 32 cases treated by anticoagulants, and a mortality rate of 37 per cent among 347 cases treated conservatively However, the mortality rates may have been determined by the basic disease rather than by the method of treatment

The details of anticoagulant therapy have been discussed (p 572) The ligation of the inferior vena cava for intractable heart failure has been mentioned (p 290)

TREATMENT OF PULMONARY EMBOLUS

The direct treatment of the pulmonary embolus itself aside from the use of anti coagulants is unsatisfactory Based on the *experimental observations which indicate the* occurrence of vagal reflexes with spasm of the coronary vessels and other smooth muscle structures *atropine* has been administered *intravenously* in repeated doses of 0 6 mg (1/100 grain), and *papaverine hydrochloride* by the same route in doses of 0 03 gm (½ grain) With massive embolization the latter may be repeated at hourly intervals Morphine or Demerol may be necessary for pain and restlessness

Oxygen should be administered in cases of massive pulmonary embolism by nasal catheter, mask or tent or in 100 per cent concentration by the special mask of Boothby and his associates [6]

Surgical removal of an embolus in the main pulmonary artery or its bifurcation (Trendelenburg operation) has been successfully performed and strongly advocated by Kirschner[19] and Meyer [11] This requires a well trained organization which may be rapidly set into action when the diagnosis is made The procedure can be utilized *for those patients who* survive more than an hour According to de Takats, Beck and Fenn,[69] the Trendelenburg operation was carried out 132 times with a mortality of 93 2 per cent, but these operations were performed almost exclusively on rapidly fatal cases

FAT EMBOLISM

Embolism of the pulmonary circulation may result from the entrance of free globules of fat into the systemic veins [31, 79] Fat embolism *occurs most commonly* after a fracture of a long bone especially the femur, tibia or both [9, 91] But it may occur also after other forms of trauma to bone marrow or subcutaneous adipose tissue osteomyelitis, various poisons or burns [90]

The released fat enters the systemic veins and may reach and obstruct the main pulmonary artery,[87] thus sharply reducing the cardiac output and causing acute cor pulmonale More frequently the fat globules reach the *pulmonary capillaries, where they may be* trapped and where they may cause widespread pulmonary obstruction with lesions in the affected lung tissue As a rule some of the globules of fat traverse the pulmonary capillaries and reach the systemic (arterial) circulation, where they block the capillaries and arterioles of the brain, the skin, heart and numerous internal organs Fat emboli may *also reach the systemic* circulation from the right side of the heart by way of a patent foramen ovale The occurrence of clinically significant coronary occlusion due to fat embolism is unproven [11]

The *clinical features* are determined chiefly by embolic lesions in the lungs and the brain *Characteristically, after an injury* the patient has a free interval of relative comfort lasting from six hours to two or three days If there is a massive occlusion of the pulmonary artery by a large quantity of liquid fat, death may occur suddenly with a clinical picture of shock air hunger and pulmonary edema *More commonly, a few days after* the injury the patient begins to suffer from dyspnea and restlessness followed by sweating pallor or cyanosis, and cough with blood tinged sputum These manifestations are due to occlusion of the pulmonary *capillaries by fat* Tachycardia tachypnea and fever are frequent There are often *diffuse moist* râles and other signs resembling those of pulmonary *consolidation* or edema Shock and pulmonary edema occur in severe cases [89] Free fat droplets may be demonstrated occasionally in the sputum by staining with Sudan III, *but it is* doubtful whether this is pathognomonic of pulmonary fat embolism *Roentgenograms* of the chest may reveal bilateral patchy pneu*monic consolidation* or pulmonary edema

Cerebral symptoms may be combined with or follow these pulmonary manifestations They should not be misinterpreted *in cases of* head injury, and must be differentiated from cerebral manifestations of concussion and cerebral hemorrhage shock, delirium tremens,

uremia diabetic coma and bronchopneumonia ■ More often they appear several hours to days after the injury without preceding pulmonary symptoms The patient suffers from somnolence disorientation or delirium There may be convulsions paralyses loss of sphincteric control and stertorous or Cheyne Stokes respiration Fat emboli in the retinal arteries have been visualized opthalmoscopically ■ Occasionally fever stupor and coma are the essential signs of fat embolism without preliminary pulmonary or localizing cerebral signs The occurrence of dark red petechial hemorrhages on the skin of the anterior chest, arms neck conjunctivae and mucous membranes is of diagnostic value

Recovery may occur,[93] probably independently of the treatment employed In fatal cases death usually occurs after two or three days The avoidance of further trauma in handling and transporting injured patients is emphasized in the prophylaxis of fat embolism Treatment is symptomatic Oxygen therapy is administered if there is cyanosis and dyspnea Norepinephrine has been recommended Sodium desoxycholate (10 cc of 20 per cent solution by slow intravenous drip every two hours) has been suggested as a therapeutic measure by Rappert ■ with the object of emulsifying the fat globules and thus reducing the elevated blood viscosity

AIR EMBOLISM

Systemic Venous (Pulmonary Arterial) Air Embolism

When air rapidly enters the systemic veins in large quantities it reaches the right ventricle where because of its easy compressibility it acts as an air trap and interferes with ventricular contraction Air embolism may obstruct the main stem of the pulmonary artery [103] causing pulmonary hypertension with reflex systemic hypotension and bradycardia [100] It may also produce pulmonary obstruction by causing widespread embolization of the pulmonary arterioles or capillaries [101] An average lethal dose is 5 to 7 5 cc per kilogram when the rate of intravenous injection is very rapid (1 to 5 seconds) According to Curtillet [94] air bubbles do not reach vessels less than 30 micra in diameter and therefore they are arrested in the arterioles The presence of air in the ventricular cavity may be revealed by a loud churning or waterwheel murmur over the precordium Death often results suddenly with or without premonitory cyanosis or pallor, evidences of shock, dyspnea and stertorous respiration and coma These manifestations result from diminished cardiac output pulmonary hypoxemia and eventually cerebral hypoxemia [94]

Systemic venous air embolism occurs mostly in the course of major surgical operations on the thyroid gland and other structures of the neck where the veins are large and kept widely patent by fascial structure but it may also complicate numerous minor diagnostic and therapeutic procedures These include among others tubal insufflation and urethroscopy perirenal insufflation, irrigation of the nasal sinuses pneumoperitoneum direct transfusions, and uterine douches or adoption of the knee-chest position in the puerperium Air embolism has been noted after criminal abortions and vaginal powder insufflations [99]

Prompt treatment is important In the experimental animal with systemic venous emboli (to the right ventricle) displacement of the air trap by turning the body into the left lateral position may be lifesaving ■ Therefore it ■ recommended that following venous air embolism the patient should be placed in the left lateral position (right side up) and given artificial respiration [96, 100] If these measures are ineffective a needle should be inserted through the chest wall into the right ventricle in an effort to aspirate air Inhalation of 100 per cent oxygen has been recommended on the basis of experimental studies [97]

Arterial Air Embolism (Pulmonary Venous Air Embolism)

According to experimental studies smaller quantities of air are required to cause death when injected into a pulmonic vein than when injected into ■ systemic vein [100] When air enters the pulmonary vein it reaches the left side of the heart and systemic arterial circulation Such arterial air emboli may also occur when air ■ introduced into a systemic vein if there is an interatrial communication As a rule air emboli reaching the pulmonary arterioles from a systemic vein do not cross to the pulmonary vein and systemic arterial circulation as do fat emboli [94] Arterial air emboli cause serious symptoms chiefly by occluding arterioles or capillaries of the brain Air emboli also involve the coronary arteries at the same time [100] Durant[95] reported a case of air embolism in which there were characteristic electrocardiographic changes such as occur

after a cardiac infarction By means of roentgenography Balogh[93] noted a reflux of air from the right ventricle into the thebesian and coronary veins He believed that this causes coronary stasis and may be responsible for clinical symptoms

Clinically *systemic arterial air embolism* results most often from the entrance of air into the pulmonic veins in the course of pleuropulmonary operations or artificial pneumothorax [98, 80] It also occurs after chest injuries and pleural lavage of empyema cavities So-called pleural shock may in reality represent air embolism Symptoms appear rapidly, beginning with dizziness or pallor and followed by mental confusion disorientation hallucinations convulsions vomiting paralyses, especially hemiplegia or monoplegia, aphasia and amaurosis The latter is due to air embolism of the retinal arteries which sometimes may be visualized clinically with the ophthalmoscope [102] Marbling of the skin may result from obstruction of the cutaneous vessels or from shock Coma and death may occur within fifteen minutes Patients surviving an hour or longer usually recover Blindness and paralyses disappear in most cases but there may be residua

Therapy is unsatisfactory Maintenance or assumption of the head-down position is recommended to avoid floating of the air bubbles into the cerebral vessels The Trendelenburg position is desirable at operations in which air embolism may be anticipated (e g chronic pulmonary abscess)

Chapter 39

CHRONIC PULMONARY HEART DISEASE—COR PULMONALE

Definitions

Pulmonary heart disease and *cor pulmonale* are terms applied to the hypertrophy of the right ventricle with or without congestive heart failure, resulting from disease of the lungs or pulmonary vascular tree Pulmonary heart disease is often divided into the *acute form* induced by massive pulmonary embolism the *subacute form* due to lymphangitic carcinomatosis of the lung and the *chronic form* due to obstructive emphysema or other chronic pulmonary disease Cor pulmonale was often called *emphysema heart* because emphysema is the commonest cause of pulmonary heart disease

Ayerza's Disease or Syndrome The term Ayerza's disease[129] or Ayerza's syndrome refers to a clinical syndrome characterized by bronchopulmonary disease, intense cyanosis polycythemia and congestive heart failure, usually associated with bronchopulmonary symptoms but without primary cardiac disease Ayerza had referred to the syndrome as *cardiacos negros* (black cardiacs),[7] because of the deep cyanosis of the affected patients At present there are multiple concepts of the etiology of Ayerza's syndrome even among Ayerza's students One theory attributes it to syphilitic pulmonary arteritis,[4, 46] another to bronchial syphilis and pulmonary arteriosclerosis[47] another to primary non syphilitic sclerosis of the pulmonary artery and still another to various bronchopulmonary diseases with or without secondary pulmonary atherosclerosis[35] Ayerza's syndrome is not synonymous with cor pulmonale but represents a clinical syndrome at one stage of cor pulmonale when there is advanced pulmonary insufficiency as well as decompensated cor pulmonale

Hypertension of the Pulmonary Circulation

Despite a varied etiology of chronic cor pulmonale, it is generally assumed that there is probably a unitary mechanism producing it namely, an increased resistance and therefore an increased pressure in the pulmonary circuit Measurements of the right ventricular pressure by intracardiac catheterization have disclosed an elevation of the systolic and pulse pressures, but the diastolic ventricular pressure was normal in the absence of heart failure[27] The occurrence of exclusive or predominant right ventricular hypertrophy is an direct evidence of increased pulmonary resistance to ventricular outflow The increased frequency and extent of pulmonary atherosclerosis in cases of chronic cor pulmonale has also been interpreted as resulting from and denoting the presence of pulmonary hypertension[132, 157]

Pulmonary Hypertension and Chronic Cor Pulmonale

Pulmonary hypertension may be caused by a variety of pulmonary, cardiac and vascular disturbances which fall into three broad groups

1 Mitral stenosis and less commonly other causes of left sided heart failure which result in pulmonary congestion

2 Extensive disease of the lungs or pulmonary arteries which greatly increases the resistance in the pulmonary circulation Obstruction of the pulmonary artery from without by a compressing aortic aneurysm or tumor may produce a similar effect[91]

3 Congenital cardiac lesions such as large and high ventricular septal defects and patent ductus arteriosus with reversal of shunt are associated with pulmonary hypertension In some instances of congenital heart disease pulmonary hypertension is due to pulmonary arterial lesions Such cases properly belong to group 2

The term chronic cor pulmonale or chronic pulmonary heart disease as used in this chap-

ter and elsewhere in this book is confined only to the second group in which pulmonary hypertension and consequent strain of the right heart are caused by primary disease of the lungs or pulmonary vessels But pulmonary hypertension due to any of the above causes may induce right ventricular hypertrophy and right heart failure

PULMONARY FUNCTION TESTS AND LUNG VOLUMES

The pulmonary lesions which are responsible for pulmonary hypertension and cor pulmonale also cause disturbances in pulmonary ventilation and aeration of the blood Consequently the physiologic disturbances and clinical manifestations of cor pulmonale are accompanied by disturbances in pulmonary ventilation and aeration An understanding of cor pulmonale therefore requires a knowledge also of pulmonary function and of the disturbances due to abnormalities in pulmonary ventilation and aeration

The ultimate function of the lung is to aerate the venous blood by supplying it with oxygen and removing carbon dioxide This involves three subsidiary functions (1) ventilation whereby air is moved into and outside of the lungs and well distributed to the pulmonary alveoli which are in contact with the pulmonary capillaries (2) alveolar capillary diffusion whereby alveolar oxygen diffuses into the capillaries and capillary carbon dioxide into the alveoli (3) circulatory or alveolar perfusion whereby the entire circulation passes through the pulmonary capillary bed Cor pulmonale is due chiefly or exclusively to the effect of intrinsic pulmonary disease on the pulmonary vascular bed However, impaired ventilation or alveolar-capillary diffusion may cause disturbances which indirectly alter the pulmonary circulation and add to the strain on the right ventricle In addition the disturbances in ventilation and aeration produce symptoms which resemble those of heart failure and must be distinguished from them

Tests of pulmonary function determine individual features such as the air capacity of the lungs the dynamic ability to move air into and out of the bronchial passages (bellows function) the ability to distribute air fairly uniformly to the perfused alveoli and the ability to diffuse oxygen and carbon dioxide across the alveolar-capillary membrane The over all function of the lung is assessed by determinations of the oxygen and carbon dioxide tensions and of the pH of the arterial blood and by the work or effort involved in breathing

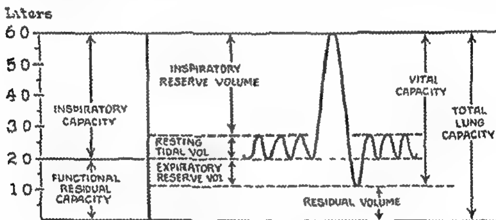

Fig 147 Subdivisions of total lung capacity

Lung Volumes (Fig 147)

The lung volumes denote the volumes of air that can be inhaled or exhaled from specific inspiratory or expiratory positions The lung volumes are conventionally measured from the so-called pulmonary mid position i e at the end of a quiet expiration Except for the residual air the various lung volumes may be measured by a spirometer preferably a recording spirometer of the closed circuit type e g, the Collins spirometer similar to the Benedict-Roth apparatus used for basal metabolism tests However the spirometer bell is larger measuring about 9 liters in capacity

and is filled with room air The tubing is of larger caliber (about 1½ inches inside diameter) and the soda lime container and flutter valves of the basal metabolism machine are removed to reduce resistance

Tidal Air The tidal air is the quantity of air inhaled and exhaled from the lungs during an ordinary respiration and amounts to about 500 cc After a quiet exhalation followed by an *ordinary inspiration an ordinary exhalation* is made into the spirometer and this quantity of exhaled air is measured as the tidal air

Inspiratory Capacity (Complemental Air) This is the maximum volume of air that can be inhaled from the resting pulmonary mid position While connected to the spirometer the subject takes a few normal breaths and then is directed at the end of a quiet expiration to inhale as deeply as possible The inspiratory capacity includes the tidal air and the inspiratory reserve which together equal about 3 liters normally

Inspiratory Reserve The amount of air which can be further inhaled at the end of an ordinary inspiration is the inspiratory reserve, which normally amounts to about 2500 cc

Expiratory Reserve Volume (Reserve Air or Supplemental Air) This is the maximum volume of air exhaled after a quiet expiration that is *from the pulmonary mid position* At the end of a quiet expiration, and without subsequent inspiration the subject exhales as much air as possible into a spirometer thus recording the reserve air Normally it is about 1000 cc

Vital Capacity (V C) The vital capacity is the maximum volume of air that can be exhaled following a maximum inspiration It includes the inspiratory capacity and the expiratory reserve The inspiratory capacity is 75 to 80 per cent *of the vital capacity and* the expiratory reserve 20 to 25 per cent Following a maximum inspiration the patient exhales as completely as possible into a spirometer thus measuring the vital capacity Normally the vital capacity is about 4 or 5 liters, with considerable variation Normal values may be calculated roughly by West s formula for males V C (liters) = 2 5 times body surface area in sq meters for females, V C = 2 times body surface area Or more accurately, by the regression formula of Baldwin et al [10] for males [27 63 − (0 112 × age in yrs)] × ht in cm , for females, [21 78 − (0 101 × age)] × ht

Residual Volume The volume of air remaining in the lung after a maximal expiration is the residual volume This air remains in the alveolar air sacs because the negative intra thoracic pressure prevents their collapse The normal residual volume is approximately 1500 cc

Total Lung Volume or Capacity This equals the sum of the vital capacity and the residual air, and *represents the total volume of air in* the lungs at maximal inspiration

Functional Residual Capacity and Residual Air (Residual Capacity) The *functional residual* capacity is the volume of air in the lungs at the end of a quiet expiration It is the sum of the expiratory reserve and the residual volume Neither the residual volume nor the functional residual capacity can be measured by direct spirometry The expiratory reserve is measured by spirometry as indicated above The functional residual capacity may be measured indirectly by the open circuit or closed circuit method (infra) The residual volume (residual air) is then determined by subtracting the expiratory reserve from the functional residual capacity

To determine the functional residual capacity by the *open circuit* method,[12, 67, 46, 11] a Tissot spirometer and tubing are washed free *of nitrogen by means* of 100 per cent oxygen and the subject then quietly breathes oxygen for 7 minutes Douglas bags instead of the Tissot *spirometer may be used for* collections of air from the lungs An alveolar sample is obtained at the end of that period by taking the sample of air at the very *end of a maximal* expiration After the volume of the air expired into the spirometer is measured, the nitrogen concentration of the expired air in *the spirom* eter and that of the alveolar sample are *determined* with the Van Slyke manometric apparatus The functional residual *air* can be calculated from a formula which essentially consists in dividing the amount of nitrogen expired by the reduction in alveolar nitrogen concentration during the period of oxygen breathing An open circuit method using helium has also been described [109, 24]

A number of methods have been devised using the closed circuit technique [43, 115, 41] The subject breathes into a closed circuit, including a spirometer containing known volumes and concentrations of oxygen,[4] hydrogen[147] or helium [83, 152] Or the nitrogen may be washed out of the lung by breathing oxygen and the

concentration of nitrogen can be serially determined with the aid of a nitrogen meter[78] Thus the need for obtaining alveolar samples can be obviated After a few breaths or several minutes of breathing it is assumed that there is complete mixing of the gases in the spirometer and lungs A katharometer which measures changing conductivity of a gas may be used to indicate completion of mixing in the circuit and lungs The functional residual volume is calculated from the known initial and final volume and the concentration of the gas in the spirometer In modern machines such as the Collins Vitalometer the helium volume introduced and the final concentration of helium are read directly from the kymographic record and a helium meter With the same spirometer the inspiratory capacity and expiratory reserve are measured and the individual lung volumes calculated

Kovack et al[1-8] described a method whereby the total lung capacity was calculated from various measurements made from a single posteroanterior film of the chest taken in deep inspiration The residual air is then determined by subtracting the vital capacity from the total lung capacity Du Bois et al[678] described a new plethysmographic method for measuring the resting end-expiratory thoracic gas volume i e the functional residual capacity There was excellent agreement with measurement by the open circuit method

Respiratory Dead Space The *anatomic dead space* refers to those parts of the respiratory system which serve primarily as conducting airways (mouth nose pharynx larynx trachea bronchi and bronchioles) and within which there is no rapid exchange of oxygen and carbon dioxide The *physiologic dead space* includes the areas of the lung (alveoli) which are ventilated but not perfused by blood and which therefore do not contribute to the exchange of oxygen and carbon dioxide The combined respiratory dead space is about one quarter of the tidal volume and should not exceed one third of the latter In certain pulmonary diseases notably emphysema there is no significant change in the anatomic dead space but the physiologic dead space is increased because of the underperfusion or lack of blood perfusion of ventilated alveoli[224] Air leaving these alveoli is virtually unchanged inspired air The dead space effect (D S) may be stated as a percentage of tidal air (or of total ventilation) and may be estimated as follows

$$DS = \frac{\text{arterial } pCO_2 - \text{Expired } pCO_2}{\text{arterial } pCO}$$

The respiratory dead space can be measured by a single breath analysis of carbon dioxide oxygen nitrogen or helium by use of the mass spectrometer and simultaneously with a Lilly nitrogen meter[17 35]

Significance of Lung Volumes The absolute values of the various lung volumes are of relatively limited value as tests of pulmonary function Comparative serial measurements of the vital capacity in contrast with absolute values may be useful in following changes in cardiopulmonary function In general only gross deviation from the predicted value of the various lung functions is of significance A reduction in vital capacity occurs with a reduction in the amount of aerated lung parenchyma (restrictive ventilatory insufficiency) and may or may not be altered with the more serious obstructive disturbances of the bronchial airways as in pulmonary emphysema In restrictive pulmonary disease both the inspiratory capacity and expiratory reserve components of the vital capacity are diminished and eventually the expiratory reserve may virtually disappear An increased expiratory reserve may denote hyperinflation due to obstruction but without loss of pulmonary elasticity since the lungs can be normally deflated

Ratio of the Residual Capacity to the Total Capacity Normally this ratio which has been found of greater significance than individual static lung volumes varies between 20 and 35 per cent and should not exceed 40 per cent Occasionally it is higher in apparently normal individuals beyond the age of 50 *It is notably* increased in obstructive pulmonary emphysema and amounts to 40 to 45 per cent in moderately severe cases 45 to 55 per cent in severe cases and more than 55 per cent in very severe cases

Dynamic Pulmonary Function Tests

Various dynamic pulmonary function tests have been devised in an effort to determine the speed and efficiency of pulmonary ventilation as well as the relatively static lung volumes The following are among those most commonly employed

Timed Vital Capacity The vital capacity is measured by a spirometer with an attached

timing device which permits measurements of the fractions of the total vital capacity moved in the first second and third seconds of the test [87, 160] The normal person exhales virtually 100 per cent of the total capacity in the first 3 seconds about 95 per cent in the first 2 seconds and about 80 to 85 per cent in the first second When smaller fractions of the vital capacity are registered during these intervals, there is a ventilatory defect which is primarily due to increased resistance to airflow or loss of pulmonary elastic tissue

Maximal Breathing Capacity [95] The subject breathes in and out of a spirometer as deeply and as rapidly as possible for about 15 to 30 seconds The resulting volume is converted into liters per minute The subject must be urged on to increased effort during the procedure The patient breathes with the aid of a mask or mouthpiece through tubing of large internal diameter and with low resistance valves into a Tissot spirometer a Douglas bag or a modified gas meter [10, 11, 237]

The average normal values of maximal breathing capacity for women vary between 60 and 125 and for men between 70 and 175 liters per minute The following formulas have been used to predict maximal breathing capacity (M B C)

Males M B C =
[86 5 − (0 522 × age in yrs)]
× sq meters body surface area

Females M B C =
[71 3 − (0 474 × age in yrs)]
× sq meters body surface area [10]

There is no constant relationship between the maximal breathing capacity and the vital capacity in patients with pulmonary disease [45] In cases of obstructive emphysema small reductions in vital capacity may be associated with marked diminution in maximal breathing capacity The maximal breathing capacity depends on the ability to move air in and out of the lung *rapidly* and is most likely to be diminished when there is increased resistance to airflow due to bronchial narrowing or obstruction

The relation of maximal breathing capacity to vital capacity is sometimes expressed in terms of the *air velocity index*,[88] which is the per cent of actual as related to predicted M B C divided by the per cent of actual as related to predicted vital capacity Normally this index is 0 9 to 1 2 Low indexes suggest the presence of bronchial obstruction

The *ventilatory reserve* is the difference between the actual minute ventilation at rest and the maximal breathing capacity [11] It is often expressed as a percentage of the maximal breathing capacity and is regarded as a measure of ventilatory efficiency Normally it is 85 per cent or more Dyspnea is usually present when the ventilatory reserve is less than 70 per cent of the maximal breathing capacity [10]

The *minute ventilation* or minute volume of natural respiration is determined by multiplying the tidal volume by the rate of respiration, or it is determined directly by the use of flow meters which register the volume respired over a given period of time When the minute volume is to be obtained during exercise it is preferable to collect the expired air into a Douglas bag or flow meter rather than into a Tissot spirometer

The *ventilation equivalent* is the volume of air which is ventilated while the subject absorbs 100 cc of oxygen This is normally between 2 and 3 liters This may also be expressed in terms of oxygen absorbed per liter of ventilation normally 40 to 50 cc per liter

Respiratory Pattern

The pattern of respiration recorded with various spirometers or with a pneumotachograph may be significant in the diagnosis of various types of pulmonary disease In the normal individual, rapid unimpeded flow of air in and out of the chest is shown by the almost perpendicular slope of the inspiratory and expiratory tracing The tracings return to the same resting position with successive performances When there is obstruction and slowing of the air flow in and out of the chest the steepness of the slope of the spirographic tracing is diminished In obstructive emphysema the patient is unable, on successive measurements of vital capacity, to return to the same resting level This is evidence of air trapping or of changes in lung elasticity Trapping is also indicated by sharp reduction in vital capacity when successive determinations are made without pause

Alveolar Distribution of Inhaled Air Index of Intrapulmonary Mixing

In certain pulmonary diseases, notably pulmonary emphysema, alveolar ventilation is often imperfect and uneven, and some over ventilated alveoli are poorly perfused with blood whereas other alveoli are perfused with

blood but inadequately ventilated A test or index of intrapulmonary mixing is obtained by having the subject breathe pure oxygen for seven minutes[45] The thoroughness of mixing is determined by the completeness with which the inert gas nitrogen has been washed out of the alveoli In normal persons the nitrogen concentration in an alveolar sample after oxygen breathing is less than 2 5 per cent In patients with emphysema the index may range from 4 to 15 per cent

Alveolar Blood Diffusion

The above tests are essentially measures of the bellows function of the lungs i e the ability to bring oxygen to the alveoli and remove carbon dioxide This represents pulmonary ventilation in the narrower sense In addition performance of the over all function of the lungs requires that the alveolar oxygen be diffused into the pulmonary capillary blood and the carbon dioxide removed therefrom The rate of diffusion of oxygen or carbon dioxide across the alveolar capillary membrane is proportional to the specific diffusion constant of that gas and the difference in tensions of the gas (in millimeters of mercury) on either side of the membrane The alveolar carbon dioxide tension is virtually identical with carbon dioxide tension in pulmonary capillary blood (about 38 to 40 mm Hg) the capillary tension being higher by about 0 5 mm Hg[74] The alveolar partial pressure of oxygen is 1 to 2 mm Hg higher than the pulmonary capillary oxygen tension the difference representing a slight alveolar-capillary oxygen gradient But because of the venous admixture the oxygen tension in the arterial blood is about 5 to 10 mm Hg lower than the partial pressure of oxygen in the alveoli[1, 9, 74, 71] (95 mm Hg in the former 100 to 105 mm Hg in the latter) When this alveolar arterial (A a) oxygen gradient is increased it is important to know whether the increase is caused by augmented venous admixture (e g due to poor or uneven alveolar ventilation) or to impaired alveolar capillary diffusion

Accurate determinations of alveolar and pulmonary capillary oxygen concentrations are difficult because direct samples of alveolar air or pulmonary capillary blood cannot be obtained Alveolar air is now obtained by continuous end-expiratory sampling or its composition is calculated from the inspired oxygen tension respiratory quotient and the arterial carbon dioxide tension the last of which is regarded as identical with alveolar carbon dioxide tension[184, 71] Arterial blood is used instead of pulmonary capillary blood to determine oxygen tension Arterial oxygen and carbon dioxide tensions are determined by equilibrating arterial blood in a tonometer with gas of known tension[152]

Differentiation of an increased alveolar arterial (A a) oxygen tension difference due to venous admixture from that due to impaired alveolar capillary diffusion (pulmonary membrane factor) is accomplished by determining the A a difference at two levels of oxygen intake e g when breathing room air and when breathing 14 per cent oxygen[1, 9, 183] Analysis of the alveolar arterial oxygen tension (P_{O_2}) gradient under these two conditions permits the estimation of the mean alveolar-capillary P_{O_2} difference which is divided into the oxygen uptake to give the diffusing capacity for oxygen (D_{O_2}) Other methods using carbon monoxide breathing have also been utilized to estimate the diffusing capacity of the lungs[74] Owing to the character of the oxygen dissociation curve venous admixture is the dominant factor determining the A a oxygen difference when the patient breathes ambient air at sea level pressures whereas the membrane component is predominant when the subject breathes lower concentrations of oxygen i e oxygen at low partial pressure In certain diseases characterized by extensive pulmonary fibrosis disturbances in aeration of the blood are due essentially to impaired alveolar-capillary diffusion (alveolar-capillary block)[9]

Work of Breathing and Respiratory Effort

From the clinical viewpoint pulmonary disease leading to significant ventilatory disturbance is important because it produces symptoms notably dyspnea In recent years dyspnea has been related to the increased work of breathing or the respiratory effort imposed on the muscles of respiration by the disturbances in ventilation This work is represented by the changes in lung volumes effected against various resistances elastic recoil or *elastance* of the lung airway resistance and frictional and other tissue resistance (viscance) The force or effort exerted is indicated by the pressure difference between that at the airway opening or mouth (atmospheric pressure) and that at the surface of the

lungs or pleura (intrapleural pressure) The rate at which the work is performed is likewise important

Measurement of Work of Breathing The work of breathing may be estimated indirectly by the oxygen utilization during quiet breathing and during hyperventilation Pulmonary disease may be associated with a high resting oxygen consumption, owing to the excessive oxygen requirement of respiration itself and with excessive oxygen consumption during hyperventilation [59]

Direct determinations of the mechanical work of respiration involve the measurement of (1) the transpulmonary pressure (mouth intrapleural pressure difference) (2) the volume of gas displaced (respiratory volume) and (3) the rate of volume displacement (rate of flow) [60] Intra esophageal pressure, measured by an intra esophageal balloon, mirrors intrapleural pressure and may be used in place of the latter, thus obviating the need for a thoracentesis [59, 86] Rates of air flow are recorded with a pneumotachograph connected to a manometer Direct measurement of volume changes is effected by electrical integration of the rate of flow curve, eliminating the need for tedious planimetry Direct plotting of the pressure flow curves is accomplished by simultaneous recording of the flow rates, volumes and pressures in a direct writing cathode ray oscillograph

Measurement of Viscoelastic Properties of Lung From the recorded loops one can determine the volume change per unit of elastic pressure change The *compliance* or distensibility of the lung is measured as the

$$\frac{\text{volume change (liter)}}{\text{pressure change (cm water)}}$$

The greater the volume change per unit of pressure change the greater the compliance of the lung and the less the *elastance* Elastance is the inverse of compliance [209, 150, 85, 81] The term elasticity of the lung as commonly used or misused, denotes pulmonary *compliance* or distensibility But according to physicists "elasticity" denotes the resistance to deformation the opposite of distensibility and this elastic resistance of the lung is now termed elastance A rigid lung has more than normal elastance, less than normal compliance Normal compliance is about 0 22 liter per centimeter of water pressure The determination of pulmonary elastic resistance (elastance) independent of airflow and frictional and other tissue resistance is determined by measurements at the moments when respiratory airflow ceases e g , at the end of inspiration

The frictional forces involved in pulmonary respiration are expressed as *resistance* or viscous work and are measured as

$$\frac{\text{pressure change (cm water)}}{\text{air flow (liters per sec)}}$$

The compliance and the resistance (frictional forces) are referred to as the *viscoelastic properties* of the lung The flow resistance component of the total transpulmonary pressure is determined by electrical subtraction of the component due to elastic resistance from the total pressure difference Normally the airway resistance is about 1 7 cm water per liter per second of airflow The normal respiratory work varies from 0 3 kg m per minute with quiet breathing to a maximum of 80 kg m per minute with maximal hyperventilation [14] A new method for measuring airflow resistance by means of a body plethysmograph has been described [a b]

In cases of severe pulmonary emphysema an increase of work of breathing has been observed which is related chiefly to airflow resistance and to a much lesser extent to elastic resistance (elastance) of the lung [144, 149] Airflow resistance is increased during expiration and especially with increased frequency and effort of respiration [41] Pulmonary compliance is relatively normal during quiet breathing, but increases with increased breathing frequency [149] Increased work of respiration has also been measured in cases of mitral stenosis especially with heart failure, and this is due chiefly to increased elastance or rigidity i e to diminished pulmonary compliance [1 7]

With quiet respiration at slow rates most of the work of breathing is performed against the elastic resistance (elastance) whereas with increased rate of respiration and less pulmonary distention more work is performed against airflow and tissue frictional resistance It has been noted that there is an optimal rate of breathing at which the necessary ventilation is accomplished by minimal work and that normal subjects at rest and during exercise breathe at that respiratory rate which is most economical in terms of work of respiration [146] This may be of interest in connection with the observation that breathing is relatively shallow and rapid in patients with left sided heart failure and pulmonary fibrosis, in which there is increased elastance with rela

tively little airflow resistance and low in patients with emphysema in which the increased resistance is due chiefly to the airflow component For airflow resistance predominates and is chiefly intensified by rapid respiration whereas elastic resistance predominates with deep respiration at low rates

Dyspnea and Inspiratory Force Recent studies have related the occurrence of dyspnea not to the *work* of breathing but to the *inspiratory force* exerted on the lungs as reflected by the negative intrapleural pressure during inspiration.[111] Each subject was found to have a limiting force exerted on the lungs at which threshhold further respiratory effort was prevented by dyspnea or occasionally by fatigue Normal individuals and patients with mitral stenosis or pulmonary emphysema may be exerting the same respiratory force at their limit of respiratory effort but at this limit normal individuals are ventilating 100 to 120 liters per minute whereas patients with mitral stenosis or emphysema are only ventilating 30 to 40 liters per minute In order to satisfy the respiratory stimulus occasioned by mild or moderate exercise the normal individual may accomplish adequate ventilation with less than this maximal inspiratory force whereas patients with mitral stenosis or emphysema must exert this maximal inspiratory force which induces dyspnea The capacity to increase respiratory work is limited also by the resistance to distention of the lung and airflow and by the maximum rate which will permit economical work of respiration.

Arterial Gases and pH Pulmonary (Respiratory) Insufficiency

Determination of the arterial oxygen saturation and tension, of the carbon dioxide content and tension and of the pH discloses whether the ultimate function of the lung namely aeration of the blood is being properly carried out The methods have been discussed (p 226) [79] Normal arterial oxygen saturation is 95 to 98 per cent and the more significant normal oxygen tension is about 95 mm Hg The arterial carbon dioxide content is 50 volumes per cent (22 millimols per liter) and the arterial carbon dioxide tension 40 mm Hg

Disturbances in ventilation or in alveolar capillary diffusion may occur but aeration of the blood (oxygenation and removal of carbon dioxide) may be normal as a result of compensatory increase in the rate force or work of breathing Thus there may be ventilatory or diffusion insufficiency without over-all pulmonary insufficiency When the carbon dioxide tension rises or the oxygen tension of arterial blood falls as a result of pulmonary disturbance *pulmonary insufficiency* is present as well as insufficiency of ventilation or diffusion. Cyanosis is the characteristic sign of pulmonary insufficiency as dyspnea and hyperventilation are the manifestations of ventilatory insufficiency But cyanosis may not be visible with minor degrees of arterial hypoxemia and increased arterial carbon dioxide content and diminished oxygen may contribute to causing dyspnea. It should be recalled that because of the nature of the oxyhemoglobin dissociation curve minor reductions in oxygen saturation may denote a significant diminution in oxygen tension (Fig 56 p. 229)

The *effect of exercise* in tests of ventilatory and diffusion function and in over all pulmonary function is of utmost importance as it is in determining cardiac function. Many of the tests thus far described are performed with the patient at rest and undergoing exercise Walking step tests foot-pedaling and raising weights and voluntary hyperventilation are some of the stresses employed

The arterial oxygen and carbon dioxide determinations are often normal in patients with pulmonary disease at rest but oxygen tension falls and carbon dioxide tension may rise with exercise [22] Pulmonary insufficiency thus appears only with exertion. Because of the much greater diffusibility of carbon dioxide than oxygen carbon dioxide concentrations are often normal in patients with arterial hypoxemia due to pulmonary disease In diseases associated with hyperventilation (pulmonary fibrosis pulmonary congestion in left-sided heart failure) the hyperventilation may actually reduce arterial carbon dioxide (hypocapnia) Eventually in extensive pulmonary disease with obstructive emphysema impaired ventilation and alveolar aeration result in the accumulation of carbon dioxide in arterial blood (hypercapnia) Hypercapnia representing gaseous acidosis is distinguished from that denoting metabolic alkalosis by determination of arterial pH with a glass electrode pH meter

Oxygen Breathing

The effect of breathing 100 per cent oxygen is of value in differentiating pulmonary from other causes of arterial hypoxemia and cyanosis In cyanotic patient with hypoxemia

to pulmonary disease the arterial oxygen saturation rises and may reach 97 per cent or more In cyanotic patients with hypoxemia due to congenital heart disease with a venous arterial shunt breathing 100 per cent oxygen does not significantly raise the arterial oxygen

Circulatory (Perfusion) Function of the Lung

This is determined by cardiac catheterization and intracardiac manometry (p 74) Thus the pressures in the right atrium right ventricle pulmonary artery and pulmonary capillaries are determined The cardiac output may be determined by the Fick principle (p 209) From the cardiac output (CO) and pulmonary artery pressure (PA) the pulmonary resistance (R) can be determined

$$R\ (\text{dynes/sec/cm}^{-5}) = \frac{\text{PA (mean) mm Hg} \times 1332}{\text{CO (cc per sec)}}$$

The effect of exercise on these measurements is ascertained Disturbances in the pulmonary vascular bed due to pulmonary disease may if severe cause a significant *increase in pulmonary resistance* and pulmonary artery pressure at rest and/or with exercise

ETIOLOGY OF CHRONIC COR PULMONALE

Cor pulmonale may occur in any chronic pulmonary disease which produces lesions sufficiently extensive or critically placed An essential requirement is that they so increase the pulmonary vascular resistance that there is a strain on the right ventricle

Pulmonary (Obstructive) Emphysema

Although many chronic pulmonary diseases are capable of causing cor pulmonale pulmonary emphysema is the classic and most common cause This is because of the relatively greater frequency of pulmonary emphysema than that of other diseases which are associated with cor pulmonale Scott and Garvin[91] found cor pulmonale due to emphysema in 50 (6 3 per cent) of 790 autopsied patients who had died of heart disease Parker[170] observed hypertrophy of the right ventricle in 75 per cent and cardiac failure in 44 per cent of 32 cases of uncomplicated pulmonary emphysema In clinical experience of course, *the incidence of cor pulmonale is much lower* since cases studied at autopsy are apt to represent the most advanced stage of this disease

Bronchial Asthma

Bronchial asthma of long standing is usually associated with extensive pulmonary emphysema[9] and may be associated with severe disturbances in pulmonary function[107] and with cor pulmonale, *as denoted by right ventricular hypertrophy and failure*[195]

Pulmonary Tuberculosis

Right ventricular hypertrophy and congestive heart failure result when there is extensive involvement of the lungs and their vascular bed[99 122 1 194] According to Griggs Coggin and Evans,[99] pulmonary tuberculosis was associated with right ventricular hypertrophy in 3 7 per cent and congestive heart failure in 1 8 per cent of 1470 cases, but a higher incidence was noted in the smaller series of Ackerman and Kasuga[1]

Pneumoconiosis

According to Griggs, Coggin and Evans,[99] pneumoconiosis or silicosis a form of pulmonary fibrosis, is associated with a higher *percentage of cases of cor pulmonale* than either pulmonary emphysema or tuberculosis although the absolute number of cases of cor pulmonale due to pneumoconiosis is less Samuelson[188] reported the findings in 83 advanced cases of silicosis, in about 70 per cent of which there were signs of cor pulmonale Thomas[16] described a consistent right ventricular hypertrophy in 50 autopsied cases of pneumoconiosis of coal miners and electrocardiographic changes suggesting right ventricular hypertrophy Cor pulmonale occurs if the lesions are very extensive[7]

Chronic Bronchiectasis Other Pulmonary Diseases

Chronic bronchiectasis is one of the commoner causes of *cor pulmonale* with congestive heart failure *but only when it produces extensive obstructive emphysema*[155]

Cor pulmonale is said to develop in 10 per cent of children dying of *fibrocystic disease of the pancreas*[130 219] owing to the associated bronchiectasis I have observed cor pulmonale with right sided congestive heart failure following *chronic pulmonary suppuration* with perforation into the pleural cavity and chronic empyema

Willius[225] reported a case of cor pulmonale including congestive heart failure secondary to diffuse bilateral *congenital cystic disease of the lungs*

Sarcoidosis

There may be extensive fibrosis of the lungs with involvement of the small pulmonary vessels and eventual involvement and failure of the right side of the heart[187 43 182] Nevertheless, in recent reported series of cases of sar

coidosis there [illegible] only brief mention of the occurrence of cor pulmonale perhaps because of primary preoccupation with pulmonary function studies[11 130 11] The epithelioid granulomata in the lung are invaded and eventually more or less completely replaced by dense collagenous tissue The smaller bronchi and blood vessels become obstructed and eventually destroyed and there is occasionally an obliterative endarteritis The disturbances in pulmonary function which may occur when the fibrosis is extensive may be characterized by restrictive fibrosis by obstructive emphysema or by impaired alveolar capillary diffusion [illegible]

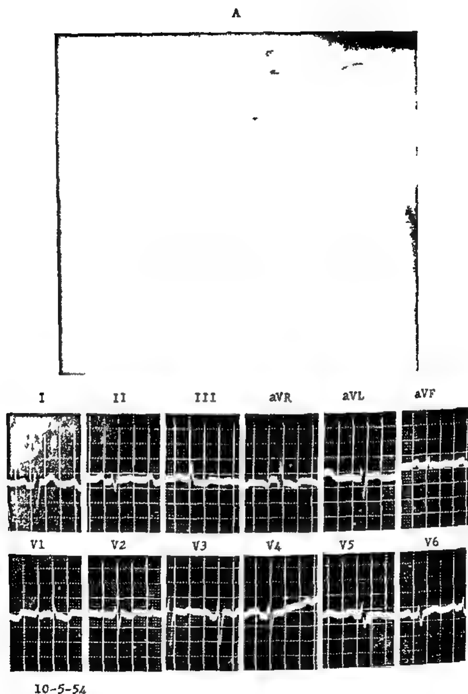
Scleroderma may be associated with extensive fibrosis fibrinoid necrosis and an inflammatory reaction Shuford et al[205] found typical reticulated and linear infiltrations in the roentgenograms of the chest in 5 of 37 patients with scleroderma Pulmonary hypertension and cor pulmonale may occur

Idiopathic Interstitial Fibrosis of the Lung

A number of cases of acute or chronic diffuse interstitial fibrosis of the lung of idiopathic origin[23] including cases of Hamman Rich syndrome[10] and chronic granulomatous pneumonitis of unknown etiology [illegible] are associated with extensive lesions involving the alveolar capillary membranes (Figs 148 149) and producing eventually right ventricular hypertrophy and right sided heart failure[3 191] I have observed several such cases in the past few years

Kyphoscoliosis and Other Thoracic Deformities

Hypertrophy and dilatation of the right ventricle have been found in about 75 per cent of cases of severe kyphoscoliosis[178] [illegible] [121] In Bachman s[8] exhaustive study of kyphoscoliosis he observed that of 154 carefully examined hearts, 56 per cent revealed dilatation and hypertrophy of the right ventricle 26 per cent, of both ventricles and 17 per cent of the left ventricle Fisher and Dolehide[73] described the development of fatal cardiac failure in patients with thoracic deformities especially kyphoscoliosis



Thoracoplasty

Zimmerman[42] described 5 patients who developed cor pulmonale eight to fifteen years after thoracoplasty The pulmonary artery pressure and pulmonary resistance were greatly increased Cor pulmonale developed even when the contralateral lung was free of disease

Fig 148 *A* Cor pulmonale secondary to interstitial (alveolar-capillary) fibrosis of the lung (Hamman Rich type)

Pneumothorax and various forms of pleural pulmonary disease which cause cardiac displacement may occasionally produce circulatory symptoms and electrocardiographic and roentgenologic abnormalities of the heart but rarely if ever cause cor pulmonale [141]

Funnel Chest (Pectus Excavatum)

This is of interest because cardiac abnormalities are often attributed to it [34] but it is only rarely responsible for significant circulatory dysfunction [23a] as in the cases reported by Ravitch[176] and Lyons et al [133] If the external anteroposterior diameter of the chest is less than 6½ inches compression and displacement of the heart are likely to occur [65] Physical examination frequently reveals a functional systolic murmur usually over the pulmonic area and displacement of the apical impulse to the left The importance of funnel chest to the cardiologist lies in the frequent misinterpretation of these signs as indicative of heart disease [14] Roentgenologic examination is diagnostic[65, 157, 17, 8] (Fig 150) In the anterior view the cardiac silhouette appears displaced to the left and the shadow is less dense than normally because of the diminution in anteroposterior mass The heart may seem enlarged but the heart volume is normal and lateral views reveal the anteroposterior narrowing and sternal depression The deformity may be corrected surgically [19, 10]

Extreme obesity in association with somnolence, Cheyne-Stokes respiration, polycythemia and alveolar hypoventilation has been described as a syndrome [8] which is associated with pulmonary hypertension and right ventricular hypertrophy (i e cor pulmonale) in the absence of significant pulmonary disease [117]

Pectus carinatum (pigeon chest) causes no cardiac abnormalities

Diseases of the Pulmonary Arteries Pulmonary Emboli and Thrombosis

Cor pulmonale results from pulmonary arterial disease only when this is very extensive and involves at least two thirds of the cross-sectional area of the pulmonary vascular bed (p 960) Chronic cor pulmonale is most likely to occur in cases of recurrent pulmonary embolization and/or thrombosis As first indicated by Ljungdahl [123] there is probably a chronic form of pulmonary heart disease resulting from chronic pulmonary emboli The cases of right ventricular hypertrophy with intense cyanosis polycythemia and congestive heart failure sometimes termed Ayerza s syndrome and reported by Jump and Baumann [118] Barnes and Yater [16] Means and Mallory [151] and Montgomery [156] were attributed to large organized thrombi in the stem or main primary divisions of the pulmonary artery The frequent site of the thrombus at the bifurcation of the pulmonary artery certain clinical features in the reported

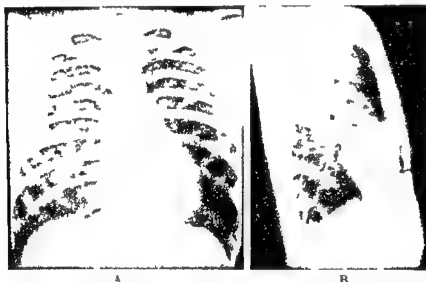

Fig 150 Funnel chest (pectus excavatum) *A* Posteroanterior view Apparent enlargement due to anteroposterior compression of heart Cardiac volume normal Most of cardiac silhouette in left chest Spine shadow prominent Ribs more horizontal than normal

histories and the studies by Belt,[21, 22] indicating the comparative rarity of autochthonous thrombi and the frequency of emboli in the main pulmonary arteries, suggest strongly that these were all instances of massive pulmonary embolism which were insufficient to cause death but which produced chronic cor pulmonale Belt[23] described 4 cases of chronic embolization of the pulmonary arteries occurring over a period varying from 3 months to 6 years Similar cases have been reported by others[37, 85, 172, 146, 169, 14] Cases described by Frothingham[64] as progressive thrombosis of the small branches of the pulmonary artery, by Rothschild and Goldbloom[169] as obliterative pulmonary arteritis by Keating et al [119] as chronic massive thromboses of the pulmonary arteries, and perhaps also the case of obliterative arteriolar sclerosis of the lungs by MacCallum[134] and that of multiple pulmonary thrombi by Balboni [8] may all be examples of chronic pulmonary embolization with secondary changes of healing and vascular reaction Cases of chronic cor pulmonale due to amniotic fluid emboli have been reported [135]

Secondary Arteriolar Sclerosis Arteriosclerosis of the small pulmonary arteries and arterioles is probably secondary to pulmonary hypertension associated with diffuse pulmonary disease and not the cause of the pulmonary hypertension [170, 157] This secondary narrowing is at most a minor contributory cause of pulmonary hypertension and cor pulmonale In many instances lesions interpreted as arteriosclerosis of the small pulmonary arteries may represent secondary intimal fibrosis due to healing of pulmonary emboli [14, 197] Such lesions have been produced experimentally by the intravenous injection of thrombotic material [103, 35] Microscopic evidence of arteriosclerosis of the main pulmonary artery is observed commonly in routine autopsies and occasionally the lesions are macroscopically visible However, they are not severe enough to be a factor in causing chronic cor pulmonale [21]

Pulmonary Obstruction with Schistosomiasis Obstruction and inflammation of the pulmonary arterioles due to massive, probably recurrent infection with ova of Schistosoma haematobium or mansoni is capable of producing right ventricular hypertrophy and congestive heart failure [13, 10, 94, 221] Shaw and Ghareeb[204] found pulmonary involvement at autopsy in one third of 282 cases of schistosomiasis In 6 of these the pulmonary obstruction was sufficient to cause a clinical picture resembling so-called Ayerza's syndrome The ova cause injury of the arteriole with consequent acute necrotizing arteriolitis, obstructive endarteritis and perivascular tubercles

Pulmonary Obstruction and Sickle Cell Anemia This disease is often associated with vascular thrombi in the pulmonary arteries and a reactive arteritis [210, 239]

Syphilis and rheumatic fever may produce a pulmonary arteritis but the pulmonary arterial lesions are not themselves a cause of cor pulmonale

Pulmonary Obstruction due to Carcinomatous Lymphangitis or Embolism Cases of occlusion of numerous small pulmonary arteries by tumor emboli as a result of carcinomatous obstruction of the perivascular lymphatics with subsequent vascular thrombosis have been described as resulting in *pulmonale* and right-sided congestive heart failure [88, 140] These lesions produce a subacute rather than a chronic form of cor pulmonale

Primary Pulmonary Hypertension

Primary hypertension is distinguished from secondary hypertension by the absence of intrinsic pulmonary or cardiac disease or of extrinsic causes of pulmonary vascular obstruction As a rule this diagnosis is entertained when cardiac catheterization discloses pulmonary hypertension and no etiologic factor can be discovered [28, 236, 207, 61]

At autopsy, primary pulmonary hypertension is suggested by the finding of right ventricular hypertrophy without evidence of intrinsic cardiac or pulmonary disease or pulmonary emboli [116] Pulmonary vascular lesions may or may not be present Examples of this type have been designated as idiopathic right ventricular hypertrophy by De Navasques et al [53] and others[41, 4] (p 625)

Primary Pulmonary Hypertension with Pulmonary Arterial Occlusive Disease When pulmonary arterial lesions are present these may be regarded as primary and the pulmonary hypertension as secondary to these lesions Examples of such hypertension due to arterial lesions have been noted in connection with recurrent pulmonary emboli, schistosomal and sickle cell arterial lesions It is uncertain whether other occlusive pulmonary lesions of unknown origin represent healed pulmonary emboli which can no longer be identified as such whether they are primary autochthonous

thrombi responsible for pulmonary hypertension or whether they represent a vascular response to intrinsic (humoral or vasomotor) increase in pulmonary arteriolar resistance

Idiopathic Primary Pulmonary Hypertension In some cases of primary pulmonary hypertension there are only minimal vascular changes [2, 4, 84] It has been postulated therefore that there is an essential or idiopathic pulmonary hypertension due to increased pulmonary vasoconstriction analagous to the essential hypertension in the systemic circulation The weak and uncertain vasomotor regulation of the pulmonary arterioles is one of the objections to this concept In some cases of idiopathic pulmonary hypertension the intimal proliferation is of such extent that the pulmonary arterioles are virtually occluded [196] In such cases the occlusive intimal changes appear to be responsible for the pulmonary hypertension

When the vascular lesions are merely intimal thickenings suggesting arteriolosclerosis these may be regarded as secondary to pulmonary hypertension This sequence is less probable when there are thrombotic lesions in various stages of organization [81] Aitchison and Richmond[2] have described a case of primary pulmonary hypertension with occlusive pulmonary arterial lesions which were regarded as secondary to the pulmonary hypertension because postmortem examination indicated that the arterial lesions were recent, whereas the right ventricular hypertrophy was old Necrotizing pulmonary arteritis has also been found at autopsy in cases of primary pulmonary hypertension [13] or of right ventricular hypertrophy of unknown etiology [146] In such cases the possibility of malignant pulmonary hypertension has been considered in analogy to the necrotizing arteriolar lesions secondary to "malignant" or "accelerated" hypertension in the systemic circulation Similar necrotizing pulmonary arteriolar lesions have been found in cases of severe pulmonary hypertension secondary to mitral stenosis [?, 110] and Eisenmenger's syndrome

A distinctive clinical syndrome of primary pulmonary hypertension has been described [?, 2, 4] Actually the findings are those of cor pulmonale without demonstrable pulmonary or cardiac disease The patients are chiefly young adults Exertional dyspnea and weakness, exertional precordial pain and effort syncope[62, 112, 196a] are the outstanding symptoms probably related to an inability to increase the cardiac output and consequent vascular reflexes A systolic murmur is audible in most cases The second pulmonic sound is accentuated The clinical course is unfavorable characterized by right-sided heart failure and occasionally terminating in sudden death There is a report of 3 cases in which death occurred following cardiac catheterization [194] Cyanosis without clubbing may be present usually as a late development The objective clinical, roentgenologic and electrocardiographic findings are determined by the presence of pulmonary hypertension right ventricular hypertrophy and right-sided heart failure On fluoroscopic examination the pulmonary artery segment and hilar vessels are prominent but the peripheral vascular markings are diminished

PATHOLOGY AND PATHOGENESIS OF CHRONIC COR PULMONALE

Insofar as the development of cor pulmonale is concerned we are interested primarily in the pathology of the pulmonary vessels Fundamentally cor pulmonale results from an increase in the pulmonary vascular resistance and the consequent increase in pulmonary blood pressure A variety of mechanisms have been listed to account for increased vascular resistance and pulmonary hypertension (Fig 151) These include (1) anatomic reduction of the pulmonary vascular bed (2) anoxia, which may act by (a) pulmonary vasoconstriction (b) increased pulmonary blood flow or (c) increased blood viscosity (3) increased intraalveolar pressure (4) increased bronchomotor tone (5) bronchial pulmonary shunts, and (6) secondary pulmonary arteriolosclerosis Of these factors the anatomic reduction of the pulmonary vascular bed is by far the most important In some cases anoxia plays an important secondary role The significance of the other facts is less well established

1 Anatomic Reduction of the Pulmonary Vascular Bed

In cases of pulmonary emphysema, the alveolar spaces are enlarged and in many places confluent and the septa are ruptured incomplete atrophic or missing entirely The changes in the alveolar septa result in fibrosis narrowing thrombosis or complete obliteration of capillaries In consequence there is a marked reduction in the total cross sectional area of the available capillary circulation As a

result there may be an increase in pulmonary vascular resistance even at rest, and a consequent pulmonary hypertension, since the cardiac output is normal With exercise, the inability of the pulmonary vascular bed to enlarge as it does normally, results in an increase in the pulmonary blood pressure This occurs only so long as the right ventricular output increases With very severe increase in pulmonary vascular resistance it may be impossible to increase the blood flow through the pulmonary bed, even with an increase in the pulmonary blood pressure

increased pulmonary vascular resistance with consequent pulmonary hypertension has been attributed to (1) diminution in the pulmonary vascular bed due to atelectasis and fibrosis of the affected lung and compensatory emphysema of the unaffected lung tissue, (2) kinking and stenosis of the pulmonary artery In the cases of cor pulmonale due to pulmonary vascular disease, the increased pulmonary resistance is clearly due to the obstruction of pulmonary vascular pathways by emboli, thrombi or narrowing of the lumina by intimal thickening But structural

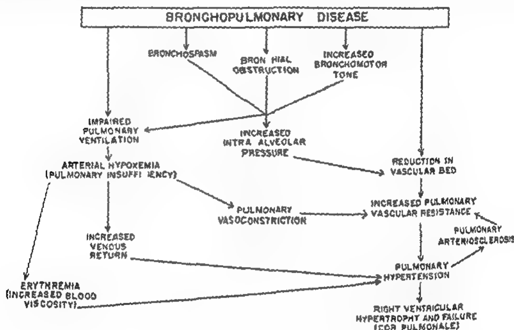

Fig 151 Mechanisms in the production of cor pulmonale

In the cases of pulmonary fibrosis whether idiopathic or associated with sarcoidosis scleroderma or other forms of fibrosis there is an increase in resistance due to compression or replacement of the pulmonary vessels by fibrotic tissue In some cases there is an associated obstructive emphysema with additional reduction in the caliber and number of capillaries The occurrence of increased pulmonary resistance and pulmonary hypertension in cases of chronic tuberculosis, pneumoconiosis, and other bronchopulmonary diseases may be similarly explained by the reduction in the number and caliber of the capillaries or their replacement by fibrous tissue due to the presence of extensive interstitial and alveolar capillary fibrosis or of associated obstructive emphysema In cases of kyphoscoliosis the

changes in the pulmonary vascular bed are not the sole cause of increased pulmonary resistance and pulmonary hypertension because the latter can increase rapidly and sharply following a bronchopulmonary infection and diminish rapidly when the bronchopulmonary infection and associated bronchospasm are relieved

2 Anoxia

Pulmonary hypertension and cor pulmonale may occur in cases of chronic pulmonary disease with or without significant hypoxemia. Therefore, anoxia is not essential to the development of pulmonary hypertension in chronic cor pulmonale In those cases in which anoxia occurs several mechanisms have been invoked to account for its effect in increasing the pulmonary resistance Von Euler and

Liljestrand[223] obtained experimental evidence in the cat indicating that hypoxemia caused pulmonary vasoconstriction and an increase in pulmonary arterial pressure. More recently Nahas et al [184] observed that the cardiac output increased in hypoxic non-narcotized dogs and that the pulmonary artery pressure was raised without an increase in the vascular resistance. Motley et al [161] demonstrated that the inhalation of 10 per cent oxygen will produce significant increase in the pulmonary blood pressure in normal individuals and this effect of hypoxia has been confirmed in normals[80, 11] and in patients with pulmonary emphysema.[2, 3] Doyle and associates[60] noted that the short term hypoxia caused an increase in pulmonary arterial pressure but that the pulmonary capillary pressure remained unchanged while the cardiac output increased. They interpreted these observations as indicating pulmonary vasoconstriction probably as a direct effect of the low oxygen tension of the returning venous blood on the walls of the pulmonary arterioles. Other experiments with breathing of low oxygen mixtures[185, 100] suggest that anoxia may cause local vasoconstriction in those areas of the lung receiving low oxygen mixtures or inadequately ventilated. In view of the evidence that there is poor vasomotor regulation of the pulmonary vessels there is some uncertainty as to the exact mechanism of the observed increase in pulmonary blood pressure during hypoxia. There is even more uncertainty whether this can be applied to the occurrence of pulmonary hypertension in chronic pulmonary diseases.

Another method by which hypoxemia may contribute to an increased pulmonary resistance is related to the occurrence of an increased venous return and an increased cardiac output observed both in short term experiments in which low concentrations of oxygen are inhaled and in direct determinations of the cardiac output in patients with chronic hypoxemia. The increased blood flow and cardiac output are related to a reduction in the peripheral *systemic* resistance, since the systemic blood pressure is unchanged. This reduced *systemic* resistance may be due to a direct effect of hypoxemia on the peripheral vessels. However the increased venous return and consequent increased right ventricular output cannot readily pass through the diminished *pulmonary* vascular bed. The normal diminution in pulmonary vascular resistance that occurs with increased blood flow as in exercise cannot occur in chronic pulmonary disease in which there is an extreme reduction in vascular caliber and in the number of patent vessels. Consequently the increased blood flow associated with hypoxemia, like the increased blood flow associated with exercise results in an increased pulmonary vascular resistance and pulmonary hypertension. Finally in many cases of chronic pulmonary disease with hypoxemia there is a marked polycythemia and an increased viscosity of the blood. This contributes to the resistance to blood flow and may play an accessory role in increasing pulmonary vascular resistance and pulmonary hypertension.

3 Increased Alveolar Pressure

In cases of obstructive pulmonary emphysema there is entrapment of air in the alveoli with consequent increase in air pressure. This may compress the pulmonary capillaries and contribute to the reduction in the pulmonary vascular bed and consequent increase in pulmonary vascular resistance. Animal experiments conducted by Hamilton et al [101] indicated that variations in intraalveolar pressure are effective in temporarily creating variations in vascular resistance.

4 Increased Bronchomotor Tone

Rodbard[198] has reviewed the evidence suggesting that bronchiolar (bronchomotor) tone plays an active part in the regulation of pulmonary blood pressure and pulmonary blood flow. Contraction of the bronchioles may cause trapping of air in the alveoli and increased pressure with compression of the pulmonary capillaries. He points out that although the innervation of the pulmonary vessels is scanty that of the bronchial musculature is rich and that there are large numbers of pressure sensitive muscle spindles of the type found in the carotid sinus.

5 Bronchopulmonary Shunts

The findings of bronchopulmonary vascular shunts in cases of chronic pulmonary disease suggests the possibility that the points of anastomosis may act as sites of increased pulmonary resistance and contribute to pulmonary hypertension [127] but there is no direct evidence substantiating this.

6 Pulmonary Arteriolosclerosis has been discussed (p 982). Arteriosclerotic changes in the small arteries and arterioles of patients with advanced pulmonary emphysema are more frequent and more severe than is usual for normal patients of similar age.[158] Most investigators believe that they are secondary

to the pulmonary hypertension resulting from the vascular lesions in pulmonary emphysema.[157, 183] Arteriosclerosis may narrow the lumen sufficiently to add to the increased pulmonary resistance due to the capillary disturbance.[170]

THE HEART

Increased pulmonary vascular resistance and pulmonary hypertension cause cor pulmonale by increasing the strain and work of the right ventricle (p. 989). The effect of pulmonary hypertension on the right ventricle is similar to that of essential hypertension on the left ventricle. A progressive increase in pulmonary vascular resistance is compensated by a gradual, usually clinically imperceptible dilatation and hypertrophy of the outflow tract of the right ventricle. Heart failure may be due chiefly to the strain imposed by increased pulmonary resistance, but in some cases arterial hypoxemia may contribute to heart failure by causing myocardial anoxia. The right cardiac chambers dilate and undergo further hypertrophy as heart failure progresses.

Anatomically, the characteristic feature of the heart in cor pulmonale is hypertrophy of the right ventricle. A variable degree of right ventricular dilatation is also present, but this is more difficult to evaluate. In cases of right-sided heart failure there is usually also dilatation and occasionally hypertrophy of the right atrium.

Right ventricular hypertrophy in cases of pulmonary emphysema has been demonstrated by weighing the chambers separately according to the method of Muller.[111, 112] By means of linear measurements of the extent of the chambers, Kirch[1, 2] found that the hypertrophy began in the outflow tract of the right ventricle (p. 106), i.e., the anterior half of the chamber extending from the apex to the pulmonary arteries. Right ventricular hypertrophy eventually develops in 25 to 75 per cent of cases of pulmonary emphysema.[1, 4, 95, 170] For simplicity many observers have assumed that the right ventricle is enlarged if its average thickness exceeds 5 mm. Right ventricular hypertrophy may be overlooked if this chamber is not separately weighed or measured, because the weight of the heart as a whole may not be significantly increased. Attention is frequently called to the presence of associated left ventricular hypertrophy in autopsied cases of pulmonary emphysema, in which hypertension, aortic valvular disease and other possible causes of such hypertrophy have been reasonably excluded.[124, 170] This observation should be further investigated and verified before attempts are made to explain it.

PATHOLOGIC PHYSIOLOGY

The functional disturbances in chronic pulmonary disease associated with cor pulmonale may be discussed under the following headings: (1) impaired pulmonary ventilation, (2) impaired aeration of the blood, (3) cardiac output, (4) pulmonary hypertension and (5) right ventricular strain.

1. Impaired Pulmonary Ventilation and Diffusion

The pulmonary diseases responsible for disturbances in ventilation and aeration have been classified into three groups according to pulmonary disturbance:[10] (a) those with obstructive ventilatory dysfunction, (b) those with restrictive ventilatory dysfunction, (c) those with alveolar-capillary or diffusional dysfunction. Frequently two or more of these are associated.

(a) Obstructive Ventilatory Dysfunction. This includes primarily cases of obstructive pulmonary emphysema and bronchial asthma,[107] but obstructive ventilatory dysfunction is often a prominent feature in extensive pulmonary tuberculosis, silicosis, kyphoscoliosis and some cases of sarcoidosis[44] and pulmonary fibrosis.

In this group bronchial or bronchiolar obstruction with alveolar trapping of air plays an important role. The lungs are maintained in a hyperinflated inspiratory position in which the bronchial passageways are most patent. The diaphragms are low. It has been generally stated that there [redacted] a loss of tissue elasticity and a diminished force of elastic recoil in expiration. Studies of the mechanics of respiration in emphysema indicate that the major disturbance [redacted] an increased resistance to air flow and that pulmonary compliance (distensibility) is but little diminished. Increased respiratory rate is inefficient because as a compensation for inadequate ventilation tachypnea greatly enhances airflow resistance. The work of breathing is markedly increased and ventilatory capacity is impaired. There is a striking maldistribution of inspired air to the various alveoli, some being overventilated, many underventilated.[188]

Pulmonary function tests[18, 15, 113, 12] disclose an increase in total lung volume and more significantly an increase in the residual volume, its ratio to total volume rises to 35 to 50 per cent or higher. Alveolar nitrogen after 7 minutes of oxygen breathing exceeds 3 per cent because of poor alveolar distribution of the oxygen and a large residual volume. The maximal breathing capacity and the breathing reserve are diminished. The vital capacity may be less strikingly reduced, but the timed vital capacity is sharply diminished.[196] Bronchospirometry discloses slowing of expiration, "trapping" of air with successive deep breaths and performance of maximum breathing in a high inspiratory position. The minute volume of ventilation is increased by an increase in tidal volume, the rate remaining unchanged or diminished.

(b) Restrictive Ventilatory Dysfunction. This group includes cases of pulmonary disease associated with diffuse fibrosis such as silicosis, fibroid tuberculosis (with minimal emphysema), pulmonary fibrosis secondary to bronchiectasis, some cases of Boeck's sarcoidosis and postradiation fibrosis and kyphoscoliosis. In many cases of silicosis and pulmonary tuberculosis significant obstructive emphysema is associated with the fibrosis.

Restrictive ventilatory function results from destruction or replacement of pulmonary parenchyma by scar tissue. Lung volumes are more or less symmetrically reduced and there is a restriction in the lung's capacity to inflate or deflate. Maximum breathing capacity and vital capacity may be reduced fairly uniformly. But often there is relatively little reduction in maximum breathing capacity when total capacity is greatly diminished, in contrast with the disproportionately greater reduction of M.B.C. in pulmonary emphysema. This suggests that diminished ability to inflate and deflate the lungs in restrictive pulmonary fibrosis may be compensated by increased speed of ventilation.

In the absence of associated emphysema the residual air in these cases is not increased and the ratio of residual air to total volume is normal (20 to 30 per cent). The mean index of intrapulmonary mixing is below 2. The form of the spirogram is normal. Tachypnea and hyperventilation, especially with slight exercise, are characteristic, particularly in severe cases. This is explained as due to more active Hering-Breuer reflexes. The tachypnea may be related to a greatly diminished compliance (increased elastance) with normal airflow resistance. Compensatory hyperventilation is most efficiently accomplished in such cases by increased rate, since vital capacity is low.

(c) Alveolar-Capillary Diffusional Dysfunction (Alveolar-Capillary Block). This group includes cases of diffuse interstitial fibrosis of undetermined etiology, scleroderma of the lung, some cases of pulmonary sarcoidosis and beryllium or other xanthomatous granulomatosis of the lung.[11] These cases are characterized by fibrosis which particularly involves the alveolar-capillary interfaces and interferes with gaseous diffusion.

The vital capacity is reduced, but the maximum breathing capacity may be normal or very slightly diminished. There is a reduction in residual and total volume, but the ratio of residual to total capacity is relatively normal. Bronchospirometry shows a normal pattern. The index of intrapulmonary mixing shows a low nitrogen concentration. The alveolar oxygen partial pressure is elevated to 120 to 150 mm. Hg when the arterial oxygen tension is normal (95 mm. Hg) or only moderately reduced. This high A-a gradient is a measure of impaired diffusion.

2. Impaired Aeration of the Blood

Impaired aeration of the blood in the cases with emphysematous (obstructive) ventilatory dysfunction results in part from subnormal and uneven alveolar oxygenation and in part from a reduction in the capillary bed with consequent faulty perfusion. The inefficient distribution of tidal air often results in disproportionate ventilation of distended alveoli and air sacs with missing alveolar septa which have the poorest blood supply[48, 186] (increased dead space effect). On the other hand, poorly ventilated alveoli are well perfused by capillary blood which leaves the alveoli without adequate aeration (venous admixture effect). This combination of increased dead space and venous admixture effects tends to reduce the arterial oxygen tension and saturation at rest and especially after exercising.

The increased minute volume of respiration compensates for the inefficiency in ventilation and impaired aeration of the blood, but reduces the respiratory reserve. With the enhanced metabolic demands of exercise further respiratory increase is limited or impossible and normal aeration of the blood cannot be maintained. With more advanced

pulmonary emphysema the arterial oxygen of the blood is reduced significantly even when the patient is at rest [114, 146] The effective pulmonary blood flow i e the percentage of pulmonary capillary blood which is oxygenated, was found to average 69 per cent in a group of patients with severe pulmonary emphysema [179]

Although in general, disturbances in ventilation and reduction in pulmonary vascular bed increase concomitantly one or the other may predominate Occasionally anatomic reduction in vascular bed increased pulmonary resistance and pulmonary hypertension cause cor pulmonale before the ventilatory disturbances cause pulmonary insufficiency i e there is cor pulmonale without arterial hypoxemia [55] More often when cor pulmonale develops the pulmonary lesions are severe enough to cause pulmonary insufficiency as well as cor pulmonale and right-sided heart failure [154]

In patients with pulmonary insufficiency and right ventricular failure there is a marked reduction in arterial oxygen saturation The latter hypoxemia is due to and is a measure of the severity of pulmonary insufficiency Congestive heart failure of other etiology is associated with little or no arterial hypoxemia in the absence of pulmonary complications (p 190) Relief of right sided heart failure by digitalis preparations may cause no significant increase in arterial oxygen and no perceptible improvement in the clinical picture because both the hypoxemia and symptomatology are due essentially to the *pulmonary* insufficiency On the other hand, relief of pulmonary insufficiency and the associated hypoxemia may relieve the right-sided heart failure because hypoxemia in some manner increases pulmonary resistance and consequently the pulmonary blood pressure and the work of the right ventricle

Because of the greater diffusibility of carbon dioxide, the hyperventilation in pulmonary emphysema more readily eliminates excessive *carbon dioxide than it maintains adequate* oxygenation Therefore a retention in carbon dioxide occurs less frequently and later than a reduction in arterial oxygen [114] But when the ratio of residual air to total capacity exceeds 45 per cent, both carbon dioxide retention and arterial hypoxemia develop [113, 173] The arterial carbon dioxide tension exceeds 45 mm Hg and there may be a reduction in the pH of the blood It is generally believed that with carbon dioxide retention the sensitivity of the respiratory center is diminished and further carbon dioxide retention is favored [216, 2] But there is evidence that inability to increase ventilation in advanced emphysema is due not to insensitivity of the respiratory center but to mechanical and metabolic factors [31] On the mechanical side, greater respiratory effort becomes limited by distressing dyspnea or fatigue On the metabolic side, increased carbon dioxide production by the muscles of respiration reaches a level which exceeds any increase in carbon dioxide elimination

In the cases of restrictive fibrosis and of impaired alveolar capillary diffusion, hyperventilation may long serve to maintain the arterial oxygen tension at normal levels But hypoxemia becomes marked with exercise, especially in the cases with diffusion dysfunction In advanced cases there is hypoxemia at rest as well as with exercise The arterial carbon dioxide may be diminished owing to hyperventilation, and a gaseous alkalosis may be indicated by a slight elevation of the pH of the blood

Although hypoxemia is *frequently present* in cases of advanced pulmonary disease with cor pulmonale, there may be little or no hypoxemia even in cases of chronic cor pulmonale and heart failure due to obstructive emphysema [55] In general, there is likely to be serious ventilatory insufficiency and deficient arterial oxygenation if the pulmonary lesions are severe and extensive enough to reduce the pulmonary vascular bed and cause cor pulmonale However, cor pulmonale may occur without hypoxemia if the restriction in pulmonary vascular bed outpaces the disturbances in pulmonary ventilation and alveolar capillary aeration Thus pulmonary insufficiency (arterial hypoxemia) may be associated with cardiac insufficiency due to cor pulmonale or the two may be dissociated When pulmonary heart failure and pulmonary insufficiency are associated recovery from *heart failure is not* accompanied by a significant rise in arterial oxygen

3 Increased Cardiac Output

When increased minute volume of respiration no longer compensates sufficiently to maintain a normal oxygen content of the arterial blood other compensatory mechanisms may serve to provide the tissues with an adequate supply of oxygen [114] As in cases of anemia, this may be accomplished by an in

creased cardiac output (minute volume blood flow[148]) In advanced pulmonary emphysema with considerable arterial oxygen unsaturation the speed of the circulation is increased and the venous return thereby augmented This in turn is translated into the greater cardiac output [148, 177, 104]

However, an increased cardiac output is frequently or usually absent in cases of pulmonary heart disease with heart failure, with or without hypoxemia [54, [illegible], [illegible], 1 6, 231] In most cases the cardiac output at rest is normal or reduced In cor pulmonale without hypoxemia the progressive diminution in vascular bed leads to right ventricular failure and the cardiac output may fall These are cases of low output heart failure

Mild or moderate hypoxemia may have no significant effect on the cardiac output, but severe hypoxemia reduces the systemic peripheral resistance increases the venous return and the cardiac output Heart failure may reduce the output somewhat but it is still above normal However even with severe hypoxemia the cardiac output may not rise or may fall if there is so severe a reduction in the pulmonary vascular bed and so great a pulmonary vascular resistance that the right ventricle is unable to expel a normal output of blood through that vascular bed Dexter[54] found that the cardiac output in cor pulmonale was not elevated when the pulmonary "arteriolar resistance rose to approximately four times normal Lewis et al [1 6] reported cases of cor pulmonale with severe hypoxemia and heart failure in which the cardiac output was normal at rest but could not be increased with exercise

4 Pulmonary Hypertension

In advanced pulmonary disease the reduction in number and caliber of the pulmonary capillaries and arterioles results in a progressive increase in pulmonary vascular resistance During the compensated stage of cor pulmonale the right ventricle maintains a normal cardiac output despite increased pulmonary vascular resistance and the pulmonary blood pressure is thus elevated [105, 104] The pulmonary capillary pressure is normal and the pulmonary artery pulmonary capillary gradient is increased [240] Whitaker[21] found the pulmonary blood pressure to range between 8 and 33 mm Hg in patients with cor pulmonale without heart failure between 37 and 59 mm Hg in patients with cor pulmonale in the stage of heart failure The pulmonary diastolic as well as systolic pressure is elevated [[illegible]] Whereas the pulmonary blood pressure is unaltered by exercise in the normal individual despite the increase in cardiac output, in patients with extensive pulmonary disease and a greatly reduced pulmonary vascular bed the increased blood flow cannot be readily accommodated and the blood pressure rises [103, 181]

Other factors, besides a reduction in the pulmonary vascular bed which increase pulmonary vascular resistance and lead to pulmonary hypertension have been discussed (p 987) In clinical practice hypoxemia is particularly important Commonly in patients with compensated cor pulmonale a bronchopulmonary infection producing or intensifying hypoxemia, causes a sharp rise in pulmonary *blood pressure and induces right-sided* heart failure Recovery from the infection is followed by increased arterial oxygen saturation reduction in pulmonary arterial pressure and disappearance of heart failure [47, 162]

5 Right Ventricular Strain

The development of pulmonary heart disease is related specifically to the narrowing and obliteration of the pulmonary vessels and the consequent pulmonary hypertension Pulmonary insufficiency without pulmonary hypertension does not cause cor pulmonale Pulmonary heart disease or cor pulmonale may be said to be present only when there is evidence of right ventricular strain as indicated by hypertrophy of the right ventricle or evidence of pure right ventricular failure

Right ventricular strain is due to an increase in pulmonary resistance which tends to cause incomplete right ventricular emptying and a diminution in stroke output Compensatory dilatation and subsequent hypertrophy restore the stroke output despite the elevation in pulmonary resistance [7] During the compensated phase measurements by intracardiac catheterization have shown an elevation in right ventricular systolic and pulmonary arterial pressure When right heart failure occurs the right ventricular diastolic and the right atrial pressure also rise The high pressure in the right ventricle in cases of pulmonary heart disease by interfering with coronary drainage into that chamber, may impair the blood supply to the hypertrophied right ventricle and accelerate heart failure [[illegible]] but it is questionable whether this is a significant factor in the production of right ven

pulmonary emphysema the arterial oxygen of the blood is reduced significantly even when the patient is at rest [114, 143] The effective pulmonary blood flow, i.e., the percentage of pulmonary capillary blood which is oxygenated, was found to average 69 per cent in a group of patients with severe pulmonary emphysema [179]

Although in general disturbances in ventilation and reduction in pulmonary vascular bed increase concomitantly, one or the other may predominate. Occasionally anatomic reduction in vascular bed, increased pulmonary resistance and pulmonary hypertension cause cor pulmonale before the ventilatory disturbances cause pulmonary insufficiency, i.e., there is cor pulmonale without arterial hypoxemia [55] More often when cor pulmonale develops the pulmonary lesions are severe enough to cause pulmonary insufficiency as well as cor pulmonale and right-sided heart failure [184]

In patients with pulmonary insufficiency and right ventricular failure there is a marked reduction in arterial oxygen saturation. The latter hypoxemia is due to and is a measure of the severity of pulmonary insufficiency. Congestive heart failure of other etiology is associated with little or no arterial hypoxemia in the absence of pulmonary complications (p 190) Relief of right-sided heart failure by digitalis preparations may cause no significant increase in arterial oxygen and no perceptible improvement in the clinical picture because both the hypoxemia and symptomatology are due essentially to the *pulmonary* insufficiency. On the other hand, relief of pulmonary insufficiency and the associated hypoxemia may relieve the right-sided heart failure because hypoxemia in some manner increases pulmonary resistance and consequently the pulmonary blood pressure and the work of the right ventricle

Because of the greater diffusibility of carbon dioxide, the hyperventilation in pulmonary emphysema more readily eliminates excessive carbon dioxide than it maintains adequate oxygenation. Therefore a retention in carbon dioxide occurs less frequently and later than a reduction in arterial oxygen [214] But when the ratio of residual air to total capacity exceeds 45 per cent, both carbon dioxide retention and arterial hypoxemia develop [113, 179] The arterial carbon dioxide tension exceeds 45 mm Hg and there may be a reduction in the pH of the blood. It is generally believed that with carbon dioxide retention the sensitivity of the respiratory center is diminished and further carbon dioxide retention is favored [215, 3] But there is evidence that inability to increase ventilation in advanced emphysema is due not to insensitivity of the respiratory center but to mechanical and metabolic factors [91] On the mechanical side, greater respiratory effort becomes limited by distressing dyspnea or fatigue. On the metabolic side, increased carbon dioxide production by the muscles of respiration reaches a level which exceeds any increase in carbon dioxide elimination

In the cases of restrictive fibrosis and of impaired alveolar capillary diffusion hyperventilation may long serve to maintain the arterial oxygen tension at normal levels. But hypoxemia becomes marked with exercise, especially in the cases with diffusion dysfunction. In advanced cases there is hypoxemia at rest as well as with exercise. The arterial carbon dioxide may be diminished owing to hyperventilation and a gaseous alkalosis may be indicated by a slight elevation of the pH of the blood

Although hypoxemia is frequently present in cases of advanced pulmonary disease with cor pulmonale, there may be little or no hypoxemia even in cases of chronic cor pulmonale and heart failure due to obstructive emphysema [55] In general, there is likely to be serious ventilatory insufficiency and deficient arterial oxygenation if the pulmonary lesions are severe and extensive enough to reduce the pulmonary vascular bed and cause cor pulmonale. However, cor pulmonale may occur without hypoxemia if the restriction in pulmonary vascular bed outpaces the disturbances in pulmonary ventilation and alveolar capillary aeration. Thus pulmonary insufficiency (arterial hypoxemia) may be associated with cardiac insufficiency due to cor pulmonale or the two may be dissociated. When pulmonary heart failure and pulmonary insufficiency are associated recovery from heart failure is not accompanied by a significant rise in arterial oxygen

3 Increased Cardiac Output

When increased minute volume of respiration no longer compensates sufficiently to maintain a normal oxygen content of the arterial blood, other compensatory mechanisms may serve to provide the tissues with an adequate supply of oxygen [4] As in cases of anemia this may be accomplished by an in

manifestations are due to the disturbances in ventilation and perfusion and to pulmonary insufficiency which dominate the clinical picture and overshadow the features of right ventricular failure

With the development of right ventricular failure the liver becomes enlarged and tender There may be gallop rhythm and a systolic murmur over the lower sternum the latter due to functional tricuspid insufficiency

Peripheral edema appears and occasionally ascites The course of heart failure is of relatively short duration and progressively unfavorable In the series of cases studied by Scott and Garvin[301] 86 per cent died of their first attack of cardiac failure In some instances I have seen death from chronic pulmonary emphysema (pulmonary failure) attributed erroneously to congestive heart failure because of a sudden intensification of cyanosis dyspnea and cough In these cases the cause of death was an unrecognized acute terminating bronchopulmonary infection In other cases however such an infection by increasing pulmonary vascular resistance and the strain on the enlarged right ventricle may precipitate congestive heart failure But heart failure precipitated by an acute bronchopulmonary infection is usually reversible and early and adequate treatment may alleviate the pulmonary insufficiency and abolish the heart failure

Circulatory Measurements

The venous pressure in uncomplicated emphysema is usually normal[2, 6] In severe cases with elevated intrapleural pressure the venous pressure may also be elevated probably due to the hindrance to venous inflow presented by the rise in intrapleural pressure[125] An asthmatic attack may further elevate the venous pressure in patients with advanced emphysema but Oppenheimer and Hitzig[169] observed normal venous pressures during paroxysms of bronchial asthma in patients without cardiac disease The development of right ventricular enlargement in cases of pulmonary emphysema is not marked by any change in venous pressure but a distinct rise occurs when the right ventricle fails Measurements by means of intracardiac catheterization showed normal right atrial and right ventricular diastolic pressures but elevated right ventricular systolic blood pressure in cases of chronic pulmonary emphysema without heart failure In the presence of heart failure the right atrial and the right ventricular diastolic pressures were also elevated[27, 18]

The *circulation time* is normal in uncomplicated pulmonary emphysema[2, 6, 215] even during an attack of bronchial asthma[163] and it remains normal during the compensated stage of chronic cor pulmonale However when the emphysema is advanced enough to induce intense arterial anoxemia the circulation time may be significantly reduced probably owing to peripheral vasodilatation as in cases of severe anemia During the stage of right sided heart failure there is a prolongation in both the arm to tongue (saccharin) time and in the arm to lung (ether) time The difference between these two times i e the lung-to-tongue time, is normal because all of the delay occurs between the systemic veins and the pulmonary capillaries When there is severe emphysema the delay in circulation due to heart failure may be neutralized by the acceleration due to pronounced arterial anoxemia On the other hand polycythemia with increased viscosity of the blood tends to slow the circulation

The *circulating blood volume* may be normal in mild cases of emphysema heart but is increased in severe cases with arterial anoxemia and polycythemia[174, 6] The increased blood volume is due to the increase in erythrocytes However in the presence of heart failure the plasma volume may also be augmented[69, 1, 8] The *hematocrit* is increased

Roentgenology

Compensated Stage of Cor Pulmonale There may be roentgenologic evidences of pulmonary hypertension i e dilatation of the pulmonary artery and its branches but enlargement of the right ventricle is rarely demonstrable The recognition of the latter is made difficult by the low diaphragm with consequent median position of the heart and by the barrel shaped chest which permits such enlargement to occur in an anterior direction without displacement of the cardiac borders to the left or right The following roentgenologic alterations in emphysema heart disease have been described[171, 184, 136]

1 Exaggeration of the hilar shadows, due to the enlargement of the main pulmonary arteries and their chief subdivisions

2 Prominence or convexity instead of the normal concavity of the left middle (pulmonary) arc

3 Enlargement of the right ventricle This may be demonstrable by angiocardiography,

which discloses a convexity of the interventricular septum to the left instead of to the right as in the normal heart [12] In the lateral view, in which the right ventricle forms the anterior border of the silhouette there may be encroachment on the retrosternal space

According to Binhold[24] there is usually an increase in the total volume of the emphysematous heart, as determined by Kahlstorf's method The left atrium is normal, but the left ventricle may appear slightly enlarged, probably due to independent disease or anoxemia

Decompensated Stage of Cor Pulmonale In addition to the above with the development of heart failure the right atrium may become enlarged as indicated by an increase in the right lower silhouette and of the entire transverse diameter The shadow of the superior vena cava may also become wide and prominent The enlargement of the right ventricle is more noticeable and involves the inflow as well as the outflow tract (p 106)

Electrocardiogram

The electrocardiogram of chronic cor pulmonale may disclose no abnormality or the following changes due to a vertical position of the heart and/or right ventricular hypertrophy [201, 171, 244] Distinct evidence of right ventricular hypertrophy is observed only in advanced chronic cor pulmonale Since patients with chronic pulmonary disease frequently have a vertical, clockwise rotated heart some of the electrocardiographic changes attributed to right ventricular hypertrophy may be due to the altered position of the electrical axis The following changes are often observed

(1) Prominent peaked P waves in leads II and III and V_F with P_3 higher than P_1 Negative P wave in V_L There may be a prominent atrial T wave
(2) S_1 is usually prominent and R_3 tall S_2 and Q_3 may be present denoting clockwise rotation of the heart
(3) T_3 is often inverted and T_2 may be isoelectric or inverted, T is also inverted in V_F
(4) In the chest leads (a) There may be a tall R in V_1 and aV_R, (b) the peak of R is delayed in right precordial leads to 0 035 second or more after the onset of QRS, (c) the R wave is small and the S deep in the left precordial leads
(d) The T and P waves are inverted in the right precordial leads

The relative importance of the position of the heart and of hypertrophy and dilatation of the right ventricle in the production of these changes is discussed elsewhere (p 113) Distinctive electrocardiographic signs of right ventricular hypertrophy are correlated with the degree of pulmonary hypertension,[118] and usually are present when the mean pulmonary artery pressure exceeds 30 mm Hg and the mean pulmonary resistance exceeds 750 dynes/sec /cm^{-5} [90]

DIAGNOSIS OF CHRONIC COR PULMONALE

The diagnosis of chronic cor pulmonale is based on recognition of (1) underlying pulmonary disease and (2) right ventricular enlargement with or without failure, and on (3) exclusion of mitral stenosis and other cardiac causes of right ventricular enlargement

The history and physical and roentgenologic examination of the chest will usually reveal the presence and nature of the pulmonary disease and exclude primary cardiovalvular disease It is often difficult to differentiate uncomplicated emphysema and other pulmonary disease from compensated cor pulmonale The diagnosis of the latter requires demonstration of right ventricular hypertrophy as indicated by the roentgenologic and electrocardiographic signs These usually disclose only extreme degrees of right ventricular hypertrophy, hence compensated cor pulmonale is usually difficult to diagnose

When evidence of right sided heart failure is added to that of the primary pulmonary disease, the diagnosis of pulmonary heart disease is more definite However dyspnea cyanosis and even a slight elevation of venous pressure may be due to emphysema alone Hepatic enlargement and subcutaneous edema in addition to a pronounced elevation in venous pressure and prolongation of circulation time are indicative of right sided heart failure Extreme intensification of cyanosis and dyspnea is usually due to pulmonary insufficiency and not to the development of right sided heart failure

TREATMENT

In the compensated stage of chronic cor pulmonale, treatment is concerned only with the underlying emphysema or other pulmonary disease But even in the presence of cor pulmonale with heart failure treatment of the pulmonary disease may be of primary im

portance As in cases of heart failure due to hyperthyroidism, anemia beriberi arteriovenous fistula or active rheumatic fever therapy of heart failure may give a satisfactory clinical result only if the primary disease is controlled or ameliorated Therefore it is important to know the type and extent of the underlying pulmonary disease in cor pulmonale Treatment of each individual pulmonary disease is outside the scope of this discussion However certain therapeutic measures which apply to the diseases associated with obstructive emphysema are not employed in diseases associated with pulmonary fibrosis and vice versa

Antibiotics

Frequently the development or marked intensification of symptoms of cor pulmonale with heart failure is precipitated by a bronchopulmonary infection with or without increased bronchial spasm edema inflammation and obstruction [11] Therefore *antibiotics* are of the greatest importance in the therapy of such cases Smears and cultures of sputum should be made to determine the causative organisms and their sensitivity But penicillin streptomycin and broad spectrum antibiotics and/or sulfonamides should be administered as soon as specimens are obtained Changes in antibiotics or their dosage will be determined by the clinical response and the results of bacteriologic study Serious pulmonary and cardiac insufficiency is most likely to be reversible when a precipitating factor such as a bronchopulmonary infection is discovered and controlled

Bronchodilators

Epinephrine 1 per cent or Isuprel 1 200 should be given by spray or as an aerosol with a positive pressure apparatus[159] in cases of obstructive emphysema especially when there is an associated bronchospastic bronchitis Ephedrine in 20 mg doses by mouth Isuprel (isopropylarterenol) sublingually 5 or 10 mg epinephrine hypodermically or aminophylline 0 25 to 0 5 gm intravenously may have to be administered if there are associated severe episodes of bronchial asthma or bronchospasm Antihistamine drugs are rarely of benefit Expectorants such as potassium iodide may be given as adjuvants to the bronchodilators Pharyngeal secretions should be aspirated Rarely bronchoscopy is essential for relief of bronchial obstruction by mucous plugs and may be lifesaving Amelioration of distressing cough may appear desirable but opiates are contraindicated and codeine or Hycodan (dihydrocodeinone) should be prescribed cautiously The cough will be best controlled by elimination of the infection and the use of bronchodilators and expectorants In some cases of pulmonary disease associated with bronchiectasis postural drainage should also be employed Morphine is contraindicated because it causes severe respiratory depression with consequent accumulation of carbon dioxide in the blood carbon dioxide narcosis coma and occasional fatalities in patients with obstructive emphysema and pulmonary insufficiency

Corticosteroid Hormones

These provide dramatic relief of symptoms and occasional improvement in pulmonary function in many cases of idiopathic pulmonary fibrosis, sarcoidosis and other forms of pulmonary fibrosis in which there is impairment of alveolar capillary diffusion [3 8] They are also dramatically effective whenever intractable bronchial asthma or bronchospastic bronchitis is associated with bronchopulmonary disease

Oxygen Therapy

Oxygen therapy is considered whenever there is severe dyspnea and particularly when there is associated hypoxemia and cyanosis However whereas it may be extremely beneficial in cases of alveolar capillary fibrosis with impaired diffusion and in cases of restrictive pulmonary fibrosis oxygen therapy is dangerous in cases of advanced obstructive emphysema with marked carbon dioxide retention In the latter cases the respiratory center is thought to become relatively insensitive to carbon dioxide and to depend on hypoxemia for its stimulation With the administration of oxygen arterial oxygen tension rises and the hypoxemic stimulus is removed Thereupon respiration is depressed carbon dioxide accumulates and usually when the pCO_2 exceeds 100 mm Hg and the pH is less than 7 2 carbon dioxide narcosis occurs [230] Increased respiratory acidosis (carbon dioxide retention) following the breathing of 100 per cent oxygen was found to be rare in emphysematous patients whose timed (3 minute) vital capacity was more than 50 per cent above the predicted value [83] But with increasing impairment of pulmonary ventilation as indicated by greater reductions of the timed vital capacity there was a progressively increased incidence of

respiratory acidosis following oxygen breathing In addition, breathing pure oxygen by the patient with pulmonary emphysema and hypoxemia results in a diminution in respiratory volume in pulmonary vascular resistance pulmonary artery and pulmonary "capillary" pressure and a reduction in cardiac output[34]

Carbon dioxide narcosis is manifested by mental confusion, occasional mania increasing stupor, coma and death[56, 46, 230] It may occur after relatively brief periods of oxygen administration e g an hour or two in an oxygen tent If oxygen therapy is administered to patients with obstructive emphysema, it should be given if at all, only for brief interrupted periods and with careful and continued observation of the clinical response Therapy should be carried out preferably with control by determination of the blood gases There is evidence that following treatment with bronchodilator drugs antibiotics and intermittent positive pressure breathing, not only is the arterial oxygen saturation increased and hypercapnia diminished but the sensitivity of the respiratory center to carbon dioxide is improved[95]

Intermittent Positive Pressure Respirators

On the other hand, oxygen may be administered to relieve hypoxemia in patients with obstructive emphysema provided artificial aids to respiration are simultaneously employed[9, 131] A Drinker Collins respirator may be used during oxygen therapy to increase alveolar ventilation This prevents increased arterial carbon dioxide tension and gaseous acidosis despite the tendency of the oxygen to cause respiratory depression The respirator also promotes bronchial drainage and helps provide an adequate airway Other simpler artificial respirators may be used to provide intermittent positive pressure breathing,[159, 202] such as the Bennett pressure therapy unit or a pneumatic balance resuscitator (PBR), Burns model These devices are effective in a comatose patient as well as in one who can cooperate Intermittent positive pressure therapy has been used effectively to relieve carbon dioxide narcosis[166] Exsufflation with negative pressure has been effected by an apparatus producing intermittent positive and negative pressure breathing thus promoting ventilation and eliminating mucoid and mucopurulent secretions[41, 203] Recent studies of the comparative value of intermittent positive pressure breathing (IPPB) alone nebulized bronchodilators alone and IPPB with nebulized bronchodilators in chronic emphysema suggest that in the patients studied the nebulized bronchodilators alone were responsible for the beneficial effects[238, 125b]

Other means have been employed to aid ventilation in obstructive emphysema with or without pulmonary or cardiac insufficiency Respiratory exercises[153, 55] and an abdominal belt have been recommended[1, 5, 11] Pneumoperitoneum has been induced to raise the diaphragm and thus promote ventilation[83, [illegible], 241]

Treatment of Heart Failure

Right sided heart failure is treated by rest digitalization low sodium intake and diuretics

Digitalis is indicated as in other forms of heart failure Its efficacy can be demonstrated by manometric studies during cardiac catheterization for the cardiac output is increased and the elevated right ventricular diastolic pressure may be reduced to normal by the intravenous administration of Digoxin[89, 97] Frequently the clinical status of the patient improves very little, despite the administration of digitalis and the alleviation of heart failure This is because of the persistent pulmonary insufficiency which dominates the clinical picture When the arterial oxygen tension rises because of control of a bronchopulmonary infection and improved ventilation, i e, when the pulmonary insufficiency is alleviated, there may be a dramatic clinical improvement Relief of the pulmonary infection, by reducing the pulmonary resistance may also relieve the strain on the right ventricle and permit recovery from right sided heart failure

There has been some disagreement as to the indication for *phlebotomy* in the treatment of cor pulmonale with heart failure It is not indicated as a rule in the cases without hypoxemia In cases of cor pulmonale with marked hypoxemia, as indicated by cyanosis, and with polycythemia, the polycythemia is regarded as compensatory for the hypoxemia Hence removal of blood has been regarded as undesirable because this would further reduce the impaired oxygen transport of the blood Clinical experience in cases of cor pulmonale with severe pulmonary and cardiac insufficiency has convinced me of the benefit, some-

times striking of phlebotomies when carried out as follows Phlebotomy is not performed during the acute stage of pulmonary insufficiency when therapy consists chiefly of antibiotics, bronchodilators, etc When the pulmonary insufficiency is alleviated complete recovery [redacted] markedly accelerated by multiple small phlebotomies of 250 cc each, several days apart

Mercurial diuretics may be employed in the presence of right sided congestive heart failure especially with edema

Diamox a carbonic anhydrase inhibitor has been used both as a diuretic and because it promotes the renal excretion of bicarbonate[163, 199] [redacted] Fishman et al[77] observed that Diamox reduced the arterial blood P_{CO_2} decreased the alkaline reserve facilitated clearing of the sensorium and reduced the hazard of carbon dioxide narcosis Bell et al[0] reported that Diamox improved alveolar ventilation as measured by increased P_{O_2} and decreased P_{CO} but caused only temporary symptomatic improvement Diamox is not indicated for patients without CO_2 retention at rest Diamox therapy should be regarded as an adjunct to treatment with artificial respirators bronchodilators and antibiotics rather than as a primary or major therapeutic factor Diamox may be administered orally in doses of 250 or 500 mg daily in a single morning dose for 5 consecutiv[redacted] days with a rest period of 2 days each week Heiskell et al[106] administered 10 mg per kilogram of body weight every [redacted] hours for four days to 4 patients with chronic emphysema and respiratory acidosis In all four there was significant improvement in pulmonary function increased exercise tolerence decreased dyspnea on exertion and lowered levels of plasma bicarbonate

Salicylates

The intravenous administration of 6 to 8 gm of sodium salicylate over a period of one hour increases the sensitivity of the respiratory center to carbon dioxide lowers the arterial P_{CO_2} raises the arterial oxygen saturation and the pH of the arterial blood in patients with obstructive emphysema[2, 5] Hypercapnia increased by breathing oxygen is ameliorated by intravenous sodium salicylate whereas oral salicylates give variable results Intravenous salicylates may have therapeutic value in pulmonary emphysema with CO_2 retention

Chapter 40

THE HEART IN HYPERTHYROIDISM

Hyperthyroidism is an important etiologic factor in the production of atrial fibrillation cardiac enlargement and congestive heart failure but there is still considerable uncertainty whether hyperthyroidism per se is responsible for these manifestations In short, it is uncertain whether there is a specific etiologic type of heart disease caused by hyperthyroidism, or whether the latter is merely a contributory or precipitating factor in individuals already predisposed by coincident heart disease

The term thyroid heart disease is restricted to cases in which hyperthyroidism is associated with recurrent paroxysmal or established atrial fibrillation or with congestive heart failure Since many symptoms such as palpitation and tachycardia dyspnea and precordial distress are commonly observed with uncomplicated hyperthyroidism their presence is not in itself sufficient to warrant the diagnosis of heart disease

In the great majority of cases of thyroid heart disease there has been found evidence of associated coronary (atherosclerotic) hypertensive rheumatic or syphilitic heart disease Kepler and Barnes[62] found organic heart disease in 18 (67 per cent) of 27 fatal cases of hyperthyroidism in which there had been evidence of congestive *heart failure Maher* and Sittler[64] reviewed a series of 180 cases of hyperthyroidism in 75 per cent of which they found complicating organic heart disease Furthermore in all of the 38 cases in which congestive heart failure was present and in 41 out of 42 cases in which atrial fibrillation was encountered, there was independent organic heart disease Therefore with one possible exception thyroid heart disease in this series was always associated with an underlying independent organic cardiac disease The great frequency if not the invariable association of organic heart disease the absence of consistent or convincing pathologic evidence of structural cardiac damage due to hyperthyroidism (p 1003) and the reversibility of the cardiac manifestations of hyperthyroidism have given rise to the belief that a characteristic form of heart disease due exclusively to hyperthyroidism does not exist

ETIOLOGY AND PATHOGENESIS

Cause

Most of the symptoms of uncomplicated Graves disease including the circulatory disturbances may be attributed to an excessive production and dissemination of thyroid hormone However the exact mechanism by which the cardiac disturbances are induced is uncertain In addition there is evidence that the pituitary gland the diencephalon and hypothalamus and the adrenal and sympathetic nervous system may be concerned in the production of some of the manifestations of Graves disease and similarly these organs and tissues may also influence the heart and circulation

Age and Sex

Uncomplicated hyperthyroidism is most common between the ages of 20 and 40 [73, 46] In contrast thyroid heart disease is exceptional before the age of 40 and in the series of 108 cases reported by Barker et al,[5] the average age was *51 and a half These* figures stress the importance either of a prolonged duration of the hyperthyroidism or of the appearance of coronary atherosclerosis in later years in the production of the so called thyroid heart

Females predominate in a ratio of 5 to 1 in uncomplicated Graves disease this predominance is reduced to 2 to 1 in cases of thyroid heart disease

MECHANISM

We are concerned here primarily with the mechanism by which atrial fibrillation cardiac enlargement or heart failure i e thyroid heart disease, develops in instances of pre-

viously uncomplicated Graves' disease. Two general possibilities should be considered.

1 Coexistent Heart Disease and Hyperthyroidism

Coexistent independent heart disease reduces the cardiac reserve but compensation is maintained for the ordinary demands placed upon the heart. With the advent of hyperthyroidism certain alterations occur which in one way or another (see below) increase the demands on the heart to a degree which the diseased heart can no longer meet. Cardiac enlargement, cardiac failure and atrial fibrillation then develop. These are all manifestations which might have appeared eventually in the absence of hyperthyroidism, but which develop earlier because of hyperthyroidism.

Conversely, in many instances hyperthyroidism antedates independent heart disease due to hypertension and coronary atherosclerosis. The normal heart for many years is capable of adjusting itself to the requirements imposed by excessive thyroid secretion and increased metabolism. But with the added burden of hypertension and the diminished cardiac efficiency due to coronary ischemia and myocardial anoxia, the heart is no longer able to maintain its normal size and remain compensated. Cardiac enlargement, atrial fibrillation and congestive heart failure are ultimate consequences.

2 Hyperthyroidism as an Exclusive Cause of Heart Disease

The second possibility also exists that prolonged and severe hyperthyroidism may by itself produce atrial fibrillation, cardiac enlargement and failure in the absence of any independent cardiac disease.

METHODS BY WHICH HYPERTHYROIDISM MAY AFFECT THE HEART

1 Effects of Thyroid Hormone on Heart Muscle

The thyroid hormone may impair the heart muscle by direct effects. Since the heart participates in the general increase of tissue metabolism, its oxygen requirement is augmented. This requirement is usually satisfied by an increased coronary flow secondary to a reduction in coronary arterial resistance.[8, 9] The depletion of glycogen in the heart muscle[1] in experimental hyperthyroidism has been attributed to relative anoxia.[78] There is experimental evidence that thyroid extract or thyroxin acts directly on heart muscle to cause tachycardia.[62, 63] However, these findings are inadequate to permit a conclusion that atrial fibrillation or heart failure in clinical hyperthyroidism is the result of a direct cardiac effect of the thyroid hormone.

2 Excessive Sympathico Adrenal Stimulation

Resemblances between the clinical manifestations of hyperthyroidism and those caused by stimulation of the sympathetic nerves or the administration of epinephrine suggest that the cardiac disturbances in Graves' disease may be due to exaggerated stimulation of the sympathico adrenal system. There is, in fact, evidence that the thyroid hormone sensitizes the sympathetic system to the action of epinephrine. In dogs made hyperthyroid by thyroid feeding there were consistently greater increases in oxygen consumption, cardiac rate and cardiac index with infusion of epinephrine or norepinephrine than occurred with the same infusions in euthyroid dogs.[14] These observations were interpreted to indicate that the cardiovascular effects of thyrotoxicosis are not due to a direct effect of thyroid hormone but rather to augmentation of the physiologic effects of epinephrine or norepinephrine by thyroxin.

Careful analysis discloses that the resemblance between the symptoms of Graves' disease and the effects of sympathetic adrenal stimulation is superficial and incomplete. For example, the cutaneous vasoconstriction with consequent pallor and coldness resulting from sympathetic stimulation contrasts notably with the cutaneous vasodilatation and warmth of hyperthyroidism. The tendency to diarrhea is a parasympathetic not a sympathetic effect. The exophthalmos attributed to excessive cervical sympathetic tone has a different pathogenesis.[75] Although sympathetic stimulation and epinephrine could account for tachycardia and are capable of producing ventricular fibrillation experimentally, they do not cause atrial fibrillation.

3 Disturbed Circulatory Dynamics

The most plausible explanation for the effects of hyperthyroidism on the heart is that altered circulatory dynamics impose an excessive cardiac strain. These altered dynamics (infra), which are in part compensatory adjustments to the elevated metabolism, increase the work of the heart and its need for oxygen and diminish its efficiency. In the presence of associated organic heart disease or with the development of coronary atherosclerosis in

middle life these hyperthyroid strains lead to atrial fibrillation and congestive heart failure

PATHOLOGIC PHYSIOLOGY

Increased Metabolism and Oxygen Consumption

An elevated basal metabolism, exceeding normal by 30 to 75 per cent or more, is the basic physiologic change in hyperthyroidism This denotes an increase in oxygen consumption As we shall see, this abnormal tissue oxygen requirement is met by a corresponding increase in minute volume (cardiac output) and not by increased oxygen utilization for the arteriovenous oxygen difference is diminished[63, 9]

Increased Heat Production

This is a consequence of increased metabolism and is disclosed clinically by a warm flushed skin A number of chemical hormonal and nervous compensatory mechanisms are called into action to maintain a constant temperature despite the increased heat production The latter by warming the blood excites nerve centers (hypothalamus and spinal cord) which stimulate the secretion of sweat perhaps also heat receptors in the skin reflexly assist this mechanism The warm sweat (vasodilatation of the skin capillaries) found in hyperthyroidism contrasts with the cold sweat found in psychoneurotic patients or those in shock in whom there is cutaneous vasoconstriction About 6 per cent of the cardiac output flows through the skin in patients with Graves' disease instead of the normal 3 per cent

Increased Cardiac Output (Minute Volume)

An increased cardiac output is characteristic of Graves' disease [4, ■, ■] Like many other physiologic adjustments it represents on the one hand a compensatory process by which the circulation attempts to keep pace with the increased metabolic needs and increased heat production of hyperthyroidism while on the other hand its useful effects are partially vitiated by the strain it imposes on the heart

When heart failure complicates hyperthyroidism the cardiac output falls somewhat but in absolute values it is still abnormally high[10, 40] (high output failure) Occasionally when heart failure is severe the fall in cardiac output may reduce it to within the normal range The response of the cardiac output to exercise is varied In uncomplicated hyperthyroidism there is an abnormally high increase in response to exercise[10] In some cases complicated by heart failure there may be a high resting output with a fall during exercise In other hyperthyroid patients whose cardiac output has been diminished to normal values by severe heart failure there may be no change in output with exercise[40a]

In the normal individual increased cardiac output, e g, during exercise is accomplished by both an increase in cardiac rate and an increase in stroke volume the better trained the individual, the less is the tachycardia and the greater the relative importance of the increased stroke output In patients with hyperthyroidism tachycardia is a cardinal feature the accelerated pulse rate corresponding closely in degree to the elevated metabolism In most if not all cases of hyperthyroidism the increased heart rate is itself capable of accounting for the observed increase in cardiac output By means of the cardiotachometer Boas[13] observed that the average sleeping pulse rate in normal subjects was 58 per minute, while that in patients with Graves disease averaged 89 an increase of 53 per cent which corresponds closely with observed average increases in both the basal metabolism and the cardiac output The tachycardia may be due to direct action of the thyroid hormone on the heart muscle or it may be a consequence of the Bainbridge reflex initiated by the increased venous return

Stroke Output

While these considerations suggest that the stroke output in Graves disease need not be elevated to explain the augmented cardiac output, direct determinations have not yielded consistent results [4] Fullerton and Harrop[34] noted a reduction in the systolic output as well as in the minute volume in ■ patients with Graves disease after thyroidectomy However the average systolic output before operation in these patients was 57 cc which was slightly less than Grollman s average of 62 cc for normal subjects From these figures it is apparent that the preoperative elevation in cardiac output was due to tachycardia and the reduction after operation was entirely or almost entirely caused by a reduction in the heart rate Bansi[3] found that the stroke volume tended to be diminished in patients with Graves' disease While *Liljestrand and Stenstrom*[67] observed a striking elevation in the cardiac output per minute in 11 cases of uncomplicated Graves disease the average out-

put per beat was only 63 cc and the range from 49 to 83 cc corresponding to Grollman's average of 62 cc and range of 38 to 84 cc for normal subjects Even with allowance for certain inconsistencies these observations strongly indicate that the stroke volume in Graves disease is neither significantly nor frequently increased and that it is a relatively unimportant factor in the augmentation of the cardiac output The stroke volume has been considered in some detail because it is an indirect measure of the diastolic tension and of the length of the cardiac fibers in diastole which in turn are related to the development of cardiac dilatation and hypertrophy

Increased Venous Return Peripheral Vasodilatation and Increased Blood Flow

The increased minute volume is itself the consequence of an enlarged venous return Heightened tissue metabolism yields an excess of local metabolites which in turn dilate small vessels establish arteriovenous shunts and lead to an accelerated venous return of blood from the periphery to the heart Roberts and Griffith,[90] with the aid of the capillary microscope observed that most of the cutaneous capillaries in the forearms were dilated in hyperthyroidism The peripheral blood flow, measured by several observers using different methods was uniformly found to be increased in patients with hyperthyroidism [100, 27]

Diminished Circulation Time and Increased Blood Volume

The minute volume (cardiac output) varies with the velocity of blood flow and with the circulating blood volume Actually both of these factors have been found to be increased in patients with hyperthyroidism A heightened velocity of blood flow i e a *diminished circulation time,* was demonstrated by Blumgart, Gargill and Gilligan[12] with the aid of radium C and by Tarr, Oppenheimer and Sagar[101] with the aid of Decholin The circulation time from arm to tongue is usually between 7 and 10 seconds in contrast to the normal of 10 to 16 seconds This acceleration of the circulation probably results from peripheral arteriovenous shunts caused by vasodilatation due to the accumulation of increased metabolites An augmented circulating blood volume was determined by Rowntree and Brown[92] with the use of Congo red, by Chang[19] with the use of carbon monoxide, and by Gibson and Harris[37] with the aid of Evans blue However, the increase in blood volume averages only about 10 per cent [34] On the other hand, the speed of circulation increases 30 to 70 per cent and can account for almost all of the increase in venous return and cardiac output [21]

Relations of Altered Circulation to Thyroid Heart Disease

To what extent are these circulatory adjustments in hyperthyroidism responsible for the manifestations of thyroid heart disease namely, atrial fibrillation cardiac enlargement and congestive heart failure? The tachycardia which is uniformly present in uncomplicated hyperthyroidism is rarely of sufficient degree to induce heart failure There is little evidence indicating that the stroke output is either consistently or significantly elevated The augmented cardiac output per minute and therefore the increased cardiac work per minute is in itself incapable of producing cardiac hypertrophy or cardiac failure as long as the work of the heart *per beat* is not greater [107]

There is however, evidence suggesting that the heart in hyperthyroidism is inefficient in its adaptation to an increased strain The hyperthyroid heart at rest is utilizing its reserves in a manner which resembles that of the normal heart performing heavy work Plummer and Boothby[85] and Briard and his associates[17] demonstrated that patients with hyperthyroidism were inefficient in converting potential energy into motion Bansi and Groscurth[4] found that the cardiac output, the oxygen consumption and the blood pressure during and after work were all increased in hyperthyroid patients to a relatively much greater extent than in normal individuals performing the same work Boothby and Rynearson[14] observed a greater augmentation in the cardiac output in patients with Graves disease than in normal subjects following similar increases in oxygen consumption caused by work

These varied observations, as well as a consideration of the circulatory changes already mentioned, suggest not only that the hyperthyroid heart is under strain to provide an adequate blood supply for the exaggerated oxygen demands of the tissues, but also that the adjustments employed are wasteful in their provision and utilization of this increased oxygen supply The heart muscle itself becomes especially sensitive to any deficiency in oxygen supply, partly because of its own in

creased metabolism and partly because it is constantly performing an excessive amount of work Although it is possible for the normal heart with rare exceptions to meet the added strains of hyperthyroidism this adjustment becomes more and more difficult if the heart is already impaired and enlarged by preexisting disease or if cardiac function becomes diseased as the result of progressive coronary deficiency in later years Cardiac hypertrophy due to rheumatic heart disease or hypertension or other cause increases the myocardial need for oxygen while coronary artery disease diminishes the supply in either circumstance the hyperthyroid heart already suffering from low oxygen reserve is especially vulnerable In summary it appears that the circulatory adjustments to the increased metabolism of Graves disease impose a heavy burden on the heart but a burden which is likely to produce congestive heart failure only when the heart is already vulnerable or becomes vulnerable because of associated independent disease

Mechanism of Atrial Fibrillation in Hyperthyroidism

The mechanism by which hyperthyroidism or its altered circulatory dynamics may cause or predispose to atrial fibrillation is unknown The high incidence of atrial fibrillation especially of the paroxysmal type is a distinctive feature in hyperthyroidism The frequency and transiency with which it appears shortly after thyroidectomy and the frequency with which preoperative transient or permanent atrial fibrillation is cured by thyroidectomy attest to more than an accidental relationship between hyperthyroidism and atrial fibrillation These observations may denote that the thyroid hormone represents a direct toxic cause of atrial fibrillation in susceptible individuals In hyperthyroid animals the oxygen consumption of cardiac tissue is greatly increased especially that of the atria [10] The excitability of the atria in hyperthyroidism has been related to this increase in oxygen consumption

It is also possible that the atrial fibrillation results from the augmented venous return to the heart with its prolonged exaggerated stimulation of the atrial muscle about the entrance of the great veins where an irritable focus may be induced Excessive vagal tonus has been credited with an important role in causing atrial fibrillation on the basis of experimental production of this arrhythmia by vagal stimulation in cats and its production in hyperthyroid patients by the administration of Mecholyl [79] Acetylcholine likewise favored the induction and maintenance of experimental atrial fibrillation whereas potassium chloride restored the fibrillation to sinus rhythm[17] However as a rule atrial fibrillation is found only in hyperthyroid patients in the older age groups and with associated cardiac disease This suggests that the latter may be the basic cause of the atrial fibrillation and that the hyperthyroidism merely increases its occurrence or hastens its development When the associated cardiac disease is sufficient in itself to cause atrial fibrillation thyroidectomy does not cure this arrhythmia

PATHOLOGY OF THE HEART IN GRAVES DISEASE

There are no constant or characteristic morphologic changes in the heart which might be attributed to hyperthyroidism Infiltrations of lymphocytes and histiocytes as well as areas of myocardial necrosis and extensive interstitial fibrosis have been reported [30, 35, 81] but careful controlled histologic studies have failed to substantiate these findings [88, 104] Likewise I have been unable to find pathologic evidence of characteristic cardiac changes due to hyperthyroidism in a postmortem study of more than 35 hearts in patients with this disease Necrosis fibrosis and reactive cellular infiltration observed in some hearts could be explained by the ischemic effects of associated coronary atherosclerosis

It is well to remember that the absence of distinctive morphologic changes in the hearts of hyperthyroid individuals does not exclude the possibility that hyperthyroidism produces important or distinctive metabolic changes which alter the function of the heart muscle fibers The evidence of glycogen depletion in the heart muscle in experimental hyperthyroidism has been noted

Size of the Heart

Postmortem studies almost uniformly disclose a high incidence of cardiac hypertrophy in Graves disease Willius and his associates[108] observed cardiac hypertrophy in 16 of 21 cases Kepler and Barnes[5] in 42 of 86 cases and Parkinson and Cookson[83] in 22 of 43 making a combined average of about 50 per cent of hypertrophied hearts

In a study of 27 autopsied cases [35] we found that 14 of the 27 hearts were hypertrophied, as determined by comparison with figures for normal heart weight relative to body weight However we observed that 12 of the 14 hypertrophied hearts were those of persons in whom the hyperthyroidism was complicated by hypertension severe coronary narrowing and/or atrial fibrillation Six of these 12 hypertrophied hearts were those of patients who had suffered from congestive heart failure The most extreme hypertrophy in the series was found in those hearts in which congestive failure had been present We concluded that cardiac hypertrophy is usually absent or of minimal degree in uncomplicated cases of Graves disease However, eventually cardiac enlargement and hypertrophy developed in about half the cases which come to autopsy in a general hospital because of complicating heart disease or hypertension Cardiac hypertrophy is found in those cases of hyperthyroidism in which there is also thyroid heart disease i e in which established atrial fibrillation or cardiac failure coexists

The absence of cardiac hypertrophy in uncomplicated hyperthyroidism may be related to the finding that the stroke output and therefore the diastolic tension are usually normal When cardiac hypertrophy occurs, it is the consequence of hypertension or associated valvular disease, most strikingly, it appears with progressive myocardial failure

CLINICAL FEATURES OF THE HEART IN HYPERTHYROIDISM

Many of the symptoms and signs referable to the heart and circulation are essential features of uncomplicated Graves' disease their presence does not warrant a diagnosis of thyroid heart disease Arbitrarily one may speak of thyroid heart disease when in addition to hyperthyroidism there is also persistent atrial fibrillation, distinct cardiac enlargement or congestive heart failure

SYMPTOMS

Palpitation is one of the commonest subjective symptoms referable to the heart in Graves disease As a rule it occurs independently of heart disease and is the consequence of rapid and forceful heart action as well as of hypersensitivity of the autonomic and central nervous system Palpitation may vary in severity from an uncomfortable awareness of the heart beat to an intense and sometimes terrifying pounding It may be present when the patient is at rest, especially when lying on his left side, but more often it appears or becomes accentuated with emotion and exertion or after a meal

Another type of palpitation occurs in paroxysms and is due to transient episodes of atrial fibrillation or, rarely, of flutter [53] It may be associated with faintness, weakness or precordial distress When these attacks of atrial fibrillation are accompanied by very rapid ventricular rates, the local distress is sometimes overshadowed by breathlessness Extreme weakness may follow subsidence of such an episode Occasionally a severe attack of paroxysmal atrial fibrillation may precipitate transient pulmonary edema or chronic congestive heart failure As a rule, however, these transient paroxysms of irregular heart action come and go and the patient learns to tolerate them

Similarly, *permanent* atrial fibrillation may provoke the subjective sensation of palpitation with or without an awareness of an irregular heartbeat, or it may be accompanied by more serious symptoms of congestive heart failure On the other hand, many patients with atrial fibrillation, transient or permanent, are unaware of the irregularity

Breathlessness is also a common symptom but its character and pathogenesis are distinctive from those of classic cardiac dyspnea It is often experienced on exertion and is associated with easy fatigability The combination reminds one of similar symptoms observed in neurocirculatory asthenia or cardiac neuroses In some of these cases the breathlessness occurs predominantly at rest and is the sighing type seen in psychoneurotic individuals

On the other hand, the dyspnea may be due to an actual disturbance in circulation or in pulmonary ventilation The oxygen consumption and cardiac output in hyperthyroid patients during and after work are increased much more than in normal persons performing the same exertion [4] The vital capacity has been found to be below normal in hyperthyroidism [■] The residual air and functional residual capacity were found to be increased [■] Because of these findings, the dyspnea has been explained as being due to increased pulmonary ventilation necessitated by coincident augmented oxygen consumption and decreased vital capacity [■]

But the dyspnea of uncomplicated hyperthyroidism, unlike that of heart failure, is not associated with evidence of pulmonary congestion, in fact the rate of blood flow through the lungs is accelerated and not delayed Therefore it appears improbable that the dyspnea is due to any circulatory abnormality It seems more likely that the respiratory distress in uncomplicated hyperthyroidism is induced by the easier fatigability of the muscles of respiration rather than by any intrinsic pulmonary disturbance The fatigability of the respiratory muscles may be the result of the increased work needed for the augmented oxygen supply or of an actual respiratory muscular weakness which is part of a general disturbance in creatine metabolism often present in hyperthyroidism [57] Dyspnea occurs more readily when the patient lives in an atmosphere of low oxygen pressure which interferes with his high oxygen requirement In fact dyspnea on exertion (occurring in 56 per cent of 140 cases) was described as the commonest symptom of hyperthyroidism in patients residing at the high altitude of Denver where the atmospheric pressure is low [18]

Finally, true cardiac dyspnea may become a prominent symptom as a result of the development of pulmonary congestion due to heart failure In such cases all of the features of cardiac dyspnea are present and there are often rales at the bases of the lungs while the circulation time although not prolonged is delayed in comparison with the rapid circulation time of uncomplicated hyperthyroidism

Precordial pain is an occasional symptom of hyperthyroidism It may represent only a mild discomfort associated with tachycardia and awareness of the heartbeat There may be a sticking type of pain in the region of the cardiac apex, such as occurs in many women with hypersensitive nervous systems On the other hand more intense precordial pain may accompany a paroxysm of atrial fibrillation with very rapid ventricular rate Occasionally such an episode may simulate an attack of acute myocardial infarction

In a small percentage of cases angina pectoris characterized by a compressing retrosternal and precordial pain with typical radiations and induced by effort and excitement may be associated with hyperthyroidism [58] Since this is seen most commonly in the older age groups it is probable that the angina pectoris results from concomitant severe coronary artery disease However, Lev and Hamburger[59] reported that the angina pectoris disappeared following subtotal thyroidectomy This suggests that the hyperthyroidism was at least a contributory factor in causing the pain perhaps by increasing the oxygen requirements of a myocardium already deficient in blood supply

OBJECTIVE MANIFESTATIONS

We are concerned here primarily with cardiac and other circulatory manifestations of hyperthyroidism but the predominant signs of this disease are usually outside the heart The latter include the characteristic stare, the warm moist and often ruddy skin the enlarged thyroid gland and the tremor In cases of thyroid heart disease many of these classic signs of hyperthyroidism are often obscure or may be overshadowed by the cardiac manifestations In particular exophthalmos is usually absent and the thyroid gland is not noticeably enlarged [44] Cases of cardiac disease or congestive heart failure with hyperthyroidism in which the classic signs of the latter seem to be absent or are easily overlooked are sometimes described under the heading of "masked hyperthyroidism" [60]

The Heart

Examination often discloses a broad striking precordial pulsation which is easily visible as well as palpable The apical thrust is often sharp and snapping These pulsations correspond to a steep rapid ascent of the ventricular contraction curve The strong pulsations may suggest the presence of cardiac hypertrophy but usually neither the position of the apical impulse nor percussion of cardiac dullness reveals any evidence of cardiac enlargement in uncomplicated cases

The *heart sounds* are loud and are distinguished especially by the first sound at the apex which is sharp and snapping often simulating the sharp first sound of mitral stenosis A systolic murmur is common and is usually most audible over the pulmonic area From time to time the sharp first apical sound in hyperthyroidism is associated with a distinct presystolic murmur under which circumstance the similarity to mitral stenosis presents a problem in differential diagnosis In my experience the association of rheumatic mitral stenosis with hyperthyroidism has been more common than is generally stated

Heart and Pulse Rate

As a rule, the pulse rate in Graves disease is between 90 and 120 per minute, but wider variations are encountered While the pulse rate in hyperthyroidism is abnormally increased by activity and emotional excitement, it also remains elevated when the patient is apparently calm and at rest Boas[12] has observed with the aid of the cardiotachometer that relatively little slowing of the heart rate occurs during sleep in contrast with the striking slowing of the tachycardia in psychoneurotic individuals

Pulse rates of 180 to 200 or more are sometimes observed in hyperthyroid patients either because of an extremely elevated metabolic rate, because of a paroxysm of atrial fibrillation or most commonly during a thyroid crisis or thyroid 'storm' following thyroidectomy

The pulse in hyperthyroidism is not only rapid, but often presents the full steep ascent and sharp rapid drop characteristic of the Corrigan or water hammer pulse found in aortic insufficiency Correspondingly, there may also be striking visible pulsations of the vessels of the neck These pulse characteristics result from the rapid discharge of blood from the heart into a dilated relaxed vascular bed

Atrial Fibrillation and Other Arrhythmias

In more than 75 per cent of the cases there is regular sinus rhythm at all times even when the heart rate is very rapid, but atrial fibrillation in paroxysmal or persistent form occurs with sufficient frequency to be considered a characteristic and diagnostic feature of hyperthyroidism Ernstene[8] noted atrial fibrillation at some time in about 21 per cent of 1000 cases but less than half of these were observed preoperatively Permanent atrial fibrillation occurred twice as often in this group as the paroxysmal variety Atrial fibrillation was recorded in 19 per cent of 279 cases of thyrotoxicosis studied by Jervell[33] mostly in the older age groups Hurxthal[47] encountered *established atrial fibrillation* in 5 8 per cent of 7363 patients operated on for hyperthyroidism, in terms of the thyrocardiac group this arrhythmia occurred in about 90 per cent of the cases More than 10 per cent of the total group of hyperthyroid patients had experienced *transient* atrial fibrillation before or after operation

Whereas *permanent* atrial fibrillation may be asociated with a variety of cardiac diseases especially rheumatic mitral stenosis and advanced coronary atherosclerosis, *paroxysmal* atrial fibrillation is highly suggestive of the presence of hyperthyroidism Temporary atrial fibrillation may appear for the first time or recur immediately following thyroidectomy, in either circumstance it usually disappears spontaneously after a few days or weeks Ernstene[28] observed that following thyroidectomy recurrent paroxysmal atrial fibrillation invariably reverted spontaneously to normal sinus rhythm if the patient survived On the other hand, thyroidectomy resulted in the spontaneous reestablishment of sinus rhythm in one third of the cases of established atrial fibrillation, of the remainder, a high percentage of restoration of sinus rhythm was effected by the administration of quinidine

Atrial fibrillation is associated predominantly with hyperthyroidism in the older age group Seventy five per cent of the cases of atrial fibrillation in Ernstene's[8] series occurred in persons above the age of 45 The severity of the hyperthyroidism does not appear to be a determining factor, for atrial fibrillation is uncommon in young persons with Graves' disease, even when the basal metabolic rate is extremely elevated When atrial fibrillation is encountered in patients under the age of 35 it is almost invariably paroxysmal Organic heart disease is frequent in cases of hyperthyroidism with atrial fibrillation, especially of the permanent variety More than half of Ernstene's patients with atrial fibrillation presented evidence of associated coronary, hypertensive or rheumatic heart disease Apparently, underlying cardiac disease is an important predisposing factor in the development of atrial fibrillation even though hyperthyroidism appears to be the trigger mechanism responsible for its appearance Finally, there is evidence that atrial fibrillation increases in frequency with the duration of the hyperthyroidism[108]

Other arrhythmias are extremely uncommon Premature beats occur occasionally but are not characteristic of hyperthyroidism *Rarely*, atrial flutter, paroxysmal atrial tachycardia or heart block is observed Davis and Smith[3] described 6 cases of complete heart block in hyperthyroidism due to acute infections or digitalis Unlike atrial fibrillation, these arrhythmias are not influenced by thyroidectomy

Blood Pressure and Pulse Pressure

The systolic blood pressure may be normal but more often it is at the upper limit of nor

mal or moderately elevated On the other hand the diastolic pressure is almost always normal unless there is an associated essential hypertension Occasionally the diastolic pressure is below normal Consequently the pulse pressure is usually elevated In fact an increased pulse pressure due to systolic hypertension is sometimes the clue to the discovery of hyperthyroidism But of course these findings are by no means limited to hyperthyroidism Occasionally an extremely wide pulse pressure resembling that of aortic insufficiency is associated with other dynamic changes characteristic of the latter disease namely prominent carotid pulsations Corrigan pulse pistol shot in the femoral arteries and capillary pulse

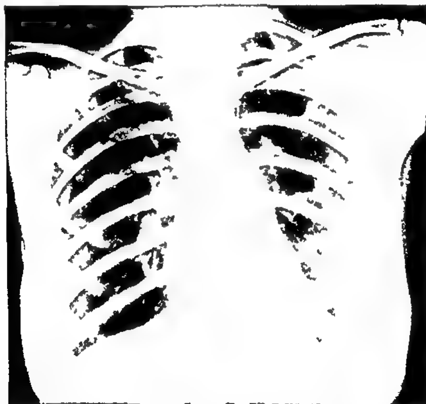

Fig 152 Heart in hyperthyroidism Pulmonary artery segment elongated and convex

The Circulation Time and Venous Pressure

In uncomplicated hyperthyroidism the velocity of blood flow is distinctly increased (p 1002) In my experience both the arm to-lung time determined with the aid of ether (p 215) and the lung to-tongue time (p 214) are significantly diminished but the greater reduction in circulation time appears to involve the segment from the antecubital vein to the pulmonary capillaries The arm to-lung time in such cases is usually between 3 and 4 seconds when the arm to-tongue time is between 8 and 10 seconds

The circulation time may remain rapid or within normal limits even when there are distinct clinical features of congestive heart failure and the venous pressure is elevated In such circumstances the circulation time may not be quite as abbreviated as in uncomplicated hyperthyroidism but usually it averages 10 to 15 seconds which is within the normal range of healthy persons This combination of congestive heart failure with a normal or rapid circulation time is distinctive of hyperthyroidism although it may also be observed in heart failure associated with vitamin B deficiency with fever, with severe cor pulmonale or with severe anemia

The venous pressure is usually normal in cases of uncomplicated hyperthyroidism When right as well as left sided heart failure develops the venous pressure becomes elevated

Roentgenologic Examination of the Heart

In uncomplicated hyperthyroidism roentgenologic examination of the heart discloses either no significant abnormality or a prominent pulmonary artery with increased pulsations (Fig 152) The sharp pulsations may extend to the remaining contours of the heart shadow [11] The prominence and accentuated pulsation of the pulmonary artery probably result from the augmented and accelerated blood flow which dilates that vessel The active pulsation of the cardiac borders resembles that seen fluoroscopically in cases of aortic insufficiency but in the latter it is the aorta which is prominent and pulsating vigorously The prominence of the pulmonary artery may result in straightening of the left border such as accompanies mitral stenosis But examination in the oblique positions fails to reveal the enlargement of the left atrium seen in mitral stenosis however both atria may become enlarged if congestive heart failure complicates hyperthyroidism

In uncomplicated cases there is no distinctive enlargement of the cardiac chambers Most observers however have described enlargement of the heart as determined roentgenologically in 25 to 45 per cent of their cases [8, 35, 66] The character of the cardiac enlargement observed is variable and in my opinion is determined by associated cardiovascular disease such as hypertension severe coronary artery disease or rheumatic heart disease When congestive heart failure is well established the heart is usually enlarged to the right and the left and the cardiac silhouette assumes a globular appearance

Electrocardiographic Examination

The electrocardiogram discloses no distinctive features except for the usual nonspecific sinus tachycardia or the occasional atrial fibrillation The former belief that the T waves become elevated in hyperthyroidism in contrast to the characteristically low T waves in myxedema has not been substantiated [9] Parkinson and Cookson[68] noted an elevated P wave (more than 3 mm) in over one third of their cases In my experience, a distinctive elevation of the P wave usually occurred when there was associated mitral stenosis and in some cases of heart failure Occasionally I have observed abnormalities of the QRS complex the RST segment or the T wave which however could reasonably be attributed to associated myocardial damage caused by coronary disease or to the effects of digitalis

Development of Congestive Heart Failure

The most serious consequence of hyperthyroidism is the development of congestive heart failure Congestive heart failure like atrial fibrillation, develops most frequently in older age groups and is rare under the age of 40[1], it occurs more often with associated hypertension coronary atherosclerotic or rheumatic heart disease than in their absence[12], it is more likely to develop the longer the duration of the hyperthyroidism, but is not distinctly related to its severity Andrus[1] encountered congestive heart failure in 18 5 per cent of 200 cases of hyperthyroidism In only 9 cases did symptoms of failure develop before the age of 40 and in 7 of the 9 there was evidence of coexisting heart disease Five of the 7 patients were found to have mitral stenosis when the basal metabolic rate was restored to normal, 1 had syphilitic heart disease, and in 1 case Aschoff bodies were found in the heart at postmortem examination Ernstene[21] reported congestive heart failure in 25 per cent of those of his cases of hyperthyroidism which were combined with various forms of heart disease, but no instances of congestive failure in 795 cases of hyperthyroidism without evidence of associated organic heart disease

Congestive heart failure usually develops after a period of established atrial fibrillation (p 1006) Hurxthal[47] noted that of 431 cases with established atrial fibrillation 55 7 per cent showed congestive heart failure But in his entire series of over 7000 cases the incidence of congestive heart failure was only 3 7 per cent The incidence of congestive heart failure in hyperthyroidism appears to be diminishing because of earlier recognition and treatment of hyperthyroidism

THE DIAGNOSIS OF THYROCARDIAC DISEASE

Diagnosis involves the recognition of both the hyperthyroidism and the cardiac complication One must recognize the presence of cardiac dysfunction in the patient with known hyperthyroidism and conversely, one must also recognize hyperthyroidism in the patient known to have atrial fibrillation and/or heart failure The diagnosis is simplest in cases in which there is a known history of hyperthyroidism or the characteristic stare and eye signs the tachycardia the warm moist skin,

the tremor the enlarged thyroid gland intolerance to heat, excessive perspiration loss of weight despite good appetite nervousness tendency to diarrhea and an elevated basal metabolic rate unexplainable by the degree of heart failure present In such cases of unmistakable Graves disease we may speak of thyroid heart disease if there is al[illegible] frequent paroxysmal or persistent atrial fibrillation unquestionable cardiac enlargement as revealed by roentgenologic examination or distinct evidences of congestive heart failure

In many cases one may discover an independent form of heart disease which could account for the atrial fibrillation cardiac enlargement or heart failure But even in cases with independent heart disease it is important to discover the associated hyperthyroidism without which the organic heart disease might not have produced clinical symptoms For in the presence of organic heart disease the alleviation of the hyperthyroidism usually causes a reversal of most or all of the important cardiac disabilities

A greater problem arises in those cases in which the predominant manifestations are cardiac and the presence and importance of the hyperthyroidism are discovered only secondarily (masked hyperthyroidism) Such discovery will occur if the possibility of hyperthyroidism is considered in all cases in which atrial fibrillation cardiac enlargement or heart failure of uncertain etiology [illegible] encountered Often in thyrocardiac patients the thyroid gland is small and there is no exophthalmos but there are usually a slight stare warm moist skin tachycardia a high pulse pressure and a history of weight loss without anorexia A search for an associated hyperthyroidism should be considered under the following circumstances

1 Paroxysmal or persistent atrial fibrillation or flutter of undetermined etiology especially if the rapid ventricular rate cannot be slowed by digitalis

2 Heart failure without apparent cause or heart failure which does not respond to digitalis and other appropriate treatment

3 Heart disease with unexplained tachycardia or tachycardia which persists despite treatment of heart failure or atrial fibrillation

4 Presence of congestiv[illegible] heart failure with out significant fever anemia or serious vitamin B_1 deficiency in which the circulation time is within the normal range

5 High systolic pressure out of proportion to diastolic pressure not explainable by other causes

Objective Tests of Hyperthyroidism

In any of the above groups adequate evidence of hyperthyroidism may be forthcoming as soon as the possibility is considered However in the presence of heart failure, it may be difficult to evaluate an elevated basal metabolism In such cases the diagnosis of hyperthyroidism can be confirmed by other objective tests

The most reliable objective tests[9, 8] of hyperthyroidism involve (1) the determination of the serum precipitable iodine (SPI) also termed protein bound iodine (PBI) and (2) the response to the administration of a tracer dose of radioactive iodine (I^{131})

Determination of the SPI involves a relatively elaborate chemical procedure[84, 6] but [illegible] probably the most reliable objective test of hyperthyroidism[84, 99] When the test is carefully performed the SPI is between 4 and 8 micrograms per 100 cc of serum in normal individuals and above 8 micrograms per 100 cc in hyperthyroidism False high values may result during pregnancy and after the administration of organic compounds of iodine e g after intravenous pyleography or after cholecystography or the diagnostic use of Lipiodol [illegible] There is evidence that SPI is increased also by the ingestion of Lugol s solution or potassium iodide[23] But it has been reported that the thyroxin fraction of the SPI as determined by butanol extraction [illegible] not elevated by the previous administration of Lugol s solution or other inorganic iodides[66] On the other hand the level of SPI may be falsely lowered in patients with congestive heart failure after intramuscular injections of Mercuhydrin[75]

Response to Tracer Dose of I^{131} The diagnosis of hyperthyroidism may also be made after the oral administration of a tracer dose of 25 to 100 microcuries of radioactive iodine (I^{131}) and determination of one of the following (1) the excretion of radioactive iodine in the urine during the subsequent 24 hours[50, 31] (2) the serum precipitable (protein bound) *radioiodine* in the blood after 48 or 72 hours[95, 103] (3) the radioiodine uptake by the thyroid gland after 4 or after 24 hours[105, 39, [illegible], 103] or (4) the thyroidal and renal plasma I^{131} clearance[10] Inorganic iodides must be withheld at least [illegible] weeks before iodine tracer studies because they diminish the radioiodine

uptake by the thyroid gland Similarly, 2 or 3 weeks should elapse after thiouracil therapy before radioiodine studies are made

The determination of the serum precipitable *radioiodine* after 72 hours has been found to be most useful for the diagnosis of hyper thyroidism [78] [81] If a 4 cc sample of serum or blood contains less than 0 27 per cent of the administered dose per liter of plasma, no further study is made and the patient is regarded as euthyroid If the value is 0 27 per cent or more of the administered dose per liter the *serum precipitable* I^{131} is determined as distinguished from the total I^{131}, which includes both inorganic I^{131} and I^{131} bound to protein The latter is precipitated by trichloracetic acid and determined separately

Hyperthyroidism is associated with a serum precipitable I^{131} exceeding 0 27 per cent of the administered dose per liter of plasma [81] According to Paley et al [82] hyperthyroidism is associated with a serum precipitable radio active I^{131} which exceeds 0 6 per cent per liter of the administered dose of I^{131}, as compared with the 0 27 per cent used as the critical level by Newburger et al [81] and 0 4 per cent of the dose per liter used by Wayne [103] Furthermore Paley et al [8] found the serum precipitable (protein bound) I^{131} determination less reliable as a test of hyperthyroidism than the thyroidal clearance of I^{131} in all their cases The serum precipitable I^{131} is frequently mislead ing in patients who have been treated with I^{131} since it may suggest persistent hypothyroidism in patients who have been rendered euthyroid by the treatment [8] [96] Despite the greater accuracy of the thyroidal clearance of I^{131} as an index of hyperthyroidism it is relatively cumbersome and requires an intravenous injection of the tracer material

The *thyroid uptake* of radioiodine in hyper thyroid patients after 24 hours exceeds 50 per cent of the administered dose, but many hyperthyroid as well as euthyroid patients have uptakes between 42 and 69 per cent [26] [81] [82] According to Greer and Smith[41] and Werner and Spooner [106] the differentiation between euthyroidism and hyperthyroidism in patients with equivocal radioiodine uptakes can be made by repeating the test after treatment with thyroid extract or triiodothyronine The latter substances sharply reduce radioiodine (I^{131}) uptake in euthyroid but not in hyper thyroid patients

The *24 hour urinary excretion* is usually less than 20 per cent of the administered dose in patients with hyperthyroidism (normal 30 to 60 per cent), but there are difficulties in obtaining complete 24 hour urine collections and false low values may result from marked oliguria in congestive heart failure

The value of these objective tests is indicated by the discovery of 8 cases of marked hyperthyroidism in a group of 55 patients with atrial fibrillation in whom hyperthyroidism was not previously suspected [■] The atrial fibrillation had been attributed to rheumatic coronary or hypertensive heart disease The accuracy of the diagnosis of hyperthyroidism appeared to be substantiated by reversion of the atrial fibrillation to sinus rhythm in 6 of 7 patients who were treated with radioiodine At the same time there was a distinct clinical improvement in their cardiac status The sinus rhythm was restored in four to nine weeks after treatment

Despite the usual accuracy of these objective tests of hyperthyroidism I have occasionally found it necessary to do a therapeutic test when there was a discrepancy between the clinical findings and the objective tests or between individual objective tests The administration of 10 to 30 minims of Lugol s solution daily for two or three weeks may confirm a diagnosis of hyperthyroidism if there is a good clinical response but in my experience this has often given equivocal results I have found it more satisfactory to give propyl thiouracil or Tapazole (infra) for six to ten weeks In cases of hyperthyroidism there is usually an excellent clinical result, and in thyrocardiac patients previously refractory heart failure is readily controlled

The differential diagnosis of hyperthyroidism is not pertinent to this volume From the cardiac point of view it may be necessary to differentiate hyperthyroidism from mitral stenosis because of the presence in both of a sharp first sound a systolic murmur and a prominent pulmonary artery However, this is not an important problem because the diagnosis of hyperthyroidism should be made on other criteria On the other hand mitral stenosis may be diagnosed and hyperthyroidism overlooked when there is a characteristic apical diastolic murmur and thrill especially in association with left atrial enlargement The presence of mitral stenosis does not exclude an associated hyperthyroidism nor conversely

TREATMENT

The treatment of thyroid heart disease is primarily *prophylaxis* Early recognition of uncomplicated hyperthyroidism and its prompt control will prevent the development of cardiac complications due to the hyperthyroid element

When atrial fibrillation or congestive heart failure is already present as well as hyperthyroidism it must be clearly recognized that the elimination of the hyperthyroidism should be the primary objective of the therapeutic attack Limitation of activity the restriction of salt and fluids, digitalization and the use of diuretics and other therapeutic measures for heart failure are all appropriate But all of these measures may be ineffective or of only limited value until the hyperthyroidism is corrected Therefore, unnecessary procrastination in an effort to control either the atrial fibrillation or the heart failure before undertaking treatment of the hyperthyroidism may be not only wasteful but dangerous Occasionally when the thyrocardiac patient is seen with atrial fibrillation and very rapid ventricular rates digitalization should be effected quickly to obtain the maximum possible slowing without toxicity Then the hyperthyroidism is treated without undue delay It is rarely desirable or necessary to administer quinidine in an attempt to restore sinus rhythm before treatment of the hyperthyroidism Sinus rhythm usually occurs spontaneously within a few weeks after the hyperthyroidism is eliminated But quinidine may be administered if the arrhythmia persists for more than a month after correction of the hyperthyroidism

Surgical Treatment

Although surgical treatment of thyrocardiac disease has given brilliant results this form of treatment is being continually superseded by the use of radioactive iodine Surgical control of the hyperthyroidism may be limited to those cases in which there is doubt as to the presence or absence of malignancy in the gland and to those cases with compression symptoms Subtotal thyroidectomy is regarded by some as the preferred treatment in the presence of a large nodular gland because of the slow response to antithyroid drugs or radioactive iodine and the larger dose required but these are not sufficiently important disadvantages to justify surgical treatment Surgery is preferred by some in the treatment of toxic goiter with solitary adenoma because of the purportedly high incidence of carcinoma in such solitary nodules[55] But the reported high incidence of carcinoma in resected solitary thyroid adenomata is at variance with the extremely infrequent appearance of thyroid carcinoma with metastases in cases studied clinically or by autopsy Radioiodine has been regarded as contraindicated and surgery preferred in the treatment of hyperthyroidism during pregnancy or lactation, in children and in uncomplicated hyperthyroidism in patients below the age of 40

Preoperatively the patient is treated with Tapazole 30 to 120 mg daily in three equal doses or propylthiouracil 300 to 600 mg daily, until the desired reduction in basal metabolism and clinical improvement are obtained[65, 67] Compound solution of iodine in doses of 10 to 20 minims daily is prescribed for ten to fourteen days to reduce vascularization of the gland before operation or iodinated thiouracil (Itrumil) may be given alone preoperatively A high caloric and vitamin intake is given Heart failure if present is treated as described elsewhere (Chapter 11) but operation is not delayed even if heart failure persists If haste is indicated the patient may be prepared with Lugol s solution alone for about two weeks, as before the use of the uracil drugs If the hyperthyroidism is not sufficiently controlled by these various therapeutic measures *corticotropin* (ACTH) may be administered for a few days preoperatively and continued through the stress period

At operation a subtotal thyroidectomy is performed[67] The importance of employing a skillful and experienced surgeon and of avoiding a prolonged operative procedure hemorrhage and other causes of shock, cannot be exaggerated It may be necessary occasionally to do the operation in two stages Endotracheal anesthesia using ethylene followed by ether has given satisfactory results[67]

Postoperatively, the patient should be placed in an oxygen tent If fluids are given parenterally they should consist of [illegible] per cent glucose in distilled water and should be administered very slowly to avoid pulmonary edema The basal metabolism rate should return to normal in two to four weeks If the patient was digitalized preoperatively, maintenance doses of digitalis are continued after operation until it is apparent that the hyper-

thyroidism has been eliminated By that time evidence of heart failure usually disappears or will respond to the appropriate therapeutic measures, and digitalis may be discontinued Atrial fibrillation almost always disappears with elimination of hyperthyroidism, although it may appear briefly postoperatively and disappear spontaneously If it persists for more than two weeks after operation it usually disappears after quinidinization (p 368) If this is ineffective the arrhythmia is probably due to independent cardiac disease and the patient should be digitalized to the desired point of slowing of the ventricular rate

[illegible][40] reported an operative mortality rate of 1 1 per cent in 181 thyrocardiacs which was about five times as high as for uncomplicated Graves disease Griswold and Keating[6] reported a series of 810 cases of hyperthyroidism with an operative mortality of 0 9 per cent among 103 thyrocardiacs as compared with 2 2 per cent for the noncardiac cases The operative mortality is now nearer 1 per cent for thyrocardiacs and only 0 2 per cent for uncomplicated hyperthyroidism since the use of the uracil preparations preoperatively There is a recurrence of hyperthyroidism in about 10 per cent of cases probably because of inadequate removal of thyroid tissue[6, 4] Myxedema due to excessive removal of tissue, tetany due to accidental removal of the parathyroid glands and hoarseness or respiratory distress due to injury of the recurrent laryngeal nerve are [illegible] postoperative [illegible]

Propylthiouracil and Tapazole (Methimazole)

[illegible]

[illegible]

[illegible]

longer period If the thyroid gland is large or if iodine has been given in the previous [illegible] weeks, the effect of the uracils is delayed Therapy may have to be continued for six months to a year or longer In the majority of cases, the improvement obtained persists when the drug is discontinued[7], in the others there is a return of symptoms within a few months

Initial control of hyperthyroidism may be obtained in 90 per cent of patients, but a remission is *maintained in only 40 to 60 per cent* after the thiouracil therapy is discontinued[21, 32, 37, 70, 40]

The chief toxic effect of the uracils is agranulocytosis, but this occurs much less frequently with propylthiouracil or Tapazole than with the other preparations Blood counts must be done at weekly intervals Prompt discontinuance of the drug, if granulocytopenia develops and the administration of penicillin almost always permit recovery from this complication Other less serious toxic effects include fever, rashes lymphadenopathy, joint pains nausea and vomiting[77] They usually disappear *promptly* after the drug is discontinued Prolonged uracil therapy may produce myxedema which may be disclosed by an elevated serum cholesterol before there is a significant reduction in the basal metabolic rate

Radioactive Iodine

Radioiodine (I^{131}) is now the preferred method of treatment of hyperthyroidism, particularly in thyrocardiac patients Patients with hyperthyroidism and a solitary nodule [illegible]

[illegible]

reserved only for patients beyond the age of 40 This risk is not important in thyrocardiac patients since they are usually well beyond the age of 40 Radioiodine therapy is contraindicated in pregnancy because the fetal thyroid can concentrate iodine after the third month during lactation it is contraindicated because the radioiodine may be secreted in the milk of lactating women

When radioactive iodine is given orally the iodine is taken up rapidly and selectively by the thyroid secreting cells of the thyroid gland There the contained radioactivity produces destructive effects similar to those of roentgen rays [illegible] Hertz and Roberts[45] and Chapman and Evans [9] showed that hyperthyroidism could be controlled with radioiodine as effectively as with subtotal thyroidectomy or the uracils I^{131} with a half life of eight days (or a biologic half life of six days to allow for excretion) is employed Dosage is given empirically with modifications according to the clinical estimate of the weight of the thyroid gland and the thyroid uptake of a tracer dose of radioiodine The normal gland weighs about 20 or 25 gm The thyroid gland in thyrocardiacs is usually only moderately enlarged (40 to 60 gm) Very large glands may weigh 100 to 200 gm or more The initial dose is usually 150 to 250 microcuries per gram of estimated thyroid weight [3, 65, 21, illegible] The usual effective dose is about 8 to 12 millicuries of I^{131} by mouth for a hyperthyroid patient with a gland estimated as weighing 40 to 60 gm , but there are considerable individual variations

Nelson et al [illegible] administered 150 to 250 microcuries per estimated gram of thyroid weight as the initial dose in cases of diffuse toxic goiter and 300 to 350 microcuries per gram of estimated thyroid weight in cases of nodular toxic goiter The average dose for remission averaged 11 millicuries for diffusely enlarged glands and 20 millicuries for nodular glands but there were large variations from these averages in individual cases Adequate dosage is usually given in one or two doses in about 75 per cent of hyperthyroid patients but three to ten doses may be necessary in the remaining patients before a remission is effected The initial dose is designed to undertreat slightly and a subsequent dose or doses are administered if there are residual clinical symptoms

An interval of at least eight weeks should elapse between doses since 99 per cent of the radioactivity is dissipated in this period Inorganic iodine must not be given in the eight weeks prior to I^{131} because the gland may become saturated with the former and will not take up the radioiodine However three days or more after the therapeutic dose of I^{131} has been given compound solution of iodine is given for three weeks to obtain a rapid therapeutic effect until the radioiodine produces a more thorough and persistent result

Clinical improvement usually is observed in ten days to three weeks and the basal metabolism is reduced to normal in two to four months A mild and transient myxedema may occur and in 5–10 per cent a more severe and persistent one, requiring small doses of thyroid

In patients with thyrocardiac disease atrial fibrillation and cardiac failure usually disappear without further treatment If atrial fibrillation persists after the basal metabolism is reduced to normal it usually responds rapidly to quinidine even if it failed to respond prior to radioiodine therapy If not the patient should be digitalized Similarly heart failure responds satisfactorily to limitation of activity, digitalization, sodium restriction diuretics etc , even if it was refractory before the hyperthyroidism was controlled B complex should also be administered

In a study of approximately 600 hyperthyroid patients followed for at least six months after treatment with radioiodine hyperthyroidism was eliminated in all and there were no recurrences [illegible] The thyroid was diminished in size in all sometimes to normal Temporary hypothyroidism requiring thyroid therapy, developed in 14 per cent but only 1 per cent had apparently permanent myxedema The exophthalmos improved in most but unilateral exophthalmos developed in 4 patients McCullagh[69] observed only 2 failures and 8 recurrences in the treatment with I^{131} of 1235 patients with Graves disease Similar satisfactory results were reported by Bloomfield et al [11] in a series of 140 cases and by Balls et al [2] in a series of 228 cases

Chapter 41

THE HEART AND CIRCULATION IN MYXEDEMA

Advanced myxedema is commonly associated with roentgenologic abnormalities in the cardiac silhouette and with electrocardiographic changes Furthermore there is a strong suspicion that myxedema predisposes to coronary atherosclerosis and its cardiac complications But the existence of a specific form of myxedema heart disease which leads to heart failure is unproven

Myxedema heart was first proposed as a clinical entity by Zondek[11] who described diffuse enlargement of the heart sluggish cardiac contraction and electrocardiographic abnormalities all of which were reversible upon treatment with thyroid substance These observations were confirmed without substantial change by many others[12, 25, 40] but there is disagreement as to the nature and significance of the observed abnormalities

The cardiac and circulatory changes to be noted are found only in cases of hypothyroidism in which the clinical picture of myxedema is fully developed These patients have not only a very low basal metabolic rate (usually below minus 25) but also cold dry, thickened and often edematous skin loss of hair and mental retardation The cardiac and circulatory alterations associated with myxedema are not observed in cases of hypothyroidism without myxedematous skin changes and mental retardation even when the basal metabolic rate is minus 20 or lower

The changes classified as "myxedema heart" are relatively rare since advanced myxedema is observed uncommonly The incidence of cardiac abnormalities among cases of myxedema is variously reported from occasional to almost 100 per cent According to Lerman, Clark and Means[5] myxedema heart as described by Zondek[5] occurred in 80 per cent of 48 adult cases of myxedema Fahr[12] noted not only cardiac changes but evidences of cardiac failure in 75 per cent of 17 severe and moderately severe cases of myxedema McGavack and his associates[20] also reported severe cardiac disturbances in 79 per cent of 24 cases of myxedema The so-called myxedema heart is observed with infantile as well as adult forms of myxedema[3] Mussio-Fournier[35] observed the characteristic cardiac changes in 7 of 18 cases (38 per cent) of infantile myxedema Blumgart and associates[7] found no increase in the degree of atherosclerosis that might be attributed to myxedema induced by total thyroidectomy for heart failure after an average period of 7 4 years

Age and Sex

Myxedema and "myxedema heart are observed predominantly among women They occur at all ages but in adults especially after the age of 40

PATHOLOGY OF THE HEART

The scanty pathologic data thus far available provide insufficient evidence of a specific histologic cardiac lesion associated with myxedema Schultz[4] described an homogenous infiltration, staining blue with hematoxylin, but differing in staining properties from the myxedematous infiltration occurring in the skin Other non specific changes have also been noted, including necrosis or degeneration of muscle fibers and replacement fibrosis[32] The muscle may appear grossly edematous,[11] and in the hearts of thyroidectomized animals edema has actually been demonstrated by measurement of the water content[43]

Pericardial effusion, sometimes of considerable size (1000 cc), has been demonstrated clinically[11] in autopsied cases[5] and in experimental hypothyroidism[49] but not in myxedema induced by radioactive iodine (I[131]) therapy[22] There is no evidence of associated pericarditis, thus the effusion represents an hydropericardium

Dilatation and hypertrophy of the heart have been reported repeatedly, hypertrophy having been noted in 7 of the 20 autopsied

cases collected by the Clinical Society of London[39] However there is no convincing evidence of true cardiac hypertrophy in myxedema uncomplicated by independent cardiac disease A pseudohypertrophy possibly due to edema was noted grossly by Means[31]

It is generally believed that atherosclerosis develops earlier and with greater frequency and intensity in cases of myxedema than usual[4] and this has been related to altered lipid metabolism in myxedema notably the associated hypercholesterolemia (p 425)[27] Fishberg[15] reported advanced arteriosclerosis in a boy of 21 with thyroid deficiency and Willius[50] observed a myxedematous patient of 23 who succumbed to heart failure due to advanced coronary sclerosis and myocardial fibrosis proven at autopsy However these appear to be exceptional cases for myxedema may be associated with normal coronary arteries There is a surprising paucity of pathologic support for a belief so widely held namely that myxedema predisposes to coronary atherosclerosis A relationship between myxedema and coronary atherosclerosis is supported by a number of reports of the production of atherosclerosis in thyroidectomized animals[17] But the application of these experimental findings to human myxedema and coronary atherosclerosis can only be considered with reservations

PATHOLOGIC PHYSIOLOGY

Basal Metabolism and Oxygen Consumption

Myxedema is characterized by a *reduction in basal metabolism* i e a diminution in the oxygen consumption of the tissues As a rule there is a reduction of 20 to 40 per cent below normal Consequent to the diminished metabolism there is a sharp reduction in heat production In contrast to patients with hyperthyroidism who experience excessive heat production and uncomfortable sensitivity to warmth patients with myxedema are unpleasantly sensitive to cold because of a deficient production of heat

Peripheral Blood Flow

The peripheral blood flow was found to be diminished by Stewart and Evans[45] and by Abramson[1] Corresponding to the diminished blood flow the peripheral vascular channels are narrowed Ellis et al[11] found the peripheral resistance regularly increased in myxedema Thus Zondek Michael and Kaatz[53] found the capillaries of the nail bed extremely reduced in number and very narrow in caliber There is an approximate linear relationship between the basal metabolism and peripheral blood flow Instead of a normal blood flow to the skin of 3 to 4 per cent of the total cardiac output only 1 3 per cent of the cardiac output was allotted to the skin in patients with an average basal metabolic rate of minus 30[46] By contrast in patients with hyperthyroidism 6 per cent of the total cardiac output is apportioned to the skin

Venous Return and Minute Volume (Cardiac Output)

The diminished peripheral blood flow results in a *reduction of the venous return* to the heart and thus in turn is reflected by a *fall in the minute volume* (cardiac output)[18, 45, 17] Ellis et al[11] found the cardiac output in 5 patients with myxedema to be diminished to a greater degree than the diminution in oxygen consumption According to the observations of Stewart et al[45] the cardiac output in cases of myxedema averaged 1 17 liters per minute per square meter of body surface before treatment and 1 98 liters after adequate treatment with thyroid It is noteworthy that whereas the cardiac output was 60 per cent of normal the proportion supplying the skin was only 25 per cent of normal This indicates that there is a relatively greater reduction of the cardiac output going to the skin in myxedema than to other organs another example of the mechanism of heat conservation in this disease

The *arteriovenous difference* is increased in cases of myxedema[45, 11] owing to slowing of the peripheral blood stream which permits greater oxygen utilization by the tissues This reduces the load on the heart consequently the cardiac output and work of the heart in myxedema are diminished to a greater degree than is the oxygen consumption Since the efficiency of the heart is greater the less work it performs for a given amount of body metabolism, the heart in myxedema is more efficient than normally Briard and his associates[5] demonstrated a very efficient conversion of calories into kg meters of work as compared to the response of the heart in hyperthyroidism In fact 19 per cent less energy was utilized by myxedematous patients in walking than by normal subjects The mechanisms described for conserving heat probably account for the improved efficiency in myxedema In hyperthyroidism the cardiac output and work of the heart are increased even more

than the oxygen consumption, i e, cardiac efficiency is diminished, probably because of the energy wasted in the dissipation of excessive heat

Heart Rate

Bradycardia is a frequent finding in advanced myxedema The pulse rate frequently ranges between 50 and 70 in the absence of conduction disturbances The mechanism of the slow pulse rate is uncertain although it may represent a reverse of the Bainbridge reflex due to the slow and diminished venous return (contrast with hyperthyroidism p 1006)

Blood Pressure and Pulse Pressure

The blood pressure shows no constant or significant change

Velocity of Blood Flow Circulation Time Venous Pressure

The blood flow is significantly slowed in proportion to the degree of reduction in basal metabolism and the slowing of the peripheral blood flow [45, 50] The circulation time from arm to tongue is frequently between 20 and 30 seconds compared to a normal of between 9 and 16 seconds But Ellis et al [11] found the circulation time in myxedema (with magnesium sulfate) to be between 15 and 18 seconds

The *venous pressure* is usually normal [45] However, Mussio Fournier and his associates[36] reported an elevation in venous pressure in at least 6 of 12 cases of myxedema heart disease But these observers could find no relationship between the venous pressure as they determined it and the presence or absence of heart failure Careful determinations of the venous pressure should help to decide whether the serous effusions and edema are evidences of heart failure or of myxedema

Blood Volume

The *circulating blood volume* was found to be diminished by Thompson[47] and by Gibson and Harris [16] According to Ellis et al ,[11] the plasma volume is normal but the total blood volume is diminished due to a lowered hematocrit The radiosodium space is high suggesting an increase in the interstitial fluid space [1]

Vital Capacity

The *vital capacity* is significantly diminished[18] in spite of the absence of pulmonary congestion The vital capacity in myxedema is similar to that in hyperthyroidism whereas most of the circulatory disturbances in these two conditions provide distinct contrast The vital capacity in myxedema may be reduced by the frequently associated elevation of the diaphragm and occasionally by the presence of pleural effusions It should be noted that there is disagreement as to the vital capacity in myxedema, for Schnitker, van Raalte and Cutler[40] failed to observe a reduction in vital capacity in cases of hypothyroidism following thyroidectomy

CLINICAL FEATURES OF MYXEDEMA HEART

Subjective symptoms referable to the heart are relatively uncommon and consist of angina pectoris or complaints due to congestive heart failure

Objective findings are more frequent and more characteristic and include enlargement of the heart sluggish cardiac action electrocardiographic changes and signs suggesting congestive heart failure

Cardiac Enlargement

The heart is definitely enlarged in most cases of advanced myxedema The enlargement, which extends both to the left and the right, gives the cardiovascular silhouette a ham shaped configuration (Fig 153) There is a close resemblance to the roentgenologic appearance of pericardial effusion In 34 of 48 cases of myxedema, Lerman Clark and Means[-] observed cardiac enlargement as denoted by a transverse diameter which exceeded half the diameter of the chest by 1 cm or more, in 22 of these the transverse diameter of the heart exceeded half the diameter of the chest by 5 cm or more

Thyroid hormone specifically reduces the size of the heart (Fig 153), withdrawal of the thyroid is followed by enlargement to its previous size [8, 11] After three to four weeks of treatment there is a noticeable shrinkage of the cardiac shadow, but complete restoration to normal size may require continuous treatment for at least six weeks and sometimes for three to four months The rapid development and reversibility of the cardiac enlargement in myxedema suggest that there is no true hypertrophy of the myocardial fibers

The cause of the cardiac enlargement is uncertain The absence of specific pathologic changes in the heart has been discussed (p 1016) The enlargement may be due chiefly or partially to myxedematous infiltration or interstitial edema similar to that occurring in the skin and subcutaneous tissue

Enlargement of the cardiac silhouette has been attributed to an associated *pericardial effusion* rather than to dilatation or hypertrophy of the heart itself [41] In fact the similarity of the roentgenologic appearance of the heart in myxedema to that of pericardial effusion has already been noted (p 1018) Pericardial effusions of considerable size have been aspirated repeatedly during life [9, 14] and have been noted also at autopsy [illegible] The findings at postmortem examination are usually obscured by the effects of thyroid administered during life Furthermore pericardial aspiration has been performed in a relatively small number of cases, even when fluid is obtained it is not always sufficient to explain the degree of cardiac enlargement [20] But Kern et al [21] by means of pericardial taps in 4 successive cases provided strong evidence that pericardial effusion is a constant and major factor in the cardiac enlargement and other features of myxedema heart In the present state of knowledge it appears most probable that the enlargement is due partially to myxedematous infiltration or interstitial edema similar to that in the skin and that pericardial effusion may contribute in varying degree to enlargement of the cardiac silhouette

Pleural and peritoneal effusions may be associated with an effusion in the pericardium Among 25 cases of myxedema with pericardial effusion with data referable to other serous cavities there were associated pleural or peritoneal effusions or both in 13 [22]

Sluggish Cardiac Action

Physical and roentgenologic examination of the heart in myxedema discloses a sluggish action which contrasts with the dynamic hyperactivity of the heart in Graves disease

On physical examination it is usually difficult or impossible to feel a precordial pulsation or to localize the apical impulse The heart sounds are soft and distant

Fluoroscopic examination discloses sluggish cardiac contractions, wormlike in character and of minimal amplitude This is remarkable because of an associated bradycardia which usually consorts with strong cardiac pulsations The pulse is extremely small and the rate slowed to 50 to 70 per minute

Cardiac Failure

There is considerable disagreement as to the incidence of congestive heart failure in patients with myxedema It is questionable whether it ever occurs independently of associated intrinsic cardiac disease such as coronary atherosclerosis with myocardial infarcts According to Fahr [12] symptoms and signs of heart failure were present in 13 of 17 cases i e in 75 per cent and in 5 of them these manifestations were severe All of the patients presented dyspnea rales at the bases of the lungs and pitting edema Similarly McGavack and his associates[30] observed 24 patients with frank myxedema of whom 19 exhibited evidence of severe heart failure But other etiologic factors could not be excluded since 1 patient had syphilitic aortitis 13 had arteriosclerotic changes and 5 had hypertension On the other hand, many observers have never witnessed congestive heart failure in association with myxedema, or have been able to attribute it to independent etiologic forms

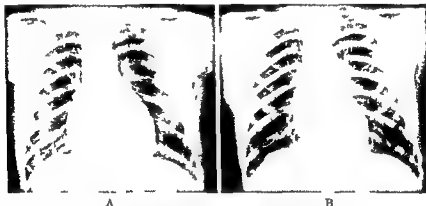

Fig 153 Heart in myxedema *A* Generalized enlargement of the heart when B M R was —50 per cent *B* After two months of treatment with thyroid hormone

of heart disease [51, 5] There are many reasons for concluding that the manifestations of myxedema which simulate those of myocardial insufficiency are actually unrelated to failure of the heart This does not contradict the occasional occurrence of true heart failure as a result of an associated independent cardiac disease

Angina Pectoris and Coronary Occlusion

The association of angina pectoris with myxedema was noted by Zondek,[52] and more recently was reviewed by Peel[38] The angina pectoris is probably due to severe coronary atherosclerosis Bartels and Bell[4] reported that among 59 patients beyond the age of 20 with spontaneous myxedema 15 presented clinical evidence of coronary artery disease The anemia sometimes found in myxedema may be a contributory factor Most frequently the angina pectoris appears only after the institution of thyroid therapy and the elevation of the basal metabolic rate as noted by Means, White and Krantz,[33] and by Christian[9] In these cases also it is probable that the angina pectoris was due to coronary atherosclerosis but myocardial anoxia sufficient to cause pain did not develop until the work of the heart was increased by thyroid therapy

A more obscure group is formed by the cases in which angina pectoris associated with myxedema is reported to have improved following treatment with thyroid Such cases have been documented by Laubry, Mussio-Fournier and Walzer[24] Beach[5] and by Beaumont and Robertson[6] A satisfactory explanation for the mechanism by which thyroid therapy could relieve angina pectoris has not been submitted The descriptions of the angina pectoris in the reported cases are quite meager and one may question whether these patients suffered from angina pectoris or from chest pain of non-cardiac origin In the case reported by Beaumont and Robertson the correlation between relief and thyroid therapy is not convincing, furthermore the reported electrocardiographic changes suggest that relief of the paroxysms followed the occurrence of myocardial infarction

Very few autopsy reports are available, but in those recorded in recent years coronary occlusion and myocardial infarction appear common In the single autopsied case described by Fahr[13] there was an atherosclerotic coronary occlusion with necrosis of the myocardium In the only 2 cases of Higgins[19] in which autopsies were obtained, old or recent coronary occlusion and myocardial infarction were present in both Similarly there was an acute coronary occlusion in the autopsied case reported by Means and Lerman[3] and in that reported by Smythe[41]

Electrocardiographic Changes

The electrocardiographic changes represent a cardinal feature of the myxedema heart as described by Zondek[52] These changes consist of (1) low voltage of all the complexes, but most frequently of T and P, (2) flattening or inversion of the T waves, (3) restoration of upright T wave and increased voltage of the ventricular complexes following thyroid therapy

The most constant feature is the flattening or inversion of the T waves, especially in leads I and II These may become upright following the administration of potassium salts[43] The P waves may also be almost flat or absent in one or more leads

The P R interval is frequently at the upper limit of normal and occasionally it is prolonged to as much as 0 4 second Partial heart block, which improved after thyroid therapy, was reported by Willius,[50] Fahr[12] and others In such cases the heart block has been attributed to myxedematous infiltration of the bundle of His or to increased vagal tone On the other hand an excessive P R interval may persist or become prolonged despite thyroid medication This usually denotes that the heart block is caused by independent cardiac disease (due to coronary atherosclerosis), for there are often associated intraventricular conduction disturbances and negative T waves which likewise persist despite specific therapy

Sometimes the QRS complex is notched widened and of low voltage in the absence of a prolonged P R interval This also suggests the presence of independent myocardial disease As a rule the QRS complex is more likely to remain unaltered in myxedema than the P or T waves The salient feature of the electrocardiographic changes due to myxedema is their correction by adequate and prolonged thyroid medication Within three weeks there is an increase in voltage the T waves if inverted become upright and the P waves reappear or become taller

The cause of the characteristic electrocardiographic abnormalities is uncertain but their rapid regression following thyroid therapy indicates a direct relationship to the

myxedema itself. Poor conductivity (i.e., increased electrical resistance) resulting from the thickened edematous skin[37] [illegible] is not the cause, since identical tracings are obtained by direct needle electrodes that pierce the skin[10] or are inserted into veins in the extremities.[35] The similarity to the electrocardiogram associated with pericardial effusion suggests that the changes observed with myxedema are actually due to a concomitant pericardial effusion.[41] But the association of a significant pericardial effusion in all cases of myxedema with typical electrocardiograms and the regular disappearance of the electrocardiographic abnormalities after pericardial paracentesis are unproven. The low voltage of the atrial and ventricular complexes may actually mirror weak action currents associated with the sluggish cardiac contraction in myxedema. A variety of other explanations[18] relating the electrocardiographic changes to vagotonia, low basal metabolism,[34] associated anemia, and myocardial anoxia have been offered without conclusive or consistent evidence. Studies of the T vector in the spatial vectorcardiogram in myxedema suggested that the observed alterations were due to altered cellular metabolism which retarded the process of repolarization in the involved muscle.[49]

DIAGNOSIS

The presence of myxedema should be recognized from the characteristic cold, dry, thickened skin, scanty hair and eyebrows, puffy eyelids, mental and physical sluggishness, constipation and intolerance to cold. In the cases associated with cardiac and circulatory changes the basal metabolic rate is usually between minus 25 and minus 35 per cent. The presence of "myxedema heart" is denoted by significant cardiac enlargement to the left and the right and by the low voltage and flattening and inversion of the T waves in the electrocardiogram in patients with the above mentioned evidences of myxedema. Diagnostic confirmation is obtained by the reduction in the size of the heart, the restoration of a normal electrocardiogram and other evidences of clinical improvement following thyroid therapy.

Occasionally, when other signs of myxedema are overlooked, the possibility of this condition should be considered when there is (1) unexplained cardiac enlargement, (2) clinical or roentgenologic evidence of pericardial effusion, (3) flattening or inversion of the T waves, or (4) diffuse anasarca without evidence of hypertension, rheumatic cardiovalvular disease or coronary atherosclerosis. The therapeutic effect of thyroid should be observed whenever there is doubt as to the possible myxedematous origin of these abnormalities.

TREATMENT

Thyroid substance or thyroxin is the specific treatment for myxedema with or without *cardiac and circulatory* abnormalities. The important point to remember is that the thyroid must be administered cautiously and in small dosage because of the danger of precipitating angina pectoris and, more seriously, heart failure, especially acute left ventricular failure.[illegible] Satisfactory initial doses range from 1/20 to 1 grain of thyroid substance daily. Ultimately stabilization can usually be attained by doses of 30 to 180 mg (½ grain to 3 grains) daily. This applies to preparations containing 0.2 per cent iodine according to U.S.P. standards. Since various preparations may differ in potency, the dosage should be adjusted accordingly.

As a rule it is safe to begin with 8 mg (⅛ grain) of thyroid daily and to increase it gradually by increments of 8 mg according to the clinical response. If possible the patient should be ambulant in order to observe the effect of activity. Four to eight weeks are usually required to obtain a satisfactory result. If angina pectoris develops, it may be necessary to maintain the patient at slightly hypothyroid levels. With satisfactory treatment there is a striking diminution in the size of the heart, increase in voltage of the ventricular complex in the electrocardiogram, more forceful cardiac activity, increase in the cardiac output and volume, heart rate and rate of circulation, as well as an elevation in the basal metabolic rate and a regression of serous effusion and other evidences of myxedema. Loss of weight and a fall in blood cholesterol are early objective signs of improvement.

Digitalis is of no benefit and is not indicated for the treatment of the cardiac and circulatory changes due to myxedema alone. Occasionally it may be difficult to distinguish whether some of the symptoms and signs represent congestive heart failure or the consequences of myxedema alone. In such cases

of heart disease[51, illegible] There are many reasons for concluding that the manifestations of myxedema which simulate those of myocardial insufficiency are actually unrelated to failure of the heart This does not contradict the occasional occurrence of true heart failure as a result of an associated independent cardiac disease

Angina Pectoris and Coronary Occlusion

The association of angina pectoris with myxedema was noted by Zondek,[52] and more recently was reviewed by Peel[38] The angina pectoris is probably due to severe coronary atherosclerosis Bartels and Bell[4] reported that among 59 patients beyond the age of 20 with spontaneous myxedema 15 presented clinical evidence of coronary artery disease The anemia sometimes found in myxedema may be a contributory factor Most frequently the angina pectoris appears only after the institution of thyroid therapy and the elevation of *the basal metabolic rate, as noted by Means,* White and Krantz,[33] and by Christian[8] In these cases also it is probable that the angina pectoris was due to coronary atherosclerosis, but myocardial anoxia sufficient to cause pain did not develop until the work of the heart was increased by thyroid therapy

A more obscure group is formed by the cases in which angina pectoris associated with myxedema is reported to have improved following treatment with thyroid Such cases have been documented by Laubry Mussio Fournier and Walzer,[24] Beach,[5] and by Beaumont and Robertson[6] A satisfactory explanation for the mechanism by which thyroid therapy could relieve a angina pectoris has not been submitted The descriptions of the angina pectoris in the reported cases are quite meager and one may question whether these patients suffered from angina pectoris or from chest pain of non cardiac origin In the case reported by Beaumont and Robertson the correlation between relief and thyroid therapy is not convincing furthermore the reported electrocardiographic changes suggest that relief of the paroxysms followed the occurrence of myocardial infarction

Very few autopsy reports are available but in those recorded in recent years coronary occlusion and myocardial infarction appear common In the single autopsied case described by Fahr[13] there was an atherosclerotic coronary occlusion with necrosis of the myocardium In the only [illegible] cases of Higgins[19] in which autopsies were obtained, old or recent coronary occlusion and myocardial infarction were present in both Similarly there was an acute coronary occlusion in the autopsied case reported by Means and Lerman[3] and in that reported by Smythe[44]

Electrocardiographic Changes

The electrocardiographic changes represent a cardinal feature of the myxedema heart as described by Zondek[illegible] These changes consist of (1) low voltage of all the complexes, but most frequently of T and P, (2) flattening or inversion of the T waves, (3) restoration of upright T wave and increased voltage of the ventricular complexes following thyroid therapy

The most constant feature is the flattening or inversion of the T waves especially in leads I and II These may become upright following the administration of potassium salts[43] The P waves may also be almost flat or absent in *one or more leads*

The P R interval is frequently at the upper limit of normal and occasionally it is prolonged to as much as 0 4 second Partial heart block, which improved after thyroid therapy was reported by Willius,[50] Fahr[1] and others In such cases the heart block has been attributed to myxedematous infiltration of the bundle of His or to increased vagal tone On the other hand an excessive P R interval may persist or become prolonged despite thyroid medication This usually denotes that the heart block is caused by independent cardiac disease (due to coronary atherosclerosis), for there are often associated intraventricular conduction disturbances and negative T waves which likewise persist despite specific therapy

Sometimes the QRS complex is notched widened and of low voltage in the absence of a prolonged P R interval This also suggests the presence of independent myocardial disease As a rule the QRS complex is more likely to remain unaltered in myxedema than the P or T waves The salient feature of the electrocardiographic changes due to myxedema is their correction by adequate and prolonged thyroid medication Within three weeks there is an increase in voltage the T waves if inverted become upright and the P waves reappear or become taller

The cause of the characteristic electrocardiographic abnormalities is uncertain but their rapid regression following thyroid therapy indicates a direct relationship to the

myxedema itself Poor conductivity (i e, increased electrical resistance) resulting from the thickened edematous skin[27, 28] is not the cause since identical tracings are obtained by direct needle electrodes that pierce the skin[10] or are inserted into veins in the extremities[35] The similarity to the electrocardiogram associated with pericardial effusion suggests that the changes observed with myxedema are actually due to a concomitant pericardial effusion[41] But the association of a significant pericardial effusion in all cases of myxedema *with typical electrocardiograms and the regular* disappearance of the electrocardiographic abnormalities after pericardial paracentesis are unproven The low voltage of the atrial and ventricular complexes may actually mirror weak action currents associated with the sluggish cardiac contraction in myxedema A variety of other explanations[18] relating the electrocardiographic changes to vagotonia low basal metabolism[34] associated anemia and myocardial anoxia have been offered without conclusive or consistent evidence Studies of the T vector in the spatial vectorcardiogram in myxedema suggested that the observed alterations were due to altered cellular metabolism which retarded the process of repolarization in the involved muscle[48]

DIAGNOSIS

The presence of myxedema should be recognized from the characteristic cold dry thickened skin scanty hair and eyebrows puffy eyelids mental and physical sluggishness constipation and intolerance to cold In the cases associated with cardiac and circulatory changes the basal metabolic rate is usually between minus 25 and minus 35 per cent The presence of myxedema heart is denoted by significant cardiac enlargement to the left and the right and by the low voltage and flattening and inversion of the T waves in the electrocardiogram in patients with the above mentioned evidences of myxedema Diagnostic confirmation is obtained by the reduction in the size of the heart the restoration of a normal electrocardiogram and other evidences of clinical improvement following thyroid therapy

Chapter 42

OTHER ENDOCRINE, METABOLIC AND NUTRITIONAL DISTURBANCES

THE PITUITARY

It is conceivable that the most important effects of the pituitary gland on the development of cardiovascular disease are still unknown. Through its influence on fat and protein metabolism it may be concerned with the pathologic lipid alterations in coronary atherosclerosis. Selye and his associates[10] have described the occurrence of renal arteriosclerosis and myocardial fibrosis following injections of anterior pituitary extracts in rats but these observations may not be transferable to human pathology. A relation of the anterior pituitary to edema has been suggested because of the occurrence of premenstrual edema[15] and of edema in the toxemia of pregnancy.[6] These may be adrenotrophic or gonadotrophic effects. More definite relationships to cardiovascular pathology are found in the specific diseases or syndromes resulting from hyperfunction or hypofunction of the anterior pituitary gland.

HYPERFUNCTION OF THE ANTERIOR PITUITARY ACROMEGALY

Acromegaly is characterized by enlargement of the skull, mandibles and the terminal parts, the adjacent soft tissues and in fact all the viscera. With respect to the heart the most impressive finding is a pronounced *cardiac hypertrophy* exceeding that to be anticipated from the generalized splanchnomegaly.[12, 14] The weight of the heart commonly exceeds 500 gm.[4] Occasionally the weight of the heart ranges approximately between 1000 and 1300 gm.[7, 4] Cronk[5] recently reported the presence of myocardial calcification and a heart weight of 950 gm. in a man with pituitary adenoma and acromegaly weighing 150 kg. A second finding which is stressed less often is the common occurrence of advanced atherosclerosis, notably coronary atherosclerosis. Hejtmancik and associates[11] observed clinical evidence of heart disease in 13 of 21 patients with acromegaly. In 5 there was frank cardiac failure. Pathologic studies in 4 cases disclosed marked cardiac hypertrophy in all and diffuse interstitial fibrosis in 2. Cardiac abnormalities are not associated with gigantism unless acromegaly is also present.

The pathogenesis of the association of atherosclerosis and cardiac hypertrophy to acromegaly is uncertain. The common occurrence of diabetes in acromegaly[3] (adrenotrophic or pituitary diabetogenic hormone) is worthy of attention in view of the striking association of diabetes with premature and advanced coronary atherosclerosis (p. 1034). Hyperthyroidism, which accompanies acromegaly frequently, has been given as a cause for the cardiac hypertrophy, but this relationship is questionable.

It is more probable that the excessive cardiac hypertrophy results from the hypertension and from progressive heart failure due to hypertensive and atherosclerotic heart disease. Hypertension was found frequently in the 21 cases analyzed by Bartelheimer[1] and was attributed to concomitant hyperfunction of the basophile portion of the anterior pituitary lobe. The occurrence of heart failure was stressed in the collection of 25 cases of acromegaly recorded by Fournier.[9] Heart failure and hypertension were observed in the patient studied by Humphry and Dixon,[13] whose heart subsequently was found to weigh more than 1100 gm. Similarly the remarkable cardiac enlargement in Zondek's[16] case could be explained by the blood pressure of 210/140 and by the dyspnea and cyanosis indicative of cardiac insufficiency. Courville and Mason[4] reported that pronounced heart failure was present in 18 (75 per cent) of their patients

with acromegaly Weakness, attacks of syncope breathlessness and anasarca were the outstanding manifestations often in contrast with the false appearance of physical strength presented by these individuals The electrocardiogram disclosed left axis deviation, widening and slurring of the QRS and occasionally T wave changes late in the disease Bartelheimer[1] found electrocardiographic evidence of myocardial damage in 14 of 21 cases of acromegaly

BASOPHILISM—CUSHING S SYNDROME

See Hyperfunction of Adrenal Cortex below

PITUITARY INSUFFICIENCY—SIMMONDS DISEASE

With respect to the heart, the effects of pituitary insufficiency may be similar to those described under myxedema (p 1016), or to those described under Addison s disease (p 1028) The heart participates in the generalized atrophy of the various organs Microscopic examination may di close brown atrophy of the heart and degeneration of the muscle fibers The electrocardiogram shows very low voltage of the QRS complexes and low, flat or diphasic T waves in standard leads [8] Congestive heart failure has been reported in association with pituitary myxedema [9]

THE ADRENAL GLANDS

HYPERFUNCTION OF THE ADRENAL CORTEX—CUSHING S SYNDROME

Hyperfunction of the adrenal cortex usually due to benign or malignant neoplasms, may cause the adrenogenital syndrome or Cushing s syndrome The former is characterized by sexual precocity, hermaphroditism virilism of females or feminization in males, loss of libido etc These cases in pure form, are not associated with distinctive cardiovascular manifestations However, in an 8 year old female with the adrenogenital syndrome complicated by hypertension there was found a defect in steroid biogenesis, namely, an inability to hydroxylate the steroid nucleus at carbon–11 The entire clinical picture including the hypertension was reversed by small doses of compound F [21a]

Cushing s syndrome [8] occurs chiefly in women and is characterized by obesity especially of the trunk, neck and face (moon face) hirsutism amenorrhea and loss of libido, bluish abdominal striae, hypertension hyperglycemia and tendency to glycosuria hypercholesterolemia, osteoporosis, especially of the spine (kyphosis), and polycythemia Many of these features are obviously similar to the effects of stimulation of the anterior pituitary gland

The most important findings with respect to the heart are hypertension, which may be of intense degree and associated cardiac hypertrophy Renal insufficiency and death from a cerebral accident may result from malignant hypertension [11, 67] In a case which I observed and which was studied and reported by Oppenheimer and Silver,[65] there was malignant hypertension, severe hypertensive neuroretinitis renal insufficiency (azotemia) and hyperglycemia Eventually death resulted from congestive heart failure

Glycosuria diminished glucose tolerance or frank diabetes is observed in many cases of Cushing s syndrome [79] This association of diabetes and hypertension, noted previously in connection with acromegaly, is of interest because it is commonly found in combination with severe coronary atherosclerosis in cases not due to apparent endocrinopathy These relationships suggest the possibility that hypertension diabetes and coronary atherosclerosis are not haphazard associates but the result of some common endocrine metabolic factor

The hypertension observed in patients with Cushing's syndrome due to adrenal cortical tumors is probably due to an hypertensive factor secreted by the adrenal cortex This belief is supported by the observation that the synthetic steroid desoxycorticosterone produce a progressive and sometimes alarming increase of blood pressure in patients with adrenal insufficiency (Addison's di ea e) [33, 74] as well as a less pronounced elevation of blood pressure in normal man [11] The reversal of the hypertension as well as the other manifestations of Cushing s syndrome following removal of an adrenal cortical tumor, substantiates the causal relationships between the adrenal cortical tumor and the hypertension in these cases The administration of excessive amounts of desoxycorticosterone to patients with Addison s disease is followed not only by hypertension, but also by subcutaneous edema and other signs of congestive heart failure, such as gallop rhythm enlargement of the heart, increased venous pressure

and roentgenologic evidence of pulmonary congestion [35, 83, 27] It is probable that these manifestations are the consequence of excessive sodium and water retention due to the effect of desoxycorticosterone on renal excretion of sodium I have also observed the development of angina pectoris simultaneously with hypertension and peripheral edema in a man with Addison's disease who received an excessive amount of desoxycorticosterone from implanted pellets of this substance

The natural sodium retaining (and potassium excreting) hormone of the adrenal cortex is aldosterone which is excreted in excessive quantities in heart failure (p 173) A clinical syndrome due to primary aldosteronism has been described It is characterized by hypernatremia hypokalemia alkalosis with periodic severe muscular paralysis intermittent tetany and paresthesia polyuria polydypsia and hypertension but no edema [26]

Electrocardiographic changes involving the T wave were noted by Raab[69] after giving desoxycorticosterone to normal men but these changes were not striking Currens and White [7] described much more pronounced abnormalities when excessive amounts of this substance and sodium chloride were administered to patients with Addison's disease There was a progressive diminution in the voltage of the QRS and T waves and subsequent isoelectric or inverted T waves in leads I and II These patients also developed congestive heart failure The T wave changes were similar to those attributed to hypokalemia in familial periodic paralysis [59]

HYPERFUNCTION OF THE ADRENAL MEDULLA—PHEOCHROMOCYTOMA PARAGANGLIOMA

Tumors of the chromaphil tissue of the adrenal medulla (pheochromocytoma) or of the extra adrenal chromaphil cells in the sympathetic paraganglia in the lumbar paravertebral region of the abdomen in the organ of Zuckerkandl[38] at the bifurcation of the aorta in the thoracic paravertebral region and in the carotid bodies (paraganglioma) produce excessive amounts of norepinephrine and epinephrine which are constantly or paroxysmally secreted into the blood stream [19, 5] Pheochromocytomas were encountered in 0 5 per cent of a series of hypertensive patients[61] but the incidence is probably even lower They are bilateral in about 10 per cent of cases and more frequent on the right than on the left side [45] Occasionally they occur in siblings and other members of the same family They may occur in young children [29] Neurofibromatosis and retinal angiomata may be associated [31, 40]

The clinical manifestations of these tumors often alarming in severity are those to be anticipated from the vasopressor effects of injecting large doses of norepinephrine and the cardiac and metabolic effects of epinephrine Patients with pheochromocytoma or paraganglioma usually exhibit paroxysms (minutes or hours) of severe hypertension (200 to 300 mm Hg) anxiety and tremulousness palpitation with tachycardia or bradycardia severe throbbing headache and nausea or vomiting glycosuria and pronounced vasomotor phenomena including pallor or flushing and sweating [11] and occasional dyspnea substernal or precordial pain or gooseflesh Neurologic complications especially cerebral hemorrhage occur in about 15 per cent[18] and rupture of an intracranial aneurysm has been reported [22] An increased basal metabolic rate occurs commonly and may lead to a mistaken diagnosis of hyperthyroidism Attacks of acute pulmonary edema occur in about half the cases Acute pulmonary edema in young individuals without cardiac or valvular disease and without cardiac enlargement should suggest the presence of pheochromocytoma During pregnancy pheochromocytoma may produce symptoms resembling those of preeclampsia Electrocardiographic changes may appear during the paroxysm e g atrial fibrillation deformed ventricular complexes and atrioventricular dissociation [24] Death may result from an acute coronary occlusion or a cerebral accident

Of particular interest are the cases in which the hypertension associated with pheochromocytoma is not paroxysmal in occurrence but persistent and severe [67] The latter have been observed more frequently than the former [41] These cases of persistent hypertension may simulate and be mistaken for cases of essential hypertension of the so-called malignant type Persistent hypertension due to pheochromocytoma or repeated paroxysms over a long period may be associated with vascular changes in the fundus cardiac enlargement and renal insufficiency

It is important to recognize such cases be

cause of the possibility of successful excision of the causative tumor with cure of the clinical symptoms including regression of the fundal, cardiovascular and renal abnormalities[21, 50] Furthermore, patients with unrecognized pheochromocytoma may die from shock due to incidental operations[6]

Diagnosis of Pheochromocytoma

The diagnosis may be made readily if the physician is familiar with the clinical picture and sees the patient during an attack The following manifestations in association with hypertension singly or in combination suggest the possibility of a pheochromocytoma attacks of palpitation attacks of pulmonary edema in young persons without heart disease excessive sweating vasomotor phenomena, hypermetabolism, hyperglycemia or glycosuria postural tachycardia and postural hypotension normal cold pressor response Between attacks the diagnosis may be suggested by the history of the paroxysms if the physician is mindful of the condition In patients with chronic hypertension due to pheochromocytoma the presence of the latter may be suggested by a history of paroxysms during which the chronically elevated blood pressure is sharply increased and by the finding of associated hypermetabolism and glycosuria or hyperglycemia[80] Confirmation in any of the above circumstances depends on pharmacologic or chemical tests for excessive secretion of epinephrine and norepinephrine[66] and on roentgenologic demonstration of a 'tumor' shadow in the adrenal region

In practice the pharmacologic or chemical tests (infra) are performed for screening purposes Then intravenous and, if indicated, retrograde pyelograms are performed and these may suggest the presence and site of an adrenal tumor Laminograms of the adrenal regions may occasionally disclose the tumor or tend to exclude its presence by revealing normal sized adrenal glands Perirenal insufflation has been used extensively but has come to be regarded by many as too hazardous a procedure At present carbon dioxide or oxygen is introduced into the presacral region, resulting in an equally satisfactory method of contrast visualization of the perirenal area without the hazard of perirenal insufflation[6, 8, 88] If a sympathectomy is performed for severe hypertension the adrenal glands should be inspected for the presence of a tumor

Tests for Pheochromocytoma (Paraganglioma)

1 **Pressor Drugs.** These are employed between attacks to provoke a rise in blood pressure in patients with paroxysmal hypertension or in those with slight chronic hypertension and paroxysmal crises They should not be used in patients whose systolic blood pressure is more than 170 mm Hg or whose diastolic pressure exceeds 110 mm Hg *Histamine* is the test drug of choice[73] Mecholyl[47] has been found to be much less reliable and TEAC (tetraethylammonium chloride or Etamon)[53] has resulted in too many false negative tests[3]

Technique The patient lies quietly for 15 minutes or more until the blood pressure is stabilized, as determined by repeated measurements at one minute intervals Sedatives should not be given An intravenous infusion of 5 per cent glucose in water is started and the blood pressure is determined repeatedly until the effect of the procedure has worn off and the blood pressure has returned to its pre infusion level

Histamine, in a dosage of 0 025 mg is infused *rapidly* through a three way stopcock attached to the intravenous infusion The blood pressure is then measured and recorded every thirty seconds for five minutes, and every minute thereafter for an additional ten minutes

A *positive response* is denoted by a rise of 60 mm Hg or more in the systolic blood pressure and 30 mm Hg or more in the diastolic blood pressure, occurring within the first five minutes after injection of the histamine and subsiding usually within the next ten minutes Among 21 definite positive tests there was an average systolic rise of 111 mm Hg (range 60 to 200) and an average diastolic rise of 60 mm Hg (range 30 to 110)[8] Benzodioxane should be readily available and 15 to 20 mg should be injected intravenously if there is a severe pressor reaction Serious reactions and even death have been reported[22] Several false negative and two possible false positive tests have been noted[3] The value of a positive histamine test may be enhanced if a cold pressor test[48] is also performed and the histamine pressor response exceeds that due to immersion of the hand in ice water for five minutes[8] The positive histamine test may be a more accurate indicator of pheochromocytoma if it is followed by a negative reaction after the previous administration of Dibenamine

2 Depressor Drugs These are designed to cause a rapid reduction in blood pressure in patients with sustained hypertension They are employed whenever the presence of pheochromocytoma is suspected in patients with persistent hypertension (systolic blood pressure above 170 and diastolic above 110 mm Hg) and in all hypertensive patients under 40 unless the hypertension is clearly due to renal disease Regitine, Benzodioxane and Dibenamine[85] have been employed but Dibenamine has given too high an incidence of false positive tests to be useful

Regitine (phentolamine C 7337) a drug of the imidazoline series is adrenolytic (i e it blocks the effects of norepinephrine and epinephrine) in small doses and a sympatholytic in higher concentrations The Regitine test is simple to perform and free of unpleasant side effects [illegible, 53, illegible, 64] It is therefore most useful to use Regitine as an office procedure for purposes of screening False negative tests are very infrequent However since Regitine may yield a false positive test [71] a positive Regitine test should be followed by a Benodaine test which rarely gives a false positive result No sedatives narcotics anesthetics or antihypertensive drugs should be given for at least 24 hours and no thiocyanates for at least a week prior to the test These drugs or the presence of uremia may account for some or many of the false positive tests with Regitine as well as with Benodaine [33, 39]

Regitine may be administered intravenously or intramuscularly but the latter method is less satisfactory The patient rests in the supine position and the blood pressure is determined at one minute intervals until it is stabilized (at hypertensive levels of 170/110 or higher) Five mg of Regitine methane sulfonate (phentolamine methanesulfonate) in 1 cc of sterile distilled water is injected rapidly intravenously in adults (or 1 mg in children) The blood pre sure is determined and recorded every 30 seconds for 3 minutes then every minute until it returns to its pre injection level (usually within an additional 7 minutes) A positive test is indicated by a maximal fall of more than 35 mm Hg in the systolic pressure and more than 25 mm Hg in the diastolic pressure within two minutes with a rapid return to previous levels usually in 10 to 15 minutes When the drug is injected intramuscularly blood pressure determinations are recorded every 5 minutes for a half hour A positive test is indicated by a fall of more than 35 mm Hg in the systolic and more than 25 mm Hg in the diastolic pressure within 20 minutes after injection The maximal hypotensive effect usually persists for approximately 30 minutes and the blood pressure gradually returns to normal in 3 or 4 hours

Tachycardia is the only side effect observed following the intramuscular injection of Regitine but occasionally weakness dizziness and flushing occur following its intravenous injection

Ben odioxane Test [43, 8] Benzodioxane (piperoxane hydrochloride or 933F or Benodaine) blocks the pressor responses of both epinephrine and norepinephrine

The patient rests quietly and blood pressures are determined and recorded every few minutes until stable A slow intravenous drip of 5 per cent glucose in water is started and after the blood pressure has again stabilized Benodaine is administered at a uniform rate through a three way stopcock attached to the infusion over a 2 minute period The dose is 0 25 mg per kilogram of body weight or 10 mg per sq meter body surface area up to a maximum dose of 20 mg The usual adult dose is between 15 and 20 mg Blood pressure determinations are made and recorded by an assistant during the injection and every 30 seconds thereafter for five minutes and thereafter every minute for 15 minutes

Many hypertensive patients *without pheochromocytoma* exhibit a slight rise in blood pressure after Benodaine or an initial brief hypotensive effect followed by a pressor effect A *positive ben odioxane test* is characterized by a prompt fall in blood pressure of at least 30 mm Hg in the systolic and 30 mm Hg or more in the diastolic blood pressure within 1 to 4 minutes after beginning the injection of benzodioxane The fall in pressure persists at least 5 minutes and is not followed by an elevation of the blood pressure above the pre injection level False positives are very rare except in patients with uremia [illegible, 33, 81] But false negative tests occur occasionally [25, illegible, 3]

Benzodioxane produces mild side reactions frequently and alarming ones occasionally The mild reactions include flushing palpitation apprehension throbbing in the head substernal pressure and hyperpnea [95] The more serious reactions are characterized by striking pressor effects in hypertensive pa

tients.[20] Amyl nitrite pearls or Hydergine may be administered for severe hypertensive reactions and Levophed (norepinephrine) or Neosynephrine (phenylephrine) may be administered in the intravenous drip for the rare severe hypotensive reaction.

Direct Estimation of Catechol Amines[42, 94] (Epinephrine and Norepinephrine) in plasma and urine. Lund[56] reported detectable amounts of norepinephrine in the blood of patients proven to have pheochromocytoma but not in normal individuals or patients with essential hypertension. Similar observations were made by Manger et al who suggested that chemical estimation of the pressor amines in plasma could be valuable as a screening test in patients suspected of having pheochromocytoma. Von Euler[92] observed a marked increase in the urinary excretion of norepinephrine and epinephrine in patients with pheochromocytoma, with a reduction or return to normal urinary excretion following removal of the tumors. Goldenberg and associates[42] have been determining chemically the urinary content of catechol amines as a basis of the diagnosis of pheochromocytoma and have found this to be more reliable than the pharmacologic tests. If further experience confirms its reliability and if the technique is simplified, this urinary test for catechol amines may well replace the pharmacologic tests. Recently Moulton and Willoughby[63] determined the urinary excretion of epinephrine and norepinephrine by bioassay after injection of the urine into cats.

Treatment of Pheochromocytoma

Cure of pheochromocytoma can be expected after its surgical removal.[97] Occasionally the tumor is malignant. From the surgical viewpoint the important aspects are accurate localization, operative technique and management of the patient during and after extirpation of the tumor.[3, 24] The patient must be managed with great care and watchfulness during positioning on the table during induction of anesthesia[17] and during handling of the tumor in order to avoid dangerous paroxysms caused by excessive release of norephinephrine and epinephrine. Regitine hydrochloride tablets (50 mg. each) may be administered orally to control hypertension while the patient is awaiting surgery and Regitine methanesulfonate may be injected intermittently during the operation to control rises in blood pressure. Other adrenolytic or hypotensive agents such as piperoxan (Benzodioxane), Dibenamine or amyl nitrite have also been used to control hypertensive crises during the operation. After the tumor has been removed profound hypotension may occur and blood or dextran infusions as well as pressor drugs (Levophed) may have to be administered.

HYPOFUNCTION OF THE ADRENAL CORTEX—ADRENAL INSUFFICIENCY—ADDISON'S DISEASE

Addison's disease, in which severe adrenal insufficiency results from tuberculosis or diffuse atrophy of the adrenal cortex, is characterized by profound asthenia, striking hypotension, brown pigmentation and by acute crises which are dominated by nausea and vomiting, dehydration, fever and shock due to loss of sodium and water.

The profound weakness overshadows any cardiac symptoms in the chronic untreated state, but dyspnea and palpitation are common. These symptoms are mitigated by the limited activity which the patient's asthenia permits. Hypotension is characteristic during the chronic and acute phases and is the most constant cardiovascular manifestation. The blood pressure is usually below 100 mm. Hg and often between 80 and 90. The diastolic pressure is usually between 60 and 70 mm. Hg and the pulse pressure is low. During a crisis the systolic pressure falls below 80 and often to such low levels that it is unobtainable. The fall in blood pressure is due to deficiency of adrenal cortical hormone and not to lack of medullary epinephrine, for the blood pressure can be restored to normal or even hypertensive levels by the administration of sodium chloride and desoxycorticosterone (p. 1024). The occurrence of frank evidences of congestive heart failure in patients with Addison's disease following excessive desoxycorticosterone therapy, has also been discussed (p. 1024).

The heart in Addison's disease, as in anterior pituitary insufficiency, is small in size and shows poor filling (i.e., it is hypodynamic) on fluoroscopic examination. To some extent the smallness of the heart parallels the severity of the disease and conversely the cardiac silhouette enlarges following treatment with sodium and desoxycorticosterone.[60, 61] In fact the varying size of the heart has been utilized as a guide to treatment with desoxycorticosterone, for according to McGavack[61] an abnormally large cardiac silhouette on teleo-

roentgenograms was the first and most reliable sign of excessive dosage The small size of the heart in Addison's disease is probably due chiefly to the reduction in blood volume, i e, to the proportionally small volume of blood in the cardiac chambers and the consequently low diastolic tension However the loss of potassium and water from heart muscle as well as other muscular tissue[93] has also been cited as a factor in diminishing the size of the heart

The electrocardiogram of Addison's disease often discloses low voltage of the QRS complexes and may show small isoelectric or rarely diphasic or inverted T waves which suggest the presence of myocardial disease [77, 96] In a study of 90 patients with Addison's disease Somerville et al [94] found the electrocardiogram to be normal in 48 per cent, and abnormal in 52 per cent of the cases The electrocardiographic changes observed were as follows in order of frequency (1) flat or inverted T waves especially in left precordial leads (2) prolonged Q T interval, (3) low voltage of the QRS complexes, (4) prolonged P R and QRS intervals, (5) depressed RS-T segment (6) prominent U waves, especially in cases treated with desoxycorticosterone Many of the changes may be related to alterations in potassium metabolism (infra) associated with Addison's disease [53] According to Somerville et al the electrocardiographic changes in Addison's disease are reversed by cortisone but not by desoxycorticosterone

At postmortem examination the heart is usually described as atrophic [75] There may be remarkable degenerative alterations of the muscle fibers but as a rule there are no striking microscopic changes Somerville et al [94] described localized areas of myocardial necrosis and fibrous tissue replacement in 3 of 5 fatal cases which they studied Goodof and MacBryde[44] reported interesting findings in the heart of a patient with Addison's disease who had been treated with desoxycorticosterone and subsequently died of cardiac failure Throughout all four chambers there were foci of necrosis resembling closely similar lesions in the hearts of rats which had received large amounts of desoxycorticosterone[30] and also resembling those lesions produced in rats which had been maintained on a low potassium diet [73, 35] The implication is that desoxycorticosterone administered to patients with Addison's disease causes retention of sodium and fluid with simultaneous excretion of potassium, this sudden reduction in serum potassium especially if the patient is on a low potassium intake is capable of producing cardiac damage and contributing to the development of congestive heart failure Thus myocardial disturbances and corresponding electrocardiographic changes (infra) have been attributed both to the high serum potassium which accompanies Addison's disease and to the reduction in serum potassium which follows effective treatment with desoxycorticosterone and sodium salts

THE HEART IN POTASSIUM DISTURBANCES

Potassium is the predominant intracellular electrolyte (90 to 150 mEq /L) The extracellular and serum concentration of potassium normally ranges from 3 5 to 5 mEq /L A normal concentration of intracellular and extracellular potassium is essential for normal myocardial contraction In the isolated heart potassium antagonizes the tendency of calcium to cause systolic standstill (calcium rigor) When present in excess potassium prolongs diastole and may cause complete inhibition with arrest of the heart Various observations have suggested an intimate relationship between the potassium ion and the action of acetylcholine the humoral effector agent produced by vagal stimulation Potassium may participate in nerve stimulation and muscular contraction by altering cell permeability Changes in the concentration of potassium may produce clinical symptoms due to impairment of muscular activity, and/or changes in the cardiac mechanism and in the electrocardiogram

Anatomic changes in the heart have been described not only in rats maintained on potassium deficient diets [73, 88, 10] but also in patients with hypokalemia of varied etiology Widespread myocardial fibrosis and areas of focal necrosis have been observed [113, 115, 104] However the electrocardiographic changes are more probably due to electrophysiologic disturbances rather than to the anatomic myocardial lesions [102] In cases with low serum potassium the potassium gradient across the cell is increased the speed of exit of potassium is accelerated and the transmembrane action potentials are altered These changes in gradient and action potentials account for the observed alterations in the ST segment T wave and U wave Conversely elevation of

serum potassium diminishes the transcellular potassium gradient and accounts for the tall peaked T waves and other changes

HYPERKALEMIA

In the presence of normal renal function, only slight increases in serum potassium can be induced by potassium infusions or by increased oral intake of potassium But significant hyperpotassemia may occur in various forms of renal insufficiency with uremia, especially in cases of acute tubular nephrosis with severe oliguria or anuria Hyperkalemia is also encountered clinically in cases of Addison's disease and in the untreated stage of diabetic acidosis and in sickle cell anemia The clinical picture is characterized by paresthesias mus

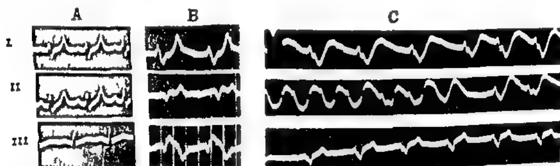

Fig 154 Hyperpotassemia in acute anuria following 7 month stillborn delivery At autopsy two days later bilateral hemorrhagic necrosis of renal cortex
A 3-12-50 K = 7 9 Na = 117 mEq /liter Tall peaked T waves
B 3-13-50 K = 8 5 Na = 120 Tall T wide QRS absence of P wave
C Ventricular tachycardia ventricular flutter fibrillation

cular weakness and flaccid paralysis of the extremities shock, bradycardia and cardiac arrest

The electrocardiogram of hyperkalemia [89, 5, 109, 105, 11] (Fig 154) is characterized by (1) Tall peaked T waves which occur early In children, the negative T waves in leads III and V_1 may become more negative The negative T waves in cases of left ventricular hypertrophy may become upright (2) Lowering of the R and increased depth of S wave (3) Widening and then disappearance of the P wave (4) Progressive widening of the QRS Occasionally this is associated with an apparent elevation of the RS T junction and a cove plane RS T segment and T wave in aV_L resembling the changes seen in myocardial infarction or pericarditis [111, 106] The electrolyte basis for these changes denoting a "current of injury" is indicated by the prompt abolition of the RS T segment elevations when electrolyte imbalance notably hyperkalemia is corrected by hemodialysis [106] (5) Prolongation of the P R interval (6) ST depression The widened QRS becomes smoother obliterates the T and assumes a diphasic appearance resembling a continuous sine wave Eventually ventricular flutter, fibrillation and standstill may occur with high but variable levels of serum potassium (Fig 155) Although there may be no electrocardiographic changes with slight elevations in serum potassium concentration and an imperfect correlation with moderate or large elevations electrocardiographic changes usually appear when serum potassium exceeds 6 5 to 7 4 mEq /L and severe changes are present with concentrations above 7 5 mEq /L [11] A depressed serum sodium or a depressed serum calcium concentration enhances the electrocardiographic effects of a given elevated serum potassium level Acidosis simulates and likewise enhances the electrocardiographic effects of hyperkalemia

If there is chemical, clinical or electrocardiographic evidence of hyperkalemia potassium intake should be interdicted otassium free resins may be administered orally and hypertonic glucose in saline or in distilled water with insulin intravenously If serious hyperkalemia persists it should be corrected with the aid of peritoneal dialysis or the artificial kidney

HYPOKALEMIA

Hypokalemia is most strikingly associated with the syndrome of familial periodic paralysis,[101] but is also encountered in cases of prolonged diarrhea prolonged vomiting fi

tulae with continued external drainage of intestinal fluids, nasogastric suction, intestinal intubation, postoperative infusions of potassium free intravenous fluids when there is no oral intake of food, in some cases of Cushing's disease, in primary aldosteronism, in some cases of chronic nephritis, following vigorous use of cathartics, following ACTH or cortisone, following treatment of diabetic ketosis with insulin, and occasionally in Addison's disease treated with DOCA.

Hypokalemia is characterized clinically by drowsiness, anorexia, nausea, marked muscular weakness progressing to paralysis, and diminution or loss of deep reflexes. The paralysis begins in the extremities and eventually involves the muscles of swallowing and of respiration. Involvement of the respiratory muscles results in the fish mouth type of respiration. Chronic ileus may occur due to disturbed gastrointestinal function.

Electrocardiographic changes are frequently absent in the presence of hypokalemia[116] but usually they are observed when the serum potassium concentration is below 3 mEq./L.[110] On the other hand, electrocardiographic changes due to the depletion of total body potassium may be observed when the serum potassium concentration is within the normal range. The electrocardiographic changes associated with potassium depletion are characterized by (1) depression of the ST segment and lowering, flattening or inversion of the T wave, (2) prolongation of the Q-T interval, (3) presence of an elevated, broad or diphasic U wave which may be responsible for the impression of a prolonged Q-T interval[104] (the combined T and U waves may form a double humped or triple contour), (4) occasional prolongation of the P-R interval. In addition many arrhythmias associated with digitalis administration occur more readily in the

presence of potassium depletion The electrocardiographic changes are reversed by the oral or intravenous administration of potassium Bellet et al[109] described a variety of electrocardiographic patterns associated with hypokalemia, depending on the causative mechanism Diabetic acidosis was associated with inversion of the T wave and with a prominent U wave whereas in cases of hypokalemia associated with vomiting there was *depression of the RST segment, with a flat* upright T wave or a normal T wave and an elevated U wave

ACIDOSIS AND ALKALOSIS[99]

Metabolic acidosis produces electrocardiographic effects resembling those of hyperkalemia notably tall, peaked T waves[114] Alkalosis induces electrocardiographic changes like those of hypokalemia, viz, lowering of T waves and prolongation of the Q T interval[107] *Lowering or inversion of T waves during* hyperventilation may be due to alkalosis or to undetermined mechanisms involving neural or electrolyte changes

THE PARATHYROIDS

PATHOLOGIC PHYSIOLOGY

The parathyroid glands are concerned with the regulation of calcium and phosphorus metabolism Their physiologic relationship to *the heart arises from the fact that calcium* (with sodium and potassium) is essential to proper cardiac contraction The perfused isolated heart will stop in diastole if there is no calcium, an excess of calcium causes systolic arrest (calcium rigor) Like digitalis, calcium *increases systolic contraction* Fear of a dangerous potentiating effect is the basis for the purported contraindication to the injection of calcium in digitalized patients (p 268) In dogs perfused with calcium in such a manner as to cause a progressive increase in serum calcium Hoff Smith and Winkler[119] observed bradycardia T wave changes and finally death from ventricular fibrillation or from cardiac standstill They concluded that calcium in low concentration was *a cardiac stimulant, in* high concentration it was a cardiac depressant Injected parathormone produces effects which are somewhat similar to those of calcium namely an early increase in heart rate followed by slowing and by cardiac arrhythmia which is characterized by premature beats and shifting of the pacemaker[118]

HYPERPARATHYROIDISM

Hyperparathyroidism in humans is not associated with distinctive cardiovascular disturbances comparable to those described above as following excessive dosage of calcium or parathormone However a shortening of the Q T interval in the electrocardiogram has been noted,[110] but the degree of shortening was slight and insufficient to be of diagnostic value A shortening of the Q T interval also follows digitalis therapy Hyperparathyroidism is frequently complicated by nephrolithiasis and secondary renal insufficiency In such cases, hypertension and its cardiovascular complications may develop (p 020) Hyperparathyroidism has been mentioned as having a possible role in aging and atherosclerosis because of the increased content of calcium in the tissues in these conditions

HYPOPARATHYROIDISM AND HYPOCALCEMIA

Hypoparathyroidism is usually due to injury or accidental removal of the parathyroids during thyroidectomy It is characterized chemically by a reduction in the serum calcium and clinically by the occurrence of tetany *With respect to the heart,* these various conditions associated with hypoparathyroid or other hypocalcemia are of interest because they are documented electrocardio*graphically by a significant and sometimes* striking prolongation of the *Q T interval*[117,113] The increased duration of the Q T interval is due primarily to prolongation of the ST segment and T wave without significant alteration in duration of the *QRS complex*[12] *As the hypocalcemia is corrected* the Q T interval is restored to normal *Although* a prolongation of the Q T interval is most distinctively associated with *conditions in which* there is hypocalcemia the Q T interval is prolonged in hypokalemia and may … be prolonged on occasion in cases of hypokalcemia diabetic acidosis, alkalosis, beriberi quinidine toxicity heart failure and various forms of myocardial disease in which *there is pronounced* cardiac enlargement and in some cases of advanced heart block *or bundle* branch block The increased Q T interval is somewhat similar to that in cases *of hypokalemia* But in hypocalcemia there is no depression of the ST wave *lowering of the* T wave or presence of a U wave as in hypokalemia

TESTES AND OVARIES

The sex hormones of the testes and ovaries are concerned chiefly with the growth development and functional activity of the sexual organs and with the development of secondary sex characteristics In addition the sex hormones produce certain metabolic effects which resemble those of the adrenal cortex whose hormones are chemically related Thus testosterone the most active of the male hormones (androgens), causes a retention of sodium and fluid probably by its effect on the renal tubules The occurrence of premenstrual edema was mentioned above as an anterior pituitary effect but it may be related directly or indirectly to ovarian function

Tumors of the male or female sex organs are not associated with distinctive physiologic or clinical cardiovascular effects Masculinizing tumors of the ovaries may be responsible for manifestations of the adrenogenital syndrome but the hypertension and metabolic changes seen in Cushing's syndrome are absent Diminution in secretion of the ovaries or testes due to disease or atrophy especially at the menopause may be associated with vasomotor and functional cardiovascular disturbances such as flushes, sweats palpitation and tachycardia Psychic factors are also important in the causation of these symptoms Hypertension often develops at the time of the menopause its relation to the sex glands is uncertain Scherf[121] described electrocardiographic changes including ST segment depressions in all limb leads and lowering of the T waves in women with hypoovarian function These alterations were corrected by estrogen therapy That these minor electrocardiographic deviations are specifically due to ovarian deficiency is questionable Former belief in the existence of heart disease secondary to uterine fibromata has almost completely faded

THYMUS

The thymus has been related in function to the sex glands the pituitary thyroid and adrenals Thymic tumors have been associated with the complete Cushing's syndrome including the hypertension[125] Such tumors have also been associated with but not necessarily responsible for myasthenia gravis Mendelow and Genkins[126] found myocardial changes at autopsy in 6 of 12 cases of myasthenia gravis The abnormalities ranged from scattered focal atrophy and vacuolization of the myofibrils with lymphocytic infiltration to severe myocardial necrosis and reactive myocarditis The severe changes were usually observed in cases with thymoma A persistent enlarged thymus and hyperplasia of the lymphoid tissues (status thymicolymphaticus) are sometimes associated with notable hypoplasia of the heart aorta and other vessels and occasionally with sudden death after minor trauma or infection The relationship of the enlarged thymus and lymphoid tissue to sudden death is obscure In fact the whole concept of status thymicolymphaticus has been rejected[128] Raab[1 7] has attributed sudden death in young individuals to ventricular fibrillation caused by excessive amounts of epinephrine like substances in the heart There was a recent report of sudden death in identical twins who were able athletes[1 4] The autopsy in one disclosed hyperplasia of the thymus and hypoplasia of the aorta but there was also pronounced atherosclerosis Attention has already been directed to recent evidence that acute coronary thrombosis is a common cause of death in young individuals (p 493)

THE PANCREAS

HYPERINSULINISM AND HYPOGLYCEMIA

Excessive secretion of insulin such as occurs in islet cell tumors of the pancreas or over dosage with insulin in the treatment of diabetes mellitus or in the shock treatment of schizophrenia results in hypoglycemia Hypoglycemia may occur also in cases of adrenal, pituitary or hepatic insufficiency and in some diseases of the diencephalon Hypoglycemia is of serious concern to patients with angina pectoris or myocardial damage secondary to coronary atherosclerosis for attacks of angina pectoris and of myocardial infarction have been attributed to too vigorous insulin therapy and consequent hypoglycemia[15 131]

Aside from the serious neuropsychiatric manifestations of hypoglycemia such as anxiety confusion ataxia syncope convulsions and coma there are striking vasomotor and cardiovascular signs such as sweating pallor palpitation tachycardia and a slight rise in blood pressure Many of these effects resemble those due to norepinephrine or epinephrine It may be that they are actually due

to a compensatory secretion of the latter, which tends to restore the lowered blood sugar to normal by converting hepatic glycogen into glucose [138] On the other hand, a reduction in blood sugar may directly interfere with cardiac metabolism and produce effects similar to those caused by myocardial anoxia [134]

In the electrocardiogram, insulin hypoglycemia is documented by a depression of the ST segment, most commonly in leads I II or both, and by low or diphasic T waves in these leads [145] These non specific changes resemble those caused by epinephrine but similar changes are observed in patients with angina pectoris during attacks or after an anoxemia or exercise test (p 408) Similar changes have been described in schizophrenic patients treated with insulin shock In addition to ST depressions and T wave changes, prolongation of the P R and Q T intervals were noted,[140, 139] changes resembling those of hypokalemia and probably due to hypokalemia

DIABETES MELLITUS

The fundamental importance of diabetes in cardiology rests on the frequency with which this disease is accompanied by atherosclerosis and its complications especially coronary artery occlusion [159, 161, 1, 9, 135] It is a striking fact that the mortality from coronary and peripheral atherosclerosis among diabetics has increased sharply despite the fact that carbohydrate metabolism has been controlled and the mortality from acidosis greatly reduced

Advanced coronary atherosclerosis has been encountered in a higher percentage of cases of diabetes studied at autopsy than in those without diabetes [131, 137, 156, 133] Clinical evidence, i e, of angina pectoris and acute myocardial infarction has been observed with much greater frequency among diabetic than among non-diabetic individuals [153, 135, 152, 1, 1] (See also p 493) Whereas coronary occlusion among non-diabetics is very predominantly a disease of males (p 493), among diabetics women suffer an occlusion as often as men [161, 132] This strongly suggests the predisposing effect of diabetes Not only does diabetes appear to enhance the likelihood of developing coronary atherosclerosis, but also it seems to hasten the time of its appearance, for coronary occlusion and other forms of atherosclerosis are encountered among relatively young diabetics [1, 1, 150, 155] The mortality rate from acute myocardial infarction is especially high among diabetic patients 60 8 per cent for all attacks and 57 8 per cent for first attacks in a recently reported series of cases [152] The chances of late survival after myocardial infarction are poor among diabetics, fewer than 20 per cent survived five years and only 3 6 per cent more than ten years [12]

The frequency of atherosclerosis increases with the duration of the diabetes Recent studies indicate that almost every diabetic is an actual or potential victim of advanced atherosclerosis of the heart extremities or retinal vessels [14, 136]

Hypertension is common among diabetics,[1, 1] but an etiologic relationship is uncertain In recent years attention has been directed to the syndrome of diabetes, hypertension and severe albuminuria often with peripheral edema and retinopathy [144, 157] The pathologic basis of this syndrome is an intercapillary glomerulosclerosis Hypertension also accompanies diabetes in cases of angina pectoris or coronary occlusion, especially among women An interesting association of hypertension with diabetes (or diminished glucose tolerance) was mentioned as occurring in cases of acromegaly (p 1023) and Cushing's syndrome (p 1024) Russi et al [146] recently observed that diabetes and hypertension occurred five times as frequently in cases in which examination at autopsy revealed small adenomata of the adrenal cortex as in the cases in which an adrenal adenoma was absent The association of diabetes hypertension and advanced atherosclerosis in patients with gross disease of the anterior pituitary (acromegaly), adrenal cortex (Cushing's syndrome) and thyroid (myxedema) suggests the fruitfulness of a search in the endocrine organs for a possible common denominator in the etiology of these diseases

Hypertension and coronary atherosclerosis in diabetics may be terminated by an acute coronary occlusion Often myocardial disease and strain secondary to coronary atherosclerosis and hypertension lead eventually to clinical manifestations of congestive heart failure A relative deficiency of vitamin B_1 in diabetes mellitus should be considered as a possible contributory factor in the development of heart failure

The common occurrence of acute myo-

cardial infarction in diabetics presents problems in diagnosis and therapy The acute coronary incident is sometimes associated with hyperglycemia glycosuria and ketonuria as well as with shock and occasional nausea and vomiting An erroneous diagnosis of impending coma based on the laboratory findings, may be considered while the cardiac infarction is overlooked On the other hand diabetic coma may actually occur with or be precipitated by an acute coronary occlusion The diabetes is properly diagnosed and treated but the occlusion may not be recognized

The association of acute coronary occlusion with diabetic coma requires special caution in treatment lest an overenthusiastic administration of insulin enhance the myocardial disturbance already present or a too vigorous administration of fluids especially as saline overload the damaged heart and induce congestive heart failure Haste in the correction of shock dehydration and ketosis is essential but continuous clinical observation and chemical study are necessary to avoid a cure of the diabetic acidosis with loss of the patient from cardiac disability Similarly in the treatment of all cases of longstanding diabetes especially in elderly patients it should be assumed that pronounced coronary atherosclerosis is probably present and sharp reductions in the blood sugar by diminishing carbohydrate intake or increasing the dose of insulin should be avoided[160] An intake of less than 125 to 150 gm of carbohydrate daily is rarely advisable Although correction of acidosis is essential and of glycosuria is desirable a moderate hyperglycemia should be maintained as a reserve against excessive reductions in blood sugar This denotes minimal insulin dosage

DIABETIC ACIDOSIS

Certain electrocardiographic abnormalities have been observed in patients during and on emergence from diabetic acidosis and coma[130 147 141] The chief alterations are a prolongation of the Q T interval depression of the ST segment, low and inverted P waves diphasic or inverted T waves, and a prominent U wave which may be fused with the T wave Recent studies have somewhat clarified the relationship between the electrocardiographic changes observed in diabetic acidosis and the stage of treatment of this metabolic disturbance and especially the relation to the concentration of plasma potassium[149] Usually the serum potassium level is elevated at the time of hospital admission of the patient with untreated diabetic acidosis The electrocardiogram may then disclose the tall peaked T waves and other changes distinctive of hyperkalemia Following institution of treatment with insulin and sodium chloride and/or glucose infusions, hypokalemia is induced[143] because of (1) deposition of glycogen with potassium in the liver (2) increased uptake of potassium by other cells, (3) renal loss of potassium due to the intravenous infusions (4) dilution caused by increased plasma and extracellular volume The electrocardiographic changes described above in patients treated for diabetic acidosis are those due to hypokalemia However Henderson[141] found no correlation between the serum potassium level and the degree of cardiac abnormality in 21 of 42 patients with diabetic acidosis and abnormal electrocardiograms and therefore considered intracellular potassium disturbances as the probable cause of the electrocardiographic abnormalities

HEMOCHROMATOSIS

Hemochromatosis or bronze diabetes is a metabolic disease characterized by pigmentation of the skin and internal organs diabetes and frequently cirrhosis of the liver The iron containing pigment is also deposited in the heart muscle in most cases but fibrosis is rare[164 167] In recent years there has been an increasing number of reports of cardiac hemosiderosis in hemochromatosis[1 2 166] Occasionally there have been reports of heart failure in cases of hemochromatosis not explained by the usual forms of heart disease[168 171 165 165] In the case of Kerr and Althausen[169] and in the case reported by Petit[17] complete heart block was present as well as the evidence of heart failure In one of the two cases reported by Lewis,[171] diagnosis was hampered by the absence of diabetes or pigmentation clinically although extensive hemosiderin deposits were found post mortem in the heart and other organs

Cardiac involvement in hemochromatosis usually in children or young adults is indicated clinically by diffuse enlargement of the heart associated with left and right sided congestive heart failure predominantly the latter Substernal or cardiac pain has been noted in a number of cases[168 172] and has led to a mistaken diagnosis of acute coronary

occlusion Low voltage of the QRS complexes and T wave depressions or inversions are observed but no RS-T deviations as a rule[172, 166] Arrhythmias and conduction disturbances[174, 168, 170] are common including paroxysmal tachycardia, atrial flutter, atrial fibrillation, occasional ventricular tachycardia, partial and complete atrioventricular block and intraventricular conduction defects The nature of the cardiac disturbance and the pathogenesis of the heart failure are obscure but the latter has been attributed to extensive deposition of hemosiderin and myocardial degeneration Occasionally there is considerable destruction of muscle and replacement fibrosis[173] But because in many cases the pathologic changes do not appear to account adequately for the development of heart failure it has been suggested that the latter is due to myocardial intracellular biochemical disturbances caused by the hemosiderin deposits with resulting impairment in enzyme systems required for the glycolytic cycle in myocardial metabolism[171]

Treatment of the heart failure may be effective but only temporarily

NUTRITIONAL DISTURBANCES

OBESITY

While obesity is ultimately the result of an excessive caloric intake relative to the metabolic requirements of the body there is considerable evidence that disturbances in the diencephalon and psychic factors may be important in its pathogenesis The relation of endocrine disturbances to obesity is noted in cases of adrenal cortical or anterior pituitary tumors causing Cushing's *syndrome and in* cases of myxedema

With respect to the cardiovascular system obesity has several important relationships There have been many studies which indicate a correlation between obesity and hypertension especially systolic hypertension[195, 185, 191] But the role of obesity in causing false high blood pressure readings must be considered in evaluating such reports (p 921) Weight reduction sometimes effects a fall in the blood pressure of obese hypertensive individuals (p 935) There is also some evidence that coronary atherosclerosis and occlusion are more common in the obese (p 416) The syndrome of extreme obesity, somnolence polycythemia hypoventilation and cor pulmonale has been noted (p 981)

Obesity influences the roentgen ray appearance of the cardiac silhouette and the electrocardiographic tracing Because of elevation of the diaphragm the heart assumes a transverse position and the left ventricle may appear enlarged in the anteroposterior view The presence of a large apical fat pad may enhance this effect by obscuring the apex Views in deep inspiration minimize these distortions In the electrocardiogram the limb leads frequently disclose an inversion of T_3 and left axis deviation[197]

Fatty infiltration of the surface of the heart is common in obese subjects The epicardial fat is increased and encases most of the heart especially the right ventricle and the interventricular sulcus It may even penetrate the superficial muscle bundles[196] But fatty *infiltration* is only rarely responsible for serious heart disease associated with clinical symptoms (p 629) Fatty *degeneration* of myocardial fibers results most often from anemia and infections and occasionally from phosphorus or other poisoning

Moderate dyspnea on exertion is common in obese persons partly because of the abnormal strain of the ballast on the circulation[183] and partly because obese individuals do not exercise and lack training Dyspnea in the very obese or dyspnea which develops concomitantly with pronounced weight gain should be carefully evaluated to avoid misinterpreting it as a symptom of congestive heart failure Excessive weight may also exaggerate symptoms in patients with heart failure due to independent organic heart disease In such cases weight reduction is an important part *of the therapeutic program*

UNDERNUTRITION AND STARVATION[111]

Undernutrition leads to a reduction in cardiac weight which is proportional to or slightly less than the reduction in total body weight[187] This is accompanied primarily by atrophy of myocardial fibers but with prolonged and severe starvation brown atrophy fatty and other degenerative changes appear

The basal metabolism is depressed and the cardiac output (minute volume) as well as the stroke output is diminished The cardiac work is reduced, because of this, undernutrition has been employed in the treatment of hypertension, acute coronary occlusion and heart failure

There is pronounced sinus bradycardia in

severe undernutrition The circulation time is prolonged the venous pressure depressed and the blood pressure and pulse pressure diminished the systolic falling more than the diastolic The extremities tend to be cold pale and slightly cyanotic

There are few *symptoms* referable to the circulatory system Dizziness may occur with sudden rising Syncope may result from prolonged standing Dyspnea palpitation and precordial pain are absent Edema is often a prominent feature but is not attributed to heart failure as the heart is not enlarged and the venous pressure is low or normal The circulating blood volume and extracellular fluid are increased[180]

The electrocardiogram shows in addition to bradycardia a reduction in the voltage of all deflections a prolonged Q T interval (but not necessarily prolonged in relation to the cardiac cycle) right axis deviation and only occasionally depression of the RST segment alteration of T waves and a prolongation of the P R or QRS intervals[181 184] These changes may be due at least in part to deficient potassium and calcium intake

The exact mechanism for *starvation edema* is uncertain The classic belief that it is due to pronounced hypoproteinemia especially to the reduction in plasma albumin was supported by the findings in German civilian internees[180] and in the civilian population of Saipan during the war[189] However this viewpoint has been challenged[183 139] because of the occasional appearance of famine edema when the plasma proteins were normal because of the absence of edema in some instances of hypoproteinemia, and occasional clinical improvement with profuse diuresis and loss of edema before there is a significant change in the concentration of plasma protein These imperfect correlations between hypoproteinemia and edema probably do not invalidate the belief that the latter is due in part to the reduction in colloid osmotic pressure associated with diminution in plasma protein according to the Starling theory However other factors such as variations in tissue pressure presence of dehydration, and especially the degree of inactivity or activity may account for discrepancies Famine edema sometimes diminishes or disappears with bed rest and increases with physical exertion Exercise may increase the venous return beyond the capacity of the atrophic heart to accept, edema may appear or increase because of a consequent elevation of venous pressure

It is probable that edema does not occur in patients with severe undernutrition and starvation despite hypoproteinemia because of minimal or no intake of sodium Commonly, edema in starved individuals appears only after food intake is resumed and sodium is thereby ingested

Although manifestations of congestive heart failure are usually absent even with prolonged starvation they may appear rapidly if nutritional rehabilitation is effected too enthusiastically,[177] or if fluid balance is restored too rapidly Dyspnea tachycardia and cardiac enlargement may develop and there may be a recurrence of edema associated with an elevated venous pressure

Nutritional Heart Disease in Africa (p 637)

Heart disease with right- and left-sided congestive heart failure due to longstanding dietary deficiency occurs frequently in the Bantu in South Africa[14 175] The syndrome differs from beriberi heart disease as described below, in the absence of the hyperkinetic circulation (increased cardiac output, etc) and in the failure to improve with thiamine chloride But there is a satisfactory response to a well balanced diet Extreme generalized edema dyspnea cardiac and hepatic enlargement (due often to pigmentary cirrhosis), gallop rhythm low cardiac output high venous pressure and prolonged circulation time are the most striking features At necropsy, the hearts were dilated and hypertrophied and there were foci of myocardial fibrosis and frequent mural thrombi and peripheral emboli

Kwashiorkor[179] is an African cardiac disease, occurring chiefly in children and characterized by hypoproteinemia, anasarca hepatic fibrosis degenerative myocardial changes involving chiefly the left ventricle and subendocardial fibrosis It is attributed to a nutritional deficiency

VITAMIN DEFICIENCY

Vitamin B_1 Deficiency—Beriberi Heart

Cardiovascular manifestations are often associated with the so called wet form of beriberi These cardiac disturbances were described in cases of beriberi in the Orient by Shimazono[2] and by Aalsmeer and Wenckebach,[197] in cases in this country by Scott and

Herrmann [3] and by Weiss and Wilkins, [4] in Cuban children by Junco[209] and by Abrilli [198] and in Brazil by Benchimol and Schlesinger [176] Weiss and Wilkins [4] were able to report in 1937 on 120 cases of beriberi with cardiovascular as well as neurologic manifestations in the Boston City Hospital an incidence far greater than the occasional case encountered in most hospitals Whereas beriberi in the Orient and elsewhere is due usually to a diet limited to polished rice in this country it has often been observed in alcoholics or drug addicts A restriction in food intake, neurotic adherence to food fads, poverty with consequent caloric and vitamin deficiency, and occasionally diabetes, pregnancy and severe gastrointestinal disease have been causative or contributory factors Pellagra is often, and scurvy occasionally, combined with beriberi in the same patient

Symptoms The cardiac symptoms often start with palpitation, fatigue and rapid heart beat Breathlessness and peripheral edema develop early Progressive dyspnea orthopnea attacks of cardiac asthma or pulmonary edema appear as evidences of left-sided heart failure Increasing subcutaneous edema serous effusions, engorgement of the cervical veins and enlargement of the liver result from failure of the right side of the heart Aalsmeer and Wenckebach[197] described only symptoms of right-sided heart failure in their cases of Oriental beriberi Shock may result from acute cardiac failure or from acute peripheral vasodilatation Late in the disease syncope with fall in blood pressure and other symptoms of shock dominate the clinical picture Sudden collapse is termed *shoshin* in the Far East

Objective Findings Physical examination discloses besides the neurologic signs enlargement of the heart in severe cases muffled first heart sound systolic murmurs embryocardia and gallop rhythm tachycardia and accentuation of the second pulmonic sound In the Cuban cases, murmurs arrhythmias and cardiac enlargement were not observed [209] The superficial veins are engorged and the venous pressure elevated The pulse may be bounding and pistol shot sounds may be heard over the femoral arteries Corresponding to these vascular signs there is a pronounced increase in the pulse pressure, but the mean arterial pressure is normal The pulse rate is rapid The skin is usually warm However, these peripheral vascular phenomena may be absent and the clinical findings may be indistinguishable from those of heart failure due to other types of heart disease

The Electrocardiogram The electrocardiogram may disclose depressed, diphasic or inverted T waves Low voltage of the QRS complexes and a prolongation of the Q T interval occur not infrequently [203] The changes resemble those of and may be due to potassium deficiency Tachycardia is usual With successful treatment there is observed slowing of the heart rate, increased voltage and disappearance of T wave abnormalities

Roentgenologic examination often reveals cardiac enlargement which regresses on a regimen of bed rest and large doses of thiamine chloride [202, 204] Garland and McKenney[207] noted an enlarged poorly contracting heart with mild pulmonary congestion in cases of beriberi heart disease

Morphologic Changes Postmortem examination reveals occasional cardiac hypertrophy but frequently the hearts are of normal weight [2,4] Aalsmeer and Wenckebach[197] stressed the occurrence of right ventricular dilatation Histologic examination usually discloses a normal myocardium but there may be hydropic degeneration of the myocardial fibers, separation of the myocardial bundles swelling of the collagen and perivascular and interstitial "edema" [2,3] The cardiac manifestations of beriberi may be attributed to actual anatomic abnormalities in some cases[2,3] but the lesions described are non specific and often absent It is more likely that disturbances in carbohydrate metabolism incident to thiamine deficiency, produce derangements in energy production and consequently in cardiac function, which may or may not have a visible anatomic basis Recent observations showed that the hearts of thiamine-deficient dogs were unable to absorb pyruvate from the blood as do normal hearts [17] In fact in these animals the T wave changes observed in the electrocardiogram could be correlated with an outpouring of pyruvate from the heart

Pathologic Physiology Many of the cardiovascular manifestations of beriberi probably originate in the peripheral vascular system and resemble those encountered in anemia hyperthyroidism fever or arteriovenous fistula Peripheral vasodilatation i e diminished peripheral vascular resistance may result from acidic metabolites (pyruvic and lactic acid) These accumulate because of the

lack of thiamine which is essential for cocarboxylase, *the enzyme required to oxidize* pyruvic acid The coefficients of myocardial extraction for lactate, pyruvate and oxygen were found to be significantly decreased in thiamine-deficient dogs[184] Thus thiamine deficiency affects cardiac action as well as the peripheral circulation

The diminished peripheral resistance has the effect of multiple arteriovenous shunts which greatly accelerate the speed of the circulation However Keefer[10] noted accelerated circulation in only one third of the cases he observed in China and Blankenhorn et al[202] stressed that acceleration of the circulation is rare in Occidental beriberi as observed in this country In the presence of heart failure the circulatory acceleration due to uncomplicated beriberi may be obscured or because of mental dulness it may be difficult to perform a reliable test of circulation time When the speed of the circulation is accelerated the venous return and the minute cardiac output are increased[174 190] Nevertheless heart failure occurs despite the abnormally great cardiac output because although elevated the output is still relatively inadequate to supply the tissues whose oxidative metabolism is impaired The venous pressure becomes elevated Oxygen consumption is increased and the arteriovenous difference is small[14] Heart failure in beriberi may be considered to result from (1) the thiamine-deficient metabolism *of heart muscle*[184] *(2) increased work of the* heart due to augmented venous return and cardiac output It is probable that there is a stage of beriberi in which the circulation is accelerated and the venous return and minute volume increased without congestive heart failure just as there are prefailure stages of increased circulation in arteriovenous fistula and hyperthyroidism

Diagnosis The diagnosis of beriberi heart is based on the recognition of the cardiovascular abnormalities in association with other evidences of beriberi such as tenderness and swelling of the calves and peripheral neuritis in subjects with a history of dietary deficiency and/or chronic alcoholism There may also be concomitant signs of pellagra and occasionally of scurvy such as psychosis dermatitis glossitis diarrhea anemia dysphagia and purpura Beriberi heart must be considered as the etiologic type in all cases of unexplained cardiac enlargement or unexplained cardiac failure A normal or diminished circulation time *in the presence of heart failure suggests beri* beri heart if hyperthyroidism can be excluded and fever is absent Severe anemia of various etiologies may produce somewhat similar circulatory disturbances but should not lead to confusion with beriberi heart In the American cases of beriberi heart disease rapid circulation is often absent or insignificant or it may be overshadowed by the slowing due to congestive heart failure The response to the administration of thiamine chloride is of diagnostic importance but failure to improve does not exclude the diagnosis of beriberi heart disease Above all a careful dietary history may aid in supporting or rejecting the diagnosis of beriberi heart On the basis of 10 cases studied at the Cincinnati General Hospital Blankenhorn[01] emphasized the following diagnostic criteria (1) enlarged heart with normal rhythm (2) dependent edema (3) elevated venous pressure (4) peripheral neuritis or pellagra (5) gross deficiency of diet for three months or more (6) no other cause for the heart disease (7) clinical improvement and reduction of heart size after specific treatment In recent years there has been a tendency to liberalize the diagnostic criteria of beriberi heart disease and to consider this diagnosis in all cases of heart failure of obscure origin in which there is a history of dietary deficiency in thiamine chloride[199]

Treatment Thiamine chloride given sub*cutaneously in doses of 100 mg daily is the* specific treatment An adequate protein intake is important for the proper utilization of thiamine In most instances in which the disease is not of long duration or far advanced the response is extremely favorable and rapid Signs of congestive heart failure including anasarca disappear first later the enlarged heart returns to normal size[07] and the electrocardiographic abnormalities disappear On the other hand too zealous a caloric intake may at first induce an exacerbation of symptoms Occasionally in cases of chronic thiamine deficiency the myocardial changes are irreversible or only partially reversible The clinical response may be slow or unsatisfactory Relapses after apparent recovery are not uncommon

Rest in bed is an important adjuvant in therapy Anasarca may disappear after rest in bed alone Conversely, as in cases of edema due to undernutrition, exercise intensifies the

manifestations of the disease or may precipitate a recurrence following recovery Sodium salts should be restricted Mercurial diuretics should be given as in other cases of congestive heart failure but their effectiveness will be only slight or moderate so long as the vitamin deficiency is uncorrected Digitalis is ineffective possibly because it acts on the energy utilization phase of myocardial contraction whereas beriberi heart disease is related to defective energy production Other vitamin deficiencies should also be corrected by the administration of niacin, ascorbic acid vitamin K, etc and a high caloric diet rich in protein should be given Correction of the anemia may require iron liver and/or folic acid Since infection may precipitate cardiac symptoms when there is an underlying vitamin B deficiency[219] this factor should be sought and eliminated

Pellagra

Pellagra is often combined with beriberi It is probable that the cardiovascular disturbances formerly attributed to pellagra are due entirely or chiefly to beriberi However electrocardiographic abnormalities have been correlated specifically with pellagra or niacin deficiency[211] Feil[206] noted electrocardiographic alterations in 40 per cent of 38 cases of pellagra Most commonly there was an inversion of T_1 or T or both (16 per cent), coronary T wave (13 per cent), inversion or eversion of ST, large T in at least one lead and low voltage (18 per cent) Q T was slightly lengthened in some cases There were no roentgenologic abnormalities and no pathologic lesions were discovered at postmortem examination

Fig 156 Glycogen storage disease in an adult Generalized cardiac enlargement

Similarly Porter and Higginbotham[18] observed electrocardiographic abnormalities in 10 of 25 cases of pellagra, but they interpreted the changes as non specific and due to vascular or toxic complications More recently Rachmilewitz and Braun[216] described 16 cases of pellagra in which electrocardiograms disclosed T wave inversions which reverted to normal after niacin therapy but not after thiamine administration Despite these interesting reports it is uncertain whether significant cardiac dysfunction may result specifically from pellagra

Other Vitamin Deficiencies

Cardiac disease has been attributed to a

lack of vitamin C (ascorbic acid) on the basis of experimental studies Deficiency of ascorbic acid has been especially related to the development of rheumatic fever and rheumatic heart disease [18, 213, 1] There has been no acceptable support for these relationships in humans Hemorrhagic pericardial effusions have been reported in severe cases of scurvy [98] as part of the hemorrhagic tendency Erdheim [95] described the occurrence of cardiac hypertrophy in children dying of scurvy and referred to the enlarged heart as "Barlow Herz In the absence of adequate clinical data the possibility that he was dealing with associated beriberi heart disease cannot be excluded

Cardiac disease due to vitamin D deficiency was reported by Meixner [212] Here too it is probable that the changes described were due to associated thiamine deficiency

On the other hand *excessive vitamin D* ingestion has resulted in metastatic calcification with gross and microscopic calcific deposits in arterial media myocardium and cardiac valves [200]

GLYCOGEN CARDIOMEGALY (See also p 786)

These are cases in which excessive glycogen storage in the heart leads to an increase in the size and weight of that organ [2, 6, 2, 8] Clinically they present the problem of cardiac enlargement and heart failure Sudden death may occur [7] without apparent cause (p 786) Pathologically they have been mistakenly incorporated in the motley group of cases of idiopathic hypertrophy of the heart Rhabdomyomata of the heart have been interpreted as glycogen rich muscle fiber accumulations representing a local form of von Gierke s disease (p 1070)

XANTHOMATOSIS AND HYPERCHOLESTEROLEMIA

Xanthomatosis is an hereditary disorder of lipid metabolism characterized by (1) yellowish plaques and nodules (xanthoma) over the elbows knees buttocks and over the tendons and joints of the fingers toes wrists and ankles and also xanthelasma of the eyelids (2) hypercholesterolemia (p 425) and possibly (3) xanthomatous biliary cirrhosis [34]

This type of primary xanthomatosis (xanthomatosis tuberosa) which is associated with an elevated serum cholesterol is of great cardiologic interest because of the frequency of angina pectoris coronary occlusion and sudden death in families subject to this metabolic disorder [232, 233] Intermittent claudication, due to involvement of the vessels of the extremities, may also occur However, hypertension is unusual

A characteristic feature is the early age at which these serious complications often appear [31] Thus Bloom Kaufman and Stevens[229] reported that of [redacted] children of a single family affected by this disease 4 died suddenly between the ages of 6 and 23 years, the cause of death being attributable to xanthomatous lesions in the cardiovascular system Observations at necropsy in one of the fatal cases, in which death occurred at 23 years of age showed advanced atheromatosis of the aorta and coronary arteries and myocardial degeneration of the heart Typical foam cells were seen in the microscopic lesions of the aorta

The hypercholesterolemia is of interest because of the possible relationship to the development of atherosclerosis (p 425) Hypercholesterolemia without cutaneous lesions may be found in some members of families with xanthomatosis [230] This suggests that the elevated serum cholesterol is the fundamental manifestation of the metabolic disorder [235] According to Wilkinson et al [35] the disease is inherited as an incomplete dominant xanthoma tuberosum representing the homozygous and hypercholesterolemia with xanthelasma the heterozygous abnormal The increase in blood cholesterol is endogenous, not dietary and [redacted] influenced little if at all by restriction of cholesterol intake

The *diagnosis* of familial xanthomatosis of the cardiovascular system should be considered whenever angina pectoris or coronary occlusion occurs among young adults or whenever there are characteristic xanthomatous cutaneous nodules and plaques associated with hypercholesterolemia A careful history may add confirmation by disclosing the occurrence of sudden death in siblings and parents at very early ages Members of the afflicted patient's family should have determinations of the blood cholesterol even if there are no symptoms and cutaneous lesions

ACUTE PORPHYRIA

This disease is characterized by psychic instability abdominal pain and findings resembling ileus flaccid paralyses and porphyrin in the urine with or without photosensitivity Hypertension and renal disease are frequently

associated possibly due to the arteriospasm of the general disease Goldman and Kaplan [38] reported tachycardia hypertension and T wave changes and degenerative and pigmentary changes in the myocardium *in cases of* acute porphyria Flaser and Kondo [37] reported elevations of the RT segment in lead I diminished voltage of the QRS and left axis deviation These changes disappeared during the period of remission The authors suggested that the electrocardiographic changes were due to *transient angiospasm* in acute porphyria which involved the coronary arteries as well as other blood vessels However, Crouch and Herrmann [illegible] found normal electrocardiograms in [illegible] patients with acute porphyria

GOUT

Although there is a tendency to hyperuricemia in the young individual with coronary *atherosclerosis* (p 116), the uricemia of gout has not been shown to contribute *to the de*velopment of atherosclerosis Neither is there evidence that the patient with gout is abnormally susceptible to clinical coronary *atherosclerosis* But uric acid crystals may be found in the heart muscle, cardiac valves or blood vessels *as in the* two cases reported by Traut et al [41] A tophus of the mitral valve *in* gout was reported by Bunim and McEwen [39] Cure of heart block in a patient with gout by the administration of Benemid was *attributed* to elimination of a gouty tophus in the conduction system [40]

HYPERSEROTONINEMIA

Serotonin (5 hydroxytryptamine) a product of tryptophan metabolism is produced in excessive quantities *and released* into the *blood stream* by a carcinoid of the small intestine with metastases to the liver *The serotoninemia* may be *responsible for* lesions of the pulmonic and tricuspid valves (pulmonic stenosis and tricuspid insufficiency) congestive heart failure with edema, as well as for distinctive irregular flushing telangiectasia mottled cyanosis diarrhea and asthma like symptoms [44, [illegible], 42, 45, 47, [illegible]] A simple diagnostic test has been devised based on the urinary excretion of 5 hydroxyindoleacetic *acid (5HIAA)* [46]

Chapter 43

THE HEART AND CIRCULATION IN ANEMIA

Anemia may affect the heart by direct impairment of its oxygen supply or by increasing its mechanical load through the alteration of its circulatory dynamics. When severe anemia develops acutely from rapid and profuse blood loss, symptoms of shock may dominate the picture not because of anemia but because of an insufficient cardiac output due to a deficient blood volume.

Anemia and Preexisting Heart Disease

Intense chronic anemia produces anatomic and physiologic disturbances as a rule only when the heart is already diseased, but occasional instances of failure of a normal heart purportedly due to anemia alone have been reported.[4] Anemia is particularly likely to cause serious anoxia in the myocardium which is already predisposed by severe coronary atherosclerosis or in the enlarged rheumatic heart with its exaggerated need for oxygen.

I have repeatedly observed in patients with atherosclerotic or rheumatic heart disease the precipitation of heart failure and/or coronary insufficiency by severe anemia due to a bleeding peptic ulcer or hiatus hernia, or occasionally due to a bleeding colonic or gastric neoplasm, bleeding hemorrhoids, ulcerative colitis or a hemolytic crisis.[9, 31] In such cases elevation of the level of hemoglobin is often the only effective method of eliminating the cardiac and circulatory symptoms. Care should be employed not to precipitate acute pulmonary edema by too rapid or too large transfusions of blood.[10] The use of concentrated red blood cells with minimal plasma is preferable to that of whole blood if the deficiency is due entirely to the anemia and not to inadequate blood volume. The patient should be propped up in bed during the transfusion to reduce the possibility of inducing pulmonary edema. Repeated determinations of vital capacity and venous pressure may disclose impending or actual overhydration of the lungs or subcutaneous tissues before they are discovered by physical examination.[9]

Degree of Anemia. Contrast between Chronic Anemia and Acute Hemorrhage

As a rule cardiac manifestations and circulatory disturbances appear in chronic anemias only when the anemia is very severe. According to Brannon, Merrill and associates,[11] serious disturbances did not usually occur in their patients until the hemoglobin fell below 7 gm per 100 cc, but moderate circulatory abnormalities appeared when the hemoglobin level was between 8 and 8 gm. The circulatory abnormalities result exclusively from the deficient oxygen content of the blood and are recounted below.

In acute hemorrhage the problem is quite different and relates to the reduction in circulating blood volume and the physiologic compensations to that reduction. Loss of about 500 cc of blood results in slight tachycardia, a slight fall in atrial pressure and little or no reduction in cardiac output.[15, 18] Occasionally a fall in blood pressure and collapse result from reflex vasodilatation and a consequent drop in peripheral resistance. But with more profuse rapid blood loss (1000 cc or more) the blood volume is reduced, the cardiac output is sharply diminished and the arterial blood pressure falls.[12] The clinical picture of shock develops concomitantly with intense sympathetic vasoconstriction. Later as hemodilution occurs the physiologic disturbances are complicated by those due to the anemia itself (infra).

Etiologic Types of Chronic Anemia and Circulatory Disturbance

The cardiac and circulatory disturbances are essentially identical whatever the cause of the anemia, so long as it is severe. As a rule these disturbances occur in chronic anemias for which there is no satisfactory treatment and in anemias with uncontrollable recurrent hemolytic crises. But they may also develop in curable anemias which remain untreated be-

cause of lack of facilities or ignorance on the part of the patient

In former years the anemia known as chlorosis commonly produced cardiac manifestations[4] but this anemia possibly nutritional in origin has mysteriously disappeared or has been absorbed under other classifications Pernicious anemia was long the common type of anemia associated with cardiovascular disturbances[17] [1] The discovery and wide spread use of B_{12} therapy has minimized the frequency of prolonged anemia of this kind At present sickle cell anemia is a frequent cause of cardiac and circulatory abnormalities because of the intensity of the anemia (the red blood counts are usually between 1 000 000 and 3 000 000 or less) and because of its relative chronicity and unsatisfactory response to treatment[5] Of interest also are the cases of intense chronic anemia with cardiac disturbances due to hookworm anemia studied and reported by Porter[43] Gelfand[**] called attention to the frequency of very severe anemias and consequent cardiac disability in tropical areas where medical attention is long delayed Among 42 cases of heart disease treated in a native hospital there were 7 with congestive heart failure due to anemia The hemoglobins in these patients had fallen to between 10 and 20 per cent before hospitalization

PATHOLOGIC PHYSIOLOGY

A sharp reduction in the hemoglobin and therefore in the oxygen transport power of the blood tends to produce relative tissue anoxia This deficiency is compensated by a variety of physiologic adjustments which restore an adequate oxygen supply to the tissues Remarkable as these compensations are they draw upon the circulatory reserves even when the patient is at rest In consequence despite severe anemia an adequate circulation becomes available when the patient is at rest but little or no further reserve is available to meet the demands of physical exertion or other circulatory strains Under the latter circumstances neither the heart nor other tissues may receive an adequate supply of oxygen and the patient may suffer from dyspnea weakness angina pectoris or swelling of the legs But as a rule the following circulatory compensations maintain the patient free of symptoms during ordinary activities despite severe anemia

Circulation Speed

This is accelerated in cases of severe anemia as demonstrated by Blumgart et al[8] by means of radium C I have frequently found the circulation time (calcium gluconate) in patients with hemoglobins between 6 and 8 gm to vary between 8 and 10 seconds whereas the normal circulation time varied between 12 and 13 seconds In general, the velocity of blood flow increases in proportion to the degree of anemia[49] [52] The circulation speed is not noticeably affected until the hemoglobin falls below 9 gm or the red blood count below 3 000 000 per cc, pronounced acceleration occurs only after the hemoglobin level is less than 7 gm[8] Because of the increased velocity of the circulation the quantity of blood passing through the tissues in a given time may be increased 100 per cent or more This permits the tissues to abstract as much oxygen in a unit of time as they would if the hemoglobin content were normal The findings with the venous occlusion plethysmographic method provide quantitative measurements of the increased blood flow through peripheral tissues[1]

The *mechanism* by which the circulation speed is increased is probably a peripheral one The tissue anoxia which develops with the onset of severe anemia leads to the accumulation of acid metabolites which by direct local or reflex action cause peripheral vasodilatation This concept is supported by the finding of greatly diminished peripheral resistance in severe chronic anemia[49] [11] [**] Such vasodilatation permits a more rapid venous return to the heart as if there were multiple peripheral arteriovenous shunts Analogous mechanisms account for the rapid circulation rate of arteriovenous fistula hyperthyroidism beriberi and pregnancy In addition to this effect the factor of diminished viscosity due to the low red blood count contributes significantly to the acceleration of circulation

In cases of intense chronic anemia complicated by congestive *heart failure the circulation* speed may be normal The slowing effect of heart failure neutralizes the acceleration due to anemia the exact resultant depends on the degree of each In the presence of congestive heart failure the finding of a normal circulation time should suggest the possibility of an associated severe anemia as well as other conditions which increase the velocity of blood flow

Oxygen Utilization

Compensation for deficient oxygen content of the blood due to severe anemia may be effected not only by an increased speed of circulation but also theoretically, by a more complete abstraction of oxygen from the blood by the tissues Actually the absolute oxygen utilization per unit of blood is diminished, i e the arteriovenous oxygen difference is less than normal [11, 45] But relative to the amount of hemoglobin oxygen available, the percentage of oxygen utilization is enhanced Normally the arterial oxygen content reaching the tissues is 19 volumes per cent and the venous oxygen content leaving the tissues is about 14 volumes per cent Therefore 5 volumes per cent of oxygen have been abstracted or 5/19 (26 per cent) of the arterial oxygen In a patient with 6 gm per 100 cc of hemoglobin the arterial oyxgen content is about 8 volumes per cent whereas the venous oxygen content may be 5 volumes per cent The absolute arteriovenous oxygen difference is 3 volumes per cent which is less than normal but the percentage of available oxygen utilized is 3/8 (37 5 per cent) which is more than normal The reduction in arteriovenous oxygen difference (i e , the absolute quantity of oxygen abstracted from a unit of blood) may be due, among other factors, to the speed with which the blood rushes past the tissues

The arterial oxygen saturation may be normal or reduced [44] There is evidence of a significant increase in the alveolar arterial gradient with a reduction in arterial oxygen tension [46]

Cardiac Output (Minute Volume)

That the cardiac output is greatly augmented in cases of severe anemia was demonstrated by Richards and Strauss[45] and Stewart et al ,[49] among others Similar findings were more recently noted by the direct Fick method catheterization of the heart being employed to obtain mixed venous blood [43, 11] Brannon Merrill and associates[11] found the cardiac index to be 6 5 (liters per sq meter body surface area) when the hemoglobin level averaged below 5 gm , 4 7 when the hemoglobin ranged between 5 and 7 gm 4 0 when the hemoglobin was between 7 and 9 gm and 3 1 or about normal when it ranged between 9 and 13 gm Not only is the cardiac output augmented, but also there may be excessive increase in response to exercise [54]

The increased cardiac output results essentially or exclusively from the accelerated speed of the circulation and the consequently augmented venous return To a variable extent the increase in minute volume is mediated by an *increase in the cardiac rate* but the stroke output is also substantially elevated Following transfusions and consequent increase in the hemoglobin level, the circulation speed diminishes and the cardiac output falls When severe chronic anemia is complicated by congestive heart failure, the cardiac output may nevertheless substantially exceed the normal (high output failure) Presumably, although the cardiac output is above normal, it is deficient relative to the needs of the tissues

The *work of the heart* may not be increased despite the augmented cardiac output, according to the studies of Stewart, Crane and Deitrick[49] in 5 cases of pernicious anemia Owing to peripheral vasodilatation the peripheral resistance is greatly diminished and the blood pressure is moderately lowered[4] Peripheral vasodilatation i e diminution in peripheral resistance, is not uniform throughout the tissues Whereas the cerebral, coronary and skeletal muscle blood flow[29] is increased owing to diminished peripheral resistance, the renal[10] and cutaneous blood flow is reduced Studies of varying degrees of anemia induced in the open chest dog disclosed an increased coronary flow per unit of left ventricular work [16] Decreased oxygen carrying capacity was largely compensated by an increased coronary flow resulting from a diminished coronary resistance The work of the heart is proportional to the cardiac output and the mean arterial pressure, the reduction in blood pressure with severe anemia may largely neutralize the effect of the increased cardiac output The fall in viscosity likewise diminishes the work of the heart

There is no evidence that the deleterious effect of anemia on the heart is due to the mechanical strain of an increased cardiac output It is more probable that the heart suffers directly because of anoxia when the limits of coronary dilatation are reached with severe anemia, no further increase in coronary blood flow is then possible to compensate for the extreme reduction in oxygen capacity of the anemic blood Compensation may then be effected only by cardiac dilatation and hypertrophy In the presence of coronary stenosis the ability to increase the coronary flow required to compensate for anemia is greatly restricted

The Circulating Blood Volume

The blood volume in anemia is slightly diminished chiefly due to the reduction in the number of erythrocytes (low hematocrit [5]) The plasma volume may be normal but often it is elevated [9] Since the total blood volume is diminished or normal it is apparent that the augmented venous return and cardiac output in severe anemia result exclusively from the increased speed of circulation In cases of severe anemia complicated by congestive heart failure the plasma volume may be greatly increased even to the point of causing an increase in total blood volume [9] This increase may be viewed as a compensatory mechanism utilized to maintain the cardiac output at required levels

The *blood pressure* tends to depression of both the systolic and diastolic levels but especially of the latter The pulse pressure tends to increase [5]

The *venous pressure* is not elevated when the patient is at rest in the absence of congestive heart failure

The *vital capacity* of the lungs is diminished The respiratory minute volume and residual air are increased [7] The explanation for this is uncertain An increased blood flow through the lungs has been held responsible but this explanation is unclear

PATHOLOGY

Severe longstanding anemia is associated with cardiac dilatation and hypertrophy (see below) In cases of anemia due to acute hemorrhage the musculature is usually firm in cases of chronic anemia the musculature is flaccid

Fatty degeneration of the heart muscle is characteristic of intense chronic anemia It is distributed in a striking fashion perpendicular to the fibers of the trabeculae and papillary muscles producing the yellow streaking known as *tigering of the heart* The fatty change is presumed to result from disturbances in cellular metabolism due to oxygen deficiency While fatty degeneration of the myocardium is characteristic of severe anemia it may also be caused by a variety of infectious processes and toxic substances as well as extensive severe coronary artery disease

Of special interest are the changes in the heart observed in instances of intense anemia due to gastrointestinal bleeding in young individuals In such cases I have observed diffuse focal or confluent areas of myocardial necrosis chiefly in the subendocardial myocardium of the left ventricle and especially of the papillary muscles [21] The coronary arteries may be normal The subendocardial regions have the poorest blood supply and suffer most from anoxia when there is a reduction in blood flow or in the oxygen content of the blood Similar subendocardial necroses have been produced experimentally in rabbits by bleeding [13]

CLINICAL FEATURES RELATED TO THE CIRCULATION IN ANEMIA

Severe anemia and the compensatory mechanisms which it invokes are responsible for a variety of clinical manifestations referable to the cardiovascular system These may closely simulate the symptoms and signs usually due to organic heart disease It is not uncommon for heart disease and heart failure to be diagnosed because of such manifestations due entirely to anemia alone On the other hand severe anemia may precipitate or intensify heart failure or coronary insufficiency in the presence of preexisting cardiac or coronary disease For this reason it is often necessary to correct the anemia by transfusion or specific therapy in order to evaluate the extent to which anemia is partly or entirely responsible for the symptoms In this connection it is well to recall that anemias of nutritional origin may be associated also with vitamin B deficiency and that the latter may also contribute to the development of cardiovascular symptoms (p 1037)

Cardiac Enlargement

The outstanding cardiac manifestation of severe chronic anemia is enlargement of the heart This was demonstrated experimentally in dogs rendered anemic by bleeding [15] Cabot and Richardson[13] reported significant cardiac hypertrophy in 18 of 19 hearts of patients who had died of pernicious anemia In one case the heart weight was 710 gm The possibility of concomitant cardiovascular disease contributing to the development of the hypertrophy may be properly considered in such cases since insufficient data are presented to evaluate the care with which the coronary arteries were studied at that time (1908 to 1919)

The most impressive evidence of cardiac enlargement in severe anemia is presented by roentgenologic observations (Fig 157A) Ball[3] demonstrated by serial films that the cardiac

enlargement associated with anemia disappeared following relief of the anemia (Fig 157*B*) Porter[43] observed cardiac enlargement regularly in his cases of severe anemia due to hookworm infestation In most of these the enlargement was reversible, as demonstrated by a reduction in the size of the cardiac silhouette following therapy But in longstanding cases the size of the heart remained unaltered an observation which led Porter to conclude that the enlargement in these cases

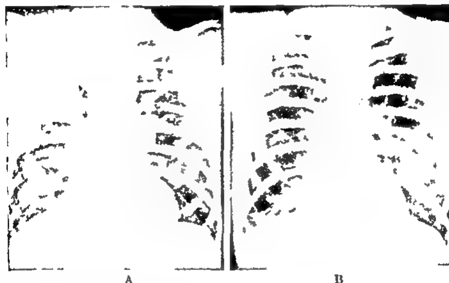

Fig 157 *A* Generalized cardiac enlargement associated with anemia probably due to sulfonamides given for pneumonia of right upper lobe
B Recession of cardiac silhouette to normal in three weeks as anemia was corrected

was due to hypertrophy Ellis and Faulkner[19] noted cardiac enlargement by roentgenologic examination in 20 of 38 cases of anemia The incidence of enlargement was greater in the group with hemoglobins below 50 per cent than in the group with hemoglobins above that level Regression of enlargement followed elevation of the hemoglobin by appropriate treatment Usually the cardiac silhouette reverted to normal size in three to twelve weeks

The *mechanism of cardiac enlargement* in anemia is uncertain That the work of the heart may not be significantly enhanced has already been mentioned (p 1048) But further investigations in cases of very intense anemia may disclose a greater work strain than in the small series of cases studied by Stewart and his associates [illegible] By exclusion it appears likely that the enlargement is due to the direct effect of anemia on the heart This may result in myocardial inefficiency due to anoxia with a tendency to reduction in the cardiac output The accumulation of blood in the chambers results in stretching of the fibers (dilatation), more forceful contraction and restoration of the needed output (p 86) When an adequate cardiac output cannot be maintained by means of this dilatation (and perhaps subsequent hypertrophy) other compensatory mechanisms are invoked which eventually lead to the clinical syndrome of heart failure

Cardiac Murmurs

The occurrence of cardiac murmurs in anemia has long been common knowledge Anemia is the classic cause of the so-called functional cardiac murmur The murmur associated with anemia is almost always systolic in time and heard either over the pulmonic area in the second or third interspace to the left of the sternum or in the apical region [illegible] The murmur may be audible throughout the precordium but then it is usually loudest in one of these two areas Occasionally the systolic murmur is heard best over the aortic area Radiation of apical systolic murmurs to the axilla or back in children has been described by Parsons and Wright[39]

Of greater interest is the occasional appearance of a diastolic murmur in patients with anemia but without organic heart disease [illegible] Such functional diastolic murmurs were heard in 6 of 39 patients with pernicious anemia studied by Goldstein and Boas[4] The diastolic murmur has a blowing quality and may occur early in diastole and be localized to the left

border of the sternum like the murmur of aortic insufficiency But late diastolic or presystolic murmurs have also been described which are heard best at the apex and simulate the murmur of mitral stenosis[24, 6] Despite the above mentioned figures, it should be emphasized that diastolic murmurs are relatively rare in cases of anemia and have been heard only when the anemia is extremely intense and chronic as in cases of sickle cell anemia and formerly in cases of pernicious anemia before specific therapy was available Even in such cases the impression of a diastolic murmur may be created by a presystolic gallop or by a booming first sound as in hyperthyroidism

The systolic murmurs heard in cases of anemia have been attributed to the speed of the blood flow and to dilatation of the ventricular chambers and atrioventricular rings Diastolic murmurs have been explained as being due to dilatation of the pulmonic or aortic rings and to incomplete opening of the mitral valve associated with flaccidity of the papillary muscle[40] When severe anemia is associated with greatly increased flood flow diastolic murmurs may be due to functional stenosis of the mitral or tricuspid valve Both systolic and diastolic murmurs are variable in occurrence appearing and disappearing with intensification or relief of the anemia respectively

Electrocardiographic Changes in Anemia

Many observers have reported no significant electrocardiographic changes[54] but others have reported consistent changes when the anemia is very intense[51, 6] The common abnormalities are[40] depression of the ST segments and flattening or inversion of the T waves findings suggestive of myocardial anoxia Similar ST deviations and alterations of the T wave attributed to coronary insufficiency have been observed after an acute loss of blood[47, 37] Occasionally low voltage of the QRS complexes and prolongation of the P R interval have been observed in cases of chronic anemia

The electrocardiographic abnormalities usually disappear when the anemia is relieved[19]

Heart Failure in Anemia

Dyspnea on exertion tachycardia and palpitation edema of the legs and cardiac enlargement occur commonly in severe chronic anemia and the combination of these symptoms and signs may be the basis of a mistaken diagnosis of congestive heart failure Enlargement of the liver as in cases of sickle cell anemia may add to the resemblance The absence of orthopnea pulmonary congestion and venous engorgement and the finding of a normal venous pressure are the bases for excluding heart failure as the cause of the exertional dyspnea and the subcutaneous edema

More study is desirable to illuminate the mechanism by which the various circulatory symptoms are initiated Breathlessness occurs as a rule only with exertion It may be that there is no pulmonary congestion at rest but that it appears during exercise because the left ventricle is unable to handle the increased venous return Reduced arterial oxygen capacity decreased oxygen saturation of the blood during effort and accumulation of blood lactic acid[7] may be contributory factors

The cause of the edema is also obscure since it may be present despite a normal venous pressure Possibly edema develops because of recurrent transient elevations of venous pressure following physical exertion during the course of the day Hypoproteinemia may be a contributory factor in some cases But Strauss and Fox[50] found no relation between edema and the plasma protein in their anemic patients The degree of water retention and visible edema following salt ingestion in their cases varied inversely with the hemoglobin level The venous pressure was normal before salt administration but no mention is made of venous pressures following the ingestion of salt and the appearance of edema Increased capillary permeability due to anoxia has also been suggested as a cause of edema in cases of anemia but it is doubtful whether the degree of anoxia is sufficient to affect vascular permeability Henry et al[37] found evidence of increased capillary permeability as indicated by protein in capillary filtrate after venous occlusion of an extremity but only when there was severe local anoxia as indicated by an oxygen saturation of the venous blood of 15 to 25 per cent or less Comparable low oxygen contents of the venous blood occur in cases of severe anemia but it is questionable whether these observations following venous occlusion can be applied to cases of anemia

But actual heart failure may complicate severe anemia Then dyspnea may occur at rest or on slight exertion orthopnea or cardiac asthma appear occasionally Rales at the bases of the lungs hepatic enlargement and tenderness subcutaneous edema, engorgement

of the superficial veins and elevation of the venous pressure may all be present In such cases it is a good rule to consider the likelihood that there is underlying cardiac disease although heart failure due to uncomplicated anemia has been noted

Angina Pectoris and Anemia (See also p 452)

Angina pectoris has been observed with varying frequency in reported series of cases of severe anemia [54, 41, 3] Pain of cardiac origin has been attributed to the lower oxygen content of the anemic blood Intermittent claudication of the lower extremities, observed by Pickering and Wayne[41] in some extremely anemic patients was attributed to similar anoxia of the calf muscles The relation of anemia to angina pectoris has been discussed above (p 1046) It appears likely that anemia is only a contributory factor in the production of angina pectoris usually in patients with underlying severe coronary atherosclerosis However angina pectoris attributed to anemia per se has been reported [13]

THE HEART IN SICKLE CELL ANEMIA

The described cardiovascular disturbances may occur in any longstanding intense anemia But sickle cell anemia merits special discussion because

(1) It is probably the commonest form of anemia observed today in which the degree of anemia is intense enough and of sufficient duration to produce cardiac symptoms,

(2) It is frequently complicated by symptoms which lead to a mistaken diagnosis of rheumatic fever rheumatic or congenital heart disease or subacute bacterial endocarditis

(3) It is occasionally associated with disseminated occlusions of the small pulmonary arteries which may result in pulmonary hypertension and chronic cor pulmonale[56, 3, 55] (p 982)

The occurrence and frequency of cardiac manifestations in sickle cell anemia have been discussed by Anderson and Ware,[2] Klinefelter,[32] Winsor and Burch[55] and by Grover [5] among others Winsor and Burch reported that 40 patients with heart disease due to sickle cell anemia were admitted to the Charity Hospital New Orleans in a single year and that heart disease due to this cause was more frequent among their Negro patients than that due to beriberi myxedema, pernicious anemia or trauma

Hemodynamic studies[24] have disclosed a high cardiac output and frequent reduction in arterial oxygen saturation, with a fall in oxygen saturation during exercise in many cases

Significant cardiac enlargement was present in at least 75 per cent of the cases of sickle cell anemia observed by Anderson and Ware and in 95 per cent of those studied by Winsor and Burch [55] Both the left and right ventricles are usually enlarged The pulmonary salient of the cardiac silhouette is often prominent and the left border is straightened but the left atrium is not enlarged [2, 55] Cardiac murmurs are heard in almost all cases Most often they are systolic in type and heard over the mitral or pulmonary areas but systolic murmurs may be audible over any part of the precordium Occasionally a diastolic murmur may also be audible over the mitral, aortic or pulmonic regions The second pulmonic sound is often accentuated and may be split Dyspnea is common but orthopnea and cardiac pain are rare Hepatomegaly occurs frequently either as an intrinsic element of the disease or due to chronic passive congestion Pulmonary infarction, pulmonary occlusion of the small arteries and pulmonary endarteritis and pulmonary edema occur frequently Electrocardiographic abnormalities are non specific and inconstant Right axis deviation is rare despite the frequency of right ventricular dilatation and hypertrophy Circulatory deaths are frequent owing to the sensitivity of patients with sickle cell anemia to anoxemia and shock, anesthesia and surgical procedures infection and loss of blood

Of special importance is the frequency with which cardiac findings due to sickle cell anemia are interpreted as being due to rheumatic or congenital heart disease [3] There are several reasons for this error Sickle cell anemia is the commonest reported cause of a functional diastolic murmur Even when there is only a systolic murmur organic heart disease is usually suspected because almost always significant cardiac enlargement is associated An apical systolic murmur, often radiating to the axilla an accentuated second pulmonic sound and cardiac enlargement with straightening of the left border of the heart on fluoroscopic examination strongly suggest rheumatic mitral valvular disease This diagnosis seems to be supported by the history of attacks of pain in the extremities especially about the joints which may be warm and swollen In

addition, fever is common during these attacks and leukocytosis is usual as in other hemolytic anemias During the acute attacks of pain and fever the finding of cardiac murmurs suggests that the above symptoms are due to recurrent acute rheumatic fever Occasionally a diagnosis of subacute bacterial endocarditis is made because of the combination of fever with a cardiovalvular lesion Occasionally, because of the youth of the patient with sickle cell anemia and because of the absence of a history of rheumatic fever a diagnosis of congenital heart disease is made

Diagnosis and Differential Diagnosis of Sickle Cell Anemia and Heart Disease

The possibility of sickle cell anemia should always be investigated in any young Negro suspected of having organic heart disease Sickling of the red blood cells should be sought also if cardiac murmurs and enlargement are discovered in any patient with a red blood count of less than 3 500 000 or a hemoglobin of less than 10 gm Differentiation from rheumatic mitral disease may be aided by the absence of left atrial enlargement in sickle cell anemia even when the pulmonary salient is prominent and by the usual absence of right axis deviation Salicylates are unlikely to relieve the joint pains and swelling The finding of ulcers or the scars of ulcers near the ankles should also suggest sickle cell anemia in young colored individuals suspected of heart disease The coexistence of rheumatic heart disease and sickle cell anemia has been described[4] and this possibility should be carefully considered

LEUKEMIA

Leukemic infiltrations of the heart were found in 43 of 123 fatal cases of leukemia [59] In chronic forms of leukemia associated with severe anemia cardiac enlargement systolic murmurs tachycardia and palpitation exertional dyspnea and subcutaneous edema may occur as in any other type of anemia Occasionally there is frank evidence of congestive heart failure [57] In such cases a diagnosis of heart disease and heart failure is usually made without recognition of the causative leukemia

Electrocardiographic changes in cases of leukemic infiltration of the heart include sinus tachycardia ST segment depression T wave inversion in limb and precordial leads prolongation of the P R interval and premature contractions [57]

Leukemic infiltrations of the pericardium with pericardial effusion which is often hemorrhagic have been described [illegible] Roentgen ray therapy in a patient with heart block presumably due to leukemic infiltrations resulted in temporary disappearance of the conduction defect [58]

CARBON MONOXIDE POISONING

Carbon monoxide poisoning like anemia, reduces the oxygen transport capacity of the blood In addition the formation of carboxyhemoglobin may interfere with the dissociation of the remaining oxyhemoglobin Cardiac damage results from myocardial anoxia and depends on the severity and duration of the carboxyhemoglobinemia Direct toxic damage to the heart muscle has also been claimed [62] Concentrations of 25 to 35 volumes per cent of carbon monoxide in the blood are necessary before clinical manifestations appear The importance of carbon monoxide poisoning as an industrial and domestic hazard is indicated by its position second in frequency only to auto injuries as a cause of accidental and suicidal death

Clinical manifestations are most commonly referable to the central nervous system but our interest here lies particularly in the cardiac symptoms due to carbon monoxide poisoning Such neurologic and cardiac symptoms may arise from prolonged exposure to concentrations of 0 01 to 0 02 per cent of carbon monoxide or they may represent the residua or sequelae from acute asphyxia due to exposure to much higher concentrations of the gas It has been emphasized that chronic disease of the nervous system and heart may develop even when there is no loss of consciousness from the intoxication

Experimental carbon monoxide poisoning of animals has resulted in vascular lesions consisting of small hemorrhages and perivascular infiltrations as well as focal areas of necrosis in the heart [illegible, 76, illegible] Similar myocardial necrosis has been observed in humans who have succumbed following carbon monoxide intoxication [73, 68, 70, 61] The lesions in the heart are confined essentially to the left ventricle and papillary muscle and more particularly to the subendocardial region These lesions resemble those observed following prolonged coronary insufficiency without coronary occlusion [55, 57] Coronary thrombosis following petrol-exhaust gas was reported by Hadley [illegible] and rupture of

the heart following coal gas poisoning by Pulvertaft.[74] In some of the reported cases which concern older individuals it is difficult to apportion the relative influence of preexisting coronary atherosclerosis and of carbon monoxide in the production of myocardial lesions.

Clinical evidence of myocardial involvement may appear promptly or several days after the acute intoxication by carbon monoxide. Or it may appear gradually after *prolonged or repeated exposure*. The chief symptoms are angina pectoris and cardiac irregularity.[64, 71, 7] Palpitation, tachycardia, precordial oppression or pain, exertional dyspnea and weakness have been noted. An attack of acute coronary occlusion has been attributed to carbon monoxide poisoning.[6] Atrial fibrillation may be precipitated. When cardiac enlargement is observed, the presence of some preexisting cardiovascular abnormality is likely. *The relative importance of such* underlying disease as the cause of the patient's cardiac symptoms and signs may present a medicolegal problem if the patient attempts to collect insurance, compensation or personal damages following carbon monoxide poisoning. As a rule, symptomatic recovery from the cardiac disturbances is complete within a few weeks or months but chronic organic heart disease may result from carbon monoxide intoxication according to Beck and Suter.[6]

Electrocardiographic changes have been repeatedly observed but they may be absent even when the carbon monoxide poisoning is severe enough to be fatal.[74, 77] The most frequent abnormalities are slight ST interval depressions and lowering or flattening, rarely inversion, of the T waves, the so-called pattern of coronary insufficiency.[77] Paroxysmal atrial fibrillation and premature beats are not rare. Occasionally lowering of the voltage of the QRS complexes, intraventricular block or prolongation of the P-R interval has been observed. As a rule the electrocardiogram reverts to normal within two months, but occasionally the abnormalities persist.

POLYCYTHEMIA

Polycythemia (erythremia) may be a consequence or a cause of cardiovascular disease. Polycythemia is a characteristic finding with certain congenital cardiac lesions such as the tetralogy of Fallot, in which there is a large venous-arterial shunt. It is also observed in cases of severe chronic pulmonary heart disease (Ayerza's syndrome) and not infrequently in cases of very severe chronic heart failure such as that associated with tricuspid stenosis (p. 714). In the presence of polycythemia, the possibility of these causative forms of heart disease should be considered. In all of these examples the polycythemia is viewed as a compensatory response to a sharp reduction in the oxygen saturation of the arterial blood.

Polycythemia, Vascular Thromboses and Coronary Disease

Polycythemia is frequently complicated by circulatory disturbances due to increased viscosity and slowing of the blood. Arterial and venous thromboses occur particularly in the cerebral and peripheral vessels.[85] Not infrequently also, polycythemia is associated with thrombosis of a coronary artery and myocardial infarction. It is likely that in such instances the polycythemia is a contributory cause and not merely coincidental with the coronary occlusion. The occurrence of coronary thrombosis in cases of polycythemia vera has been documented by Christian,[81] Oppenheimer,[87] Boyd[79] and by Dameshek and Henstell[8] among others. Tinney, Hall and Giffin[83] found clinical evidence of coronary disease in 10 (6 per cent) of 163 cases of polycythemia vera. Four of these patients with coronary disease had angina pectoris. One of these, a woman 48 years old, suffered a coronary occlusion in the absence of hypertension or diabetes.

Polycythemia and Absence of Heart Failure

Polycythemia is associated with a greatly augmented blood volume which might be considered to produce an unusual load on the heart and congestion of the viscera. Nevertheless, heart failure is a rare complication except when there is associated myocardial infarction or hypertensive and atherosclerotic heart disease. The increased blood volume is due essentially or exclusively to the increased cell volume and there is a consequent increase in viscosity and a corresponding slowing of the blood stream. The venous return and cardiac output are normal[85, 84] since the effect of the increased blood volume on the venous return is neutralized by the slowing of the circulation. The work of the heart is unaltered except when there is *hypertension*. Similarly cardiac enlargement is notably absent when there are no complications.[80]

Polycythemia and Hypertension

The combination of polycythemia vera and hypertension has been segregated as [redacted] separate syndrome[83] but it [redacted] more probable that the hypertension is [redacted] coincidental abnormality Brown and Giffin[80] found the average blood pressure in 14 cases of polycythemia vera to be 138 mm Hg systolic and 90 diastolic Tinney and his associates[88] found the systolic blood pressure above 150 mm Hg in about 40 per cent and above 180 in about 10 per cent of their 163 cases of polycythemia vera It is uncertain whether these blood pressures exceed those to be found in subjects of similar age groups without polycythemia vera

Chapter 44

TRAUMATIC HEART DISEASE

Traumatic heart disease includes the anatomic lesions and functional disturbances of the heart which result from external injury or from an intense unusual physical exertion. According to the causative mechanism, cardiac trauma may be classified as follows: (1) penetrating lesions of the chest wall, including those involving foreign bodies in the heart; (2) non-penetrating lesions; (3) physical strain. In addition there are instances of so-called spontaneous rupture, perforation or tear of a cardiac structure in which physical strain may be a *significant contributory factor*.

HEART DISEASE DUE TO PENETRATING LESIONS

Since Rehn[83] successfully sutured a stab wound of the human heart in 1896, numerous similar reports have attested to the curability of penetrating cardiac lesions when the diagnosis is made early and proper surgical repair instituted rapidly. In this country interest in penetrating wounds of the heart has been stimulated in great measure by the reports of Bigger,[1] Elkin,[7] Beck[10] and Harken.[29]

In civilian life, penetrating wounds of the heart result usually from stabbing by knife and occasionally from bullet wounds. Other sharp instruments such as the ice pick, stiletto or needle[25] may be responsible. Needle wounds of the heart may occur accidentally or during pericardial aspiration or intracardiac injections of epinephrine.[7] In warfare, penetrating cardiac injuries are usually due to bullet wounds or shell fragments. Penetrating wounds of the heart may result indirectly when shattered glass or splinters perforate the chest wall in auto or plane accidents or when the heart is torn by the sharp ends of broken ribs.

The usual site of entrance of the penetrating object is the precordium, but occasionally cardiac injury results from penetrating wounds elsewhere in the chest wall or even in the neck, abdomen or pelvic region. Of special interest are the lesions associated with *foreign bodies in the heart*[91] such as needles, bullets and shell fragments, which may enter the heart directly or as emboli from a nearby or distal vessel. The foreign body may lodge in a peripheral vein and reach the cardiac chambers by way of the venae cavae or pulmonary veins.[30, 40, 41] Sharp foreign bodies which accidentally reach the esophagus may perforate its wall and thence lacerate *or perforate the heart. McCartney and* Drummond[71] reported a case of gunshot wound of the liver in which the foreign body entered an hepatic vein, reached the right side of the heart and lodged in the right ventricle.

PATHOLOGY

Any portion of the heart may be injured by the penetrating object. Injury to the pericardium alone may give rise to a fibrinous pericarditis or pericarditis with effusion. The concomitant introduction of infectious agents may lead to a purulent pericarditis. The anterior surface of the right ventricle is the most commonly involved portion of the heart, but the right atrium and the left ventricle are also wounded frequently. The intrapericardial portions of the great vessels may be perforated. Traumatic aorto-pulmonary fistula has been reported.[3] Injury to a coronary artery, especially the anterior descending branch of the left coronary, is a common complication of cardiac wounds.[33-38, 99] Although uninjured, the coronary artery may have to be ligated during cardiac suture. Perforation of the myocardium, great vessels or coronary artery is followed usually by hemopericardium. Coronary arterial perforation and thrombosis may be associated with myocardial infarction. The interventricular septum may be injured[19, 26] and the atrio-

ventricular conduction system impaired or interrupted Occasionally, valvular cusps, chordae tendineae or the papillary muscles are perforated or torn with consequent valvular insufficiency and cardiac strain

A ventricular or atrial thrombus may develop at the site of injury or at the site of lodgment of a foreign body Cerebral, pulmonary or peripheral embolization may result from such mural thrombi or from passage of migrating foreign bodies In the majority of cases the foreign bodies lodge in the pericardium or myocardium without further migration Occasionally such a foreign body causes local myocardial injury, hemorrhage and hemopericardium local myocardial abscess or a purulent pericarditis or mediastinitis

CLINICAL FEATURES

The symptoms and signs associated with penetrating lesions of the heart are caused by hemorrhage, acute cardiac tamponade, fibrinous or suppurative pericarditis contusion or infarction of heart muscle valvular rupture or embolism Death may occur suddenly from ventricular fibrillation or ventricular standstill If treatment is delayed death often ensues in a few hours after the injury, due to cardiac compression or exsanguination

Usually the patient when first seen presents some degree of shock from loss of blood, cardiac compression or both He may be stuporous or unconscious confused or delirious Tachycardia a weak rapid pulse, tic tac heart sounds (embryocardia) restlessness and cold moist skin are noted commonly Pallor, a fall in hemoglobin and leukocytosis result from an acute massive loss of blood Sometimes circulatory insufficiency is due not to loss of blood or cardiac compression but to a reflex arteriolar dilatation and consequent reduction in blood pressure [7]

With the rapid development of hemopericardium the heart is compressed, diastolic filling is restricted, the venous inflow is retarded and the cardiac output is sharply curtailed [96] These physiologic disturbances are expressed clinically by a falling blood pressure and pulse pressure, a rising venous pressure, a quiet heart (small excursions fluoroscopically) and a small and paradoxical pulse There may or may not be dyspnea or cyanosis Eventually the frank picture of circulatory shock unfolds Not infrequently the bleeding is moderate and slow and many hours elapse before there is evidence of cardiac tamponade or other signs of cardiac injury There may be a symptom free interval with normal activity prior to circulatory collapse from hemorrhage or cardiac tamponade Sometimes hemopericardium may be delayed for as long as 6 to 22 days after a stab wound to the heart [68]

Pericarditis may be signalled by precordial pain, a friction rub or by signs of pericardial effusion (p 593) If infection develops fever appears and there are progressive signs of cardiac tamponade due to purulent pericarditis

Valvular tears or rupture of the chordae are denoted by loud, rough murmurs and by progressive cardiac insufficiency Injury to a coronary artery usually causes hemorrhage hemopericardium and cardiac tamponade Subsequent spontaneous occlusion or ligation during surgical repair may cause myocardial infarction, sometimes with classic electrocardiographic signs of infarction but without apparent clinical symptoms of that condition

Embolization with resultant hemiplegia pulmonary infarction or acute cor pulmonale or peripheral vascular occlusion and gangrene may result from local mural thrombi at the site of the penetrating lesion or more often from migrating intravascular foreign bodies

Roentgenology

Roentgenologic examination may reveal an enlarged cardiac silhouette due to hemopericardium, but often the hemorrhagic effusion is too small to affect the size of the cardiac shadow The fluoroscopic examination which is of special value discloses an almost complete absence of pulsation during the stage of cardiac tamponade It is also essential for the recognition and localization of intravascular and intracardiac foreign bodies In addition the roentgenologic examination may disclose associated intrathoracic lesions such as fractured ribs hemothorax, pneumothorax and extensive pulmonary hemorrhage

The Electrocardiogram

Electrocardiographic tracings from patients with stab and gunshot wounds of the heart have been published by many authors, but of the most comprehensive reports are those of Wood,[88] Solovay, Rice and Solovay,[88] Herve and Forero and Noth,[75] Kapp and Graham[41] and Biber and Limbeck [11] In the first hours after the injury and before operation there is definite evidence of cardiac involvement in most cases This evidence consists of electro-

cardiographic signs of pericarditis bundle branch block or of myocardial infarction Pre cordial leads may disclose significant abnormalities when none are present in the standard leads[22] However, minor RST deviations and T wave alterations are non specific and may be observed in thoracic wounds without cardiac injury

In the first few postoperative days, the electrocardiogram usually depicts changes associated with pericarditis whatever the site of the wound and whether or not a coronary artery has been injured or ligated during suture A serofibrinous pericarditis is an almost constant sequel of surgical exploration of a cardiac wound There are characteristic RT elevations in leads I and II or in all standard leads As in other forms of pericarditis the elevated RT segment is concave upward while in myocardial infarction it is convex upward

Gradually after one or more weeks the T waves are flattened and later become fully inverted The T wave inversions may persist for many months or years[75] but usually they revert to normal after three months Definite localizing electrocardiographic signs directly due to a left or right ventricular injury may be seen very early before they are masked by the pericarditis or after three or more months when the pericardial signs have disappeared These localizing signs consist of QT patterns similar to those seen with ventricular infarcts or occasionally of evidence of bundle branch block When an injury or suture occludes the anterior descending branch of the left coronary artery there may be a Q_1T_1 pattern due to infarction of the anterior wall of the left ventricle or possibly to a left ventricular wound without coronary artery involvement Multiple precordial leads may reveal localizing signs as evidenced by T wave inversion in one or more leads The important point to emphasize is that electrocardiographic changes represent the most constant evidence of cardiac involvement in penetrating chest wounds their subsidence or persistence may be a reliable index of the functional or organic basis of symptoms which remain for a long time after operation They are less reliable for localization of the exact site of injury

DIAGNOSIS

It is usually simple to diagnose a penetrating wound of the heart if due regard is given to the history of the injury the site of entrance of the penetrating object in the precordial region and the clinical manifestations of cardiac tamponade Greater diagnostic difficulty is encountered when the penetrating object reaches the heart through some point removed from the precordium Then cardiac involvement may be suspected from symptoms and signs of hemopericardium (see pericarditis with effusion p 593 and cardiac compression, p 594) or from loud murmurs a pericardial rub, heart block or congestive heart failure

The association of a stab or gunshot wound of the chest with electrocardiographic changes suggesting myocardial infarction or pericarditis is also diagnostic of cardiac injury The presence of ST and T wave abnormalities following a penetrating chest wound denotes cardiac injury concordant ST elevations and T wave inversions in leads I and II or in all standard leads denote pericarditis not involving the coronary artery, reciprocal ST elevation and depression in leads I and III with inversion of only T_1 or T_3 denote coronary artery injury[6]

It is important to seek and diagnose traumatic lesions associated with that of the heart especially hemothorax hemopneumothorax sucking wounds of the chest and abdominal wounds[79]

In cases of a foreign body in the heart angiocardiographic examination is essential for exact localization[26]

PROGNOSIS AND TREATMENT

Many patients succumb from exsanguination shock and possibly ventricular fibrillation or cardiac standstill before reaching the hospital

Operative intervention was formerly recommended in most cases of penetrating wounds of the heart[27, 8] In recent years there has been a trend toward conservative (non surgical) therapy in most cases[■] In general conservative therapy is maintained when hemorrhage is moderate or slight when there is no evidence of cardiac tamponade or when the signs of tamponade diminish following medical treatment *Pericardial aspiration* is performed promptly for cardiac tamponade and repeated if necessary[8, 9] Operation is indicated when there is severe persistent hemorrhage (free pericardiopleural communication) and when there is evidence of cardiac

tamponade which is not relieved by pericardial aspiration or recurs rapidly after aspiration [87]

When the patient is first seen measures are instituted to counteract hemorrhage and shock Transfusions of compatible whole blood should be given or plasma dextran solution or other fluids may be administered by venoclysis if there is a delay in obtaining whole blood Intravenous infusions may improve the cardiac output and clinical condition even in the presence of cardiac tamponade [21] [86] Norepinephrine should be included in the infusions in the presence of severe hypotension, it may have a favorable effect on the circulation by raising the blood pressure Antibiotics are administered prophylactically A booster dose of tetanus toxoid or tetanus antitoxin is given if indicated The thorax should be examined for the presence of pneumothorax hemothorax or splashing sounds indicative of a free pericardiopleural communication Determinations of the blood pressure and observations of the cervical veins and of the radial pulse should be made during preparations for operation

An anesthetic is usually employed but in cases of extreme urgency if the patient is unconscious and respirations have ceased, the heart may be exposed without anesthesia while artificial respiration is performed If possible the heart is approached extrapleurally through a left anterior thoracic incision But often it is necessary to incise the pleura and occasionally better exposure is obtained by an incision to the right of the sternum Positive pressure anesthesia with endotracheal intubation is necessary in the presence of extensive lacerations of the pleura Ligation of the internal mammary or of an intercostal or coronary artery may be required for the control of bleeding Bleeding from the heart or from a coronary artery is usually associated with an intrapericardial clot which should be evacuated The surgical technique has been described by Maynard et al [70]

If the outstanding clinical signs are those of cardiac compression oxygen is administered a dextran or plasma infusion or blood transfusion is started and the pericardium should be promptly aspirated preferably by the costoxiphoid or left fourth or fifth intercostal approach Recovery may follow paracentesis even when there is massive hemopericardium [66] If tamponade recurs following temporary relief, aspiration should be repeated However, operative intervention is indicated if the signs of compression are not relieved or recur promptly or repeatedly Although recovery has been reported following non operative treatment,[60] [18] cardiac tamponade should not be allowed to persist for many hours because of the danger of the irreversible changes of shock such as renal insufficiency [11] When hemothorax accompanies hemopericardium, early and repeated aspiration of the pleural cavity without air replacement is necessary to permit undelayed expansion of the lung and to avoid hemofibrothorax

If a *foreign body in the heart* is presented soon after the accident prompt removal may be advisable in order to avoid the danger of cardiac erosion, hemorrhage rupture or infection (bacterial endocarditis or myocardial abscess), recurrent pericardial effusion injury to a coronary artery, and the possibility of embolic vascular occlusion [11] Operation may be indicated to prevent or cure a psychoneurosis due to the patient's knowledge that there is a foreign body in his heart In general, very large foreign bodies those with sharp edges or points, those which are free in a cardiac chamber and those which impinge on the valve or myocardium during systole should be removed [31] In the absence of symptoms the foreign body may be left in situ if continued observation discloses no change in its position If the foreign body is discovered accidentally weeks months or longer after the injury it is undesirable to attempt removal if there is evidence that the object is fixed by scar tissue But an exploratory operation may be necessary if the patient has complaints which appear to be referable to the foreign body e g, pain or a cardiac neurosis develops because of the presence of pain Many instances have been reported of the successful removal of foreign bodies including bullets shell fragments and needles [35] Harken[35] reported no deaths in a series of 131 patients operated for foreign body in the heart or great vessels

The results of surgical operations for penetrating wounds of the heart have been reported by Bigger,[12] Elkin [7] and others [67] [35] [70] Bigger[12] estimated the mortality of cardiac suture to be about 30 per cent Elkin [7] obtained recoveries in 22 of 38 patients on

whom he operated for cardiac wounds. The mortality in the series of operated cases reported by Griswold and Drye[37] decreased from 46 per cent between 1933 and 1934 to 31 per cent *with an operative mortality of 25* per cent in subsequent years. Complete recovery may follow even when a major coronary artery must be ligated.[38] Cardiac infarction need not follow. Follow up studies of 119 cases of cardiac wounds in which the patient survived operation disclosed restoration of function that was complete in 77.3 per cent, fair in 22.7 per cent and poor in 1.7 per cent.[44] Ligation of the anterior descending branch of the left coronary artery did not influence the result. The site of the sutured wound heals to a firm scar. A series of such cases in which the heart was later studied histologically has been collected and reported by Gronwald.[43] In a series of 28 cases of penetrating wounds of the heart treated by non *operative means (cardiac aspiration and* transfusion) the mortality was only 10.7 per cent.[20]

NON PENETRATING INJURIES OF THE HEART

Increasing recognition has been given in recent years to the occurrence of cardiac damage following a non penetrating blow to the chest wall. Our knowledge of these non penetrating cardiac lesions has been especially enhanced by the studies and reviews of Barger,[4] Beck,[9] Warburg[9, 34] and others. The following discussion is designed to call attention to the occurrence of cardiac damage from blunt injury to the chest wall but at the same time to caution against attributing to a preceding trauma a host of unrelated cardiac disturbances which are the consequences of the natural course of underlying independent organic heart disease.

Contusion or rupture of the heart following a blow to the chest was demonstrated experimentally in rabbits and dogs by Kulbs,[69] Schlomka[88] and by Kissane, Fidler and Koons.[85] By controlled measured forces which struck but did not penetrate the chest wall they were able to cause subepicardial and subendocardial myocardial hemorrhages and hemopericardium, cardiac necrosis and heart failure, arrhythmias and various electrocardiographic abnormalities and sudden death due to ventricular fibrillation or cardiac standstill. More severe injuries including cardiac rupture and lesions resembling myocardial infarction were noted when the blows were applied directly to the exposed hearts of animals.[74]

Support for the concept of cardiac disease following blunt injuries of the chest wall is also provided by numerous clinical and pathologic observations.[34, 49, 83, 8, 4, 85] Necropsy studies had long ago demonstrated that fatal rupture of the heart can follow a severe blunt injury to the chest.[34] Recently, rupture of the heart following a non penetrating injury was diagnosed during life and the ruptured myocardium was successfully sutured.[4] But only recently has emphasis been placed on the frequency of less severe cardiac injuries with asymptomatic recovery or of survival with a variety of transient or persistent and serious cardiac symptoms. In an analysis of 175 cases of non penetrating wounds of the heart Bright and Beck[16] found 152 instances (87 per cent) *of death from cardiac rupture (proven by* necropsy), 11 instances (6 per cent) of death from myocardial failure and only 12 instances (7 per cent) of recovery. Beck[9] believed that the percentage of recoveries was much higher but that there was a failure to recognize or a fear to diagnose clinical heart disease due to cardiac contusion.

In some cases the demonstration of hemopericardium by paracentesis following non penetrating chest trauma strongly supports the clinical diagnosis of cardiac contusion. More often in reported cases in which transient or persistent clinical manifestations are interpreted as evidence of myocardial damage or of acute or chronic heart failure due to cardiac contusion there is great uncertainty as the the accuracy of the diagnosis or interpretation. In particular it seems to me that neurocirculatory asthenia or cardiac neurosis, independent coincident cardiovascular disease, reflex cardiovascular disturbances following trauma and its emotional concomitants and pulmonary embolism have been interpreted in different cases as heart disease due to cardiac contusion.

ETIOLOGY

Direct Non penetrating Blunt Injury

A frequent cause of non penetrating cardiac injury is the well publicized steering wheel accident.[27, 9] The driver's chest is pinned against the steering wheel when the forward momentum of the car is suddenly arrested

Severe cardiac injury or rupture of the heart often follows crushing chest accidents when an auto train or other vehicle runs over the prostrate body Falls from a great height result in similar cardiac damage often associated with serious injuries in other parts of the body Direct blows to the anterior chest wall by a baseball golf or tennis ball traveling at high speed, by heavy falling or swinging objects which strike at great velocity fist blows, kicks by a horse or other powerful animal and compression of the chest between two moving objects are among other causes of non penetrating cardiac trauma In battle experience blast injuries form an additional causative mechanism

As a rule the non penetrating force strikes over the precordium but cardiac injury occasionally follows blows to the posterior thorax abdomen or lumbar region Serious contusion and even rupture of the heart often occurs without any significant visible external injury of the chest wall and without fracture of the ribs[16, 9, 8] In fact in the series of 250 non penetrating chest injuries reported by Arenberg[2] the greater cardiac damage occurred among the cases without rib fracture Conversely bilateral multiple fractured ribs were usually unaccompanied by cardiac damage And among the 152 cases of ruptured heart following non penetrating injuries of the chest assembled by Bright and Beck[16] evidence of fractured ribs was found only in 58

Clinical and experimental observations suggest that blunt injury is more likely to damage the diseased heart than the normal one Kulbs and Strauss[61] found that the hearts of rabbits previously rendered atherosclerotic and the hearts of dogs intoxicated with excessive doses of digitalis or thyroxin were more readily injured by blunt force applied to the chest than were the normal hearts of these animals It may be that diseased human hearts are similarly more susceptible to non penetrating blows, but preexisting cardiac disease is by no means as important a predisposing factor as in the cases of cardiac injury following unusual and severe physical strain

Cardiac Strain

In discussions of non penetrating cardiac trauma there is often a lack of distinction between lesions produced by blunt injuries to the chest wall and those due to overstrain of the heart Cardiac strain refers to the anatomic lesions and functional disturbances which result from some intense and unusual physical effort Because this type of traumatic heart disease is frequently involved in compensation and other medicolegal problems and because it rests on less scientific foundation than the type due to blunt injury of the chest wall, it should be distinctly segregated

There is always uncertainty about reported instances of damage to the normal heart due to physical effort Doubt usually surrounds the claim that the heart was previously normal When arrhythmias follow a physical strain there is also a question of coincidence, for arrhythmias not infrequently arise in the normal heart without unusual effort or other apparent cause

The so called "athlete s heart,' i e cardiac dilatation and hypertrophy formerly attributed to athletic activity, is now believed to be the consequence of independent rheumatic congenital or syphilitic heart disease Transient cardiac enlargement occurs occasionally during strenuous physical exertion but this is a reversible compensatory dilatation (p 94) which disappears promptly with cessation of the activity[25, 84] There are no well authenticated cases of congestive heart failure developing as a result of a physical effort in an individual with a normal heart Disorders of rhythm, including premature beats paroxysmal tachycardia and even atrial fibrillation may first appear in a normal heart after strenuous exertion much more commonly this sequence is observed when there is underlying cardiac disease Rarely is a normal valve or chorda tendinea ruptured by physical exertion Physical effort especially in combination with emotional stress commonly induces a paroxysm of angina pectoris but only in subjects with advanced coronary atherosclerosis or other disease diminishing the coronary reserve The precordial oppression sometimes experienced by normal subjects during a prolonged race and before ' second wind may represent angina pectoris due to functional coronary insufficiency but this disappears rapidly and recurs only with very unusual and strenuous exertion

In the previously diseased heart the strain of physical effort apparently may induce the disorders of rhythm already mentioned rupture of a valve chorda or papillary muscle, a paroxysm of angina pectoris and occasionally congestive heart failure Severe

prolonged exertion is theoretically capable of causing myocardial necrosis without coronary occlusion but there is great controversy as to whether it ever precipitates the occlusion itself (p 494) Physical effort in contrast with blunt injury to the chest wall is not the cause of pericarditis myocardial contusion or rupture The specific cardiac lesions attributed to non penetrating injuries and to cardiac strain are discussed under Pathology

PATHOLOGY OF NON PENETRATING CARDIAC TRAUMA

The pericardium and myocardium are most frequently injured by blunt injuries of the chest the valves or their attachments are most commonly said to be torn by an unusual physical effort

The Pericardium

Fibrinous pericarditis and hemopericardium result from non penetrating trauma the latter much less frequently than after penetrating wounds Contusion of the pericardium and epicardium is probably fairly common but is easily overlooked in non fatal cases because of the paucity or absence of physical signs and symptoms Pneumopericardium and hydropericardium have been reported [67] Occasionally a non penetrating cardiac trauma stirs up a tuberculous or purulent pericarditis

The Myocardium

The myocardium may be merely bruised (cardiac contusion) it may be partially lacerated or it may suffer a through and through perforation involving the wall of one or more chambers or of the septa (rupture of the heart) [6] Traumatic rupture of the heart may occur with an intact pericardium [15] Bright and Beck[18] assembled 152 cases of rupture of the heart in which the various chambers were involved with almost equal frequency but in which the left ventricle and right atrium predominated In addition in this series the interventricular septum was perforated 13 times the interatrial septum once and multiple chambers 13 times Isolated traumatic rupture of the interventricular septum following blunt force has been reported in a previously healthy 21 year old man [73] The papillary muscle may be ruptured by blunt injury to the chest as in the cases reported by Kleberger[67] and by Glendy and White [34] *Rupture of the heart may occur promptly* after the injury but there is often an interval *of five to fifteen days before the hemorrhagic disorganized softened area perforates* [76 95]

Rupture of the heart is a fatal consequence of the most intense crushing injuries of the chest wall Of greater clinical interest and importance are the less severe contusions characterized by less extensive subendocardial and subpericardial myocardial hemorrhage and dissolution of tissue often associated with overlying local pericarditis As in the experimentally induced cardiac contusions [74] these bruised areas of heart muscle *may heal with the formation of a firm scar in*distinguishable from the scar of a cardiac infarct due to coronary artery occlusion [44] That cardiac contusion may be followed by cardiac aneurysm is suggested by the report of Joachim and Mays [64] Endocardial thrombosis and cerebral embolism may also follow contusion of the heart [77]

Coronary Thrombosis and Myocardial Infarction

The effect of non penetrating chest injuries and of physical strain must be considered The above mentioned form of myocardial hemorrhage necrosis and scarring caused by a blunt chest injury (contusio cordis or commotio cordis) should be distinguished from the cases of myocardial infarction secondary to atherosclerotic coronary occlusion in which the coronary occlusion is believed to have been precipitated or accelerated by the strain of some physical exertion [73 80] The possible causal relationship of atherosclerotic coronary occlusion to physical strain has come to assume medicolegal importance particularly in connection with insurance and workmen s compensation This problem has been discussed under the heading of etiology of acute coronary occlusion (p 494)

In many reported cases the sequence of events after a severe and unusual physical strain strongly suggests that the strain in some way initiated or accelerated the coronary artery occlusion and the consequent infarct [73 84] There is no doubt that the fundamental cause of the occlusion in these cases is atherosclerosis but the unusual effort is believed to precipitate the occlusion either by causing intimal hemorrhage in the atherosclerotic plaque or by some other undetermined mechanism Master[83] and his associates have marshalled considerable evidence to

refute these interpretations but admit that in 2 per cent of a large series of cases of coronary artery occlusion there was a chronologic if not causal relation to unusual exertion Since about 500 000 cases of coronary occlusion occur annually, *at least the possibility that* effort is a precipitating factor must be considered in 10 000 cases Certainly this relationship should be given credibility in relatively few instances of this potential group

Occasionally a strenuous or unusual exertion occurs in a person with severely narrowed (atherosclerotic) coronary arteries The exertion may so intensify the coronary insufficiency relative to the needs of the myocardium that myocardial anoxia and necrosis develop usually in the subendocardium of the left ventricle and papillary muscles Such cardiac necrosis without recent coronary occlusion[10] may present a clinical picture identical with that of acute coronary thrombosis, there may be symptoms of angina pectoris with corresponding electrocardiographic changes or there may be no detectable clinical manifestations

Finally there are instances in which a blunt injury to the chest wall did not cause a cardiac contusion but purportedly precipitated a coronary artery occlusion and myocardial infarction [95, 63, 82] Injury to the heart may possibly cause a thrombosis of a coronary artery[34] or, as a better established fact a necrosis of cardiac muscle simulating infarction without coronary thrombosis Or a coincidental atherosclerotic coronary thrombosis may follow a non penetrating blow to the chest and be attributed to that trauma *Great care is necessary in interpretation* Thus in the case reported by Kienle[63] of a 40 year old man who fell while skiing and then experienced the typical clinical course of coronary occlusion and posterior wall infarction one must consider not only the possibility of coincidence but also the possibility that the occlusion was the cause not the consequence of the fall In some instances the youth of the patient is used to support the interpretation that the blunt chest injury and not the natural course of preexisting disease was responsible for the coronary occlusion The report of MacDonald[65] concerns a 21 year old man who was struck on the chest by a soft ball There was clinical and electrocardiographic evidence of myocardial infarction Postmortem examination disclosed old and recent coronary occlusions However, recent studies have amply demonstrated that the premature occurrence of advanced coronary atherosclerosis is no rarity [29] In clinical reports without autopsy studies it is always *difficult to differentiate* between cardiac contusion following blunt chest injuries and coincident or causally related coronary artery occlusion

Valvular Lesions

Rupture of a valve or of chordae tendineae may follow non penetrating injury to the chest or severe physical strain More often the affected valve is the seat of preexisting rheumatic, syphilitic, congenital or atherosclerotic disease but normal valves have also been lacerated or perforated by these forms of indirect trauma

In experimental cardiac contusions in animals valvular hemorrhages were sometimes seen but no ruptures [59] Barié[5] found in his experiments with human hearts *post mortem* that extremely high pressures were required to rupture a valve Nevertheless there are apparently well authenticated cases of rupture of normal human valves as a result of both physical exertion and non penetrating injury to the chest Fourteen such cases were assembled from the literature by Adam[1] who also reported a case of his own Howard[44] reported an instance of traumatic aortic insufficiency due to rupture by strain of a normal aortic valve, while Kissane, Koons and Fidler[48] described a proven case of rupture of the aortic valve due to crushing injury to the chest following an explosion Proudfit and McCormack[79] described a case of aortic insufficiency *due to rupture* of the aortic valve following an automobile accident in which there was good therapeutic control of the initial symptoms during the terminal 14 months of life Diagnosis of a ruptured aortic valve is important because of the possibility of surgical correction of the resulting aortic insufficiency [41]

The aortic valve is most commonly affected[18, 84], the mitral valve is next in frequency of involvement while the pulmonic and tricuspid valves are torn more rarely The greater frequency of the left sided valvular injuries may be attributed both to the higher intracardiac pressures on that side and to the greater frequency with which these valves are the site of underlying disease Injuries to the mitral valve include tears of the cusp itself or

more commonly rupture of chordae tendineae or occasionally of a papillary muscle Rupture of apparently normal mitral chordae following severe exertion was reported by Frothingham and Haas[31] Rupture of the mitral chordae may occur spontaneously usually as a result of underlying bacterial endocarditis Bailey and Hickam[3] reported 7 cases of spontaneous rupture of mitral chordae tendineae in which rheumatic endocarditis was the underlying condition In such cases of spontaneous rupture of diseased valves the actual event may be attributed properly or improperly to some physical effort In the cases reported by Bailey and Hickam[3] the histories failed to indicate that vigorous exertion or external trauma was of primary importance in the rupture

Other Cardiac Lesions Attributed to Indirect Trauma

Acute and subacute bacterial endocarditis suppurative myocarditis and pericarditis have each at times been ascribed to commotio cordis In these cases the injury is credited with creating a locus minoris resistentiae lighting up a latent infection or permitting the entrance of bacterial agents which then produce bacterial endocarditis in a heart predisposed by an underlying valvular lesion[33] However in some of the recorded cases the clinical diagnosis of endocarditis is questionable and in all the cases of subacute bacterial endocarditis the insidious onset of the disease makes it impossible to relate it accurately in point of time to the trauma Sometimes traumatic lesions in distant parts of the body or in the lungs pleura or mediastinum lead to infections which later extend to the pericardium or heart

CLINICAL FEATURES OF NON PENETRATING CARDIAC TRAUMA

Rupture of the heart is rapidly fatal but occasionally not until the second week after the injury On the other hand mild cardiac contusion may be asymptomatic When symptoms do develop they may appear immediately or after a variable interval of days or even weeks There may or may not be a loss of consciousness even after serious blows to the chest wall

Chest pain is probably the commonest complaint after nonpenetrating trauma but its onset may be delayed for several hours This may arise in the traumatized chest wall the pleura pericardium or the heart A persistent or recurrent dull ache in the precordium or apical region may be a symptom of cardiac neurosis following trauma Occasionally a severe or unusual exertion or a non penetrating chest injury precipitates the first attack of typical angina pectoris[55] The angina pectoris may be due exclusively to cardiac contusion but as a rule there is underlying atherosclerotic coronary artery disease or syphilitic coronary ostial narrowing[54] Prolonged cardiac pain with all the other features of acute coronary thrombosis has been recorded following cardiac contusion[11]

Weakness is a frequent complaint after cardiac contusion or after valvular rupture It usually subsides after a brief period but may persist especially if cardiac failure develops

Palpitation may result from tachycardia arrhythmia or exaggerated awareness of the normal heart beat

Disorders of rhythm and rate are among the commonest reported manifestations of non penetrating cardiac trauma *Tachycardia* is common but sinus bradycardia has also been recorded[40] Usually the tachycardia is transient but may persist in the presence of cardiac neurosis Occasionally ventricular tachycardia and ventricular fibrillation have been noted *Atrial fibrillation* usually transient is the commonest important arrhythmia associated with non penetrating cardiac trauma or severe effort[4] It may occur in the previously healthy heart[49 4] In Warburg s[61] series there were at least 32 instances of atrial fibrillation or about one third of the entire group In nearly half of the cases the arrhythmia persisted *Atrial flutter* has also been recorded[31] *Heart block* incomplete[33] or complete[11] has been observed on occasion This may be due to traumatic hemorrhage into the conduction tissues But unless the subject has been examined previously congenital heart block is difficult to exclude (p 389) Transient *right bundle branch block* was recorded in a young man of 22 following a blow on the chest when thrown from his motorcycle[41] Transient disturbances in conduction following non penetrating trauma in 3 cases were reported by Taylor[9]

Congestive heart failure commonly follows severe injuries to the heart It may start rapidly after the trauma with progressive acute pulmonary edema or it may evolve more slowly from symptoms of mild left heart

failure to advanced left- and right sided con gestive heart failure But in cases of rupture of a valve or its chordae, signs and symptoms of heart failure may not appear for many months Heart failure may also result from prolonged paroxysmal tachycardia or atrial flutter or fibrillation and rapid ventricular rate When there are only a few symptoms such as dyspnea and fatigability, the diagnosis of heart failure should be differentiated from cardiac neurosis and pulmonary injuries

Enlargement of the heart is usual in those individuals who develop heart failure after cardiac trauma But hemopericardium may simulate cardiac enlargement and by causing cardiac tamponade may produce symptoms of congestive heart failure

Angina pectoris and manifestations of cardiac infarction have been mentioned *Sudden death* may occur after cardiac trauma with or without preceding symptoms of angina pectoris

Distinctive clinical features may be produced by *rupture of valves* or by *pericarditis and hemopericardium* Rupture of a valve or chorda tendinea may be characterized by sudden onset of precordial pain, dizziness weakness breathlessness palpitation or shock The diagnostic feature is a very loud coarse precordial murmur In aortic lesions, there is an aortic diastolic murmur with the usual circulatory dynamics accompanying aortic insufficiency The diastolic murmur of aortic insufficiency due to rupture of the aortic valve may have a distinctive musical quality described as sea gull spinning top or cooing dove, but this is not heard in all cases The sea gull type of murmur is heard more commonly in aortic insufficiency due to destruction of the aortic valve in bacterial endocarditis and in syphilitic aortic insufficiency with eversion of the right anterior aortic cusp (p 688) In cases of rupture of the mitral valve or chordae there is a loud systolic murmur maximal at the apex and left sternal border, usually accompanied by a thrill and occasionally accompanied by an apical diastolic murmur Cardiac enlargement and congestive heart failure usually develop gradually after many months Rupture of a papillary muscle may give similar signs, but there is likely to be a rapid development of acute left heart failure and death within hours or days Recent previous cardiac examination with negative findings is an important and often the decisive clue to diagnosis

Superficial *pericarditis* may be disclosed by the presence of a friction rub or there may be associated physical, roentgenologic and electrocardiographic signs of pericardial effusion With rupture of the heart there is likely to be a hemopericardium which causes cardiac tamponade[11] Extensive hemothorax is commonly associated due to rupture into the pleural cavity

Electrocardiographic changes may result from pericarditis or hemopericardium, from direct myocardial injury or from myocardial necrosis secondary to thrombosis of a coronary artery In cases of pericarditis caused by non penetrating chest injuries, Wood[38] described electrocardiographic abnormalities similar to, though often distinguishable from those characterizing myocardial infarction He emphasized that in cases of cardiac contusion T wave inversion and ST deviations were most striking in lead II while in cardiac infarction discordant ST and T wave changes were most apparent in leads I and III Burstein and Marshak[17] reported two cases of cardiac contusion with electrocardiographic findings of T wave depression or inversions in one of which these abnormalities alone permitted the diagnosis The precordial lead disclosed the earliest and most constant findings

Numerous reports of cardiac injury by penetrating or non penetrating trauma have confirmed the occurrence of ST elevations or depressions or T wave inversions but no uniform pattern has been described Apparently the site and extent of the lesion and the interval between the injury and electrocardiographic examination account for the described variations As a rule ST and T wave changes are transient and disappear within a few weeks and almost always within three months In addition to the above the electrocardiograph may disclose transient or persistent atrial fibrillation, heart block or bundle branch block

DIAGNOSIS

The diagnosis of cardiac contusion must be entertained whenever an individual experiences a blunt injury of the chest wall In general the greater the momentum of the blow and the greater the proximity to the precordium, the more likely the cardiac injury Occasionally cardiac contusion or rup-

ture follows extreme compression of the abdomen or thighs[3]

Serial electrocardiograms should be taken in all cases of chest trauma Depressed or inverted T waves atrial fibrillation or heart block may suggest cardiac injury whether clinical symptoms and signs are present or not Roentgenologic films of the chest should be made to study the size form and pulsations of the cardiac silhouette Such study may determine the presence of pericardial effusion and serves also to exclude pulmonary lesions as the possible cause of the patient s symptoms

Pericardial paracentesis should be performed if there are physical or roentgenologic signs of pericardial effusion or if there are symptoms and signs of acute cardiac tamponade If there are symptoms and signs of acute circulatory failure the findings should be reviewed to determine the presence of cardiac compression Hemopericardium following a non penetrating chest injury suggests cardiac contusion and perforation of a chamber or laceration of a coronary artery

The diagnosis of cardiac damage to non penetrating trauma should also be considered if a pericardial friction rub appears soon after the injury if loud murmurs or thrills develop or if clinical or electrocardiographic signs of cardiac anoxia or cardiac infarction appear

The presence or absence of preexisting disease is often of primary importance in the interpretation of post-traumatic symptoms and signs Since cardiac trauma is often likely to involve insurance workmen s compensation or liability problems careful cardiac examination when insurance is first granted and when the patient is first seen after an accident are essential

PROGNOSIS

There are inadequate data for definitive statements as to prognosis Rapid fatalities follow rupture of the heart either immediately after the injury or a week or two later Less serious but severe injury may be complicated by heart failure angina pectoris or evidence of myocardial infarction The outlook is then similar to that in cases due to non traumatic causes Rupture of a valve is usually followed by fatal heart failure within a year or two Arrhythmias such as paroxysmal tachycardia atrial fibrillation and heart block usually disappear within a few days or weeks but may be prolonged and may be complicated by heart failure Greater recognition of the frequency of cardiac contusion and more careful diagnostic methods are leading to discovery of the mild cases in which recovery is the rule[2]

TREATMENT

In cases with very severe injuries and rupture of the heart death often occurs too rapidly to permit surgical treatment But when a sufficient interval elapses and there are signs of increasing cardiac compression pericardial aspiration should be performed If hemopericardium is proved and no relief is obtained or if following aspiration there is only transient improvement with recurrent relapse surgical exploration of the heart should be undertaken If a cardiac rupture is discovered it should be sutured as noted above (p 1060) or a pericardial graft can be sutured over a softened area The use of the newer blood products and absorbable gelatin or cellulose preparations[47] may be valuable to control bleeding of softened areas as in rupture of the liver In cases of ruptured aortic valve an artificial aortic valve may be inserted into the descending aorta[31] (p 692)

In patients with symptoms such as weakness arrhythmia angina pectoris or heart failure or in patients with significant electrocardiographic changes sharp restriction of activity or limited confinement to bed for three to six weeks or longer may be necessary to avoid rupture of a lacerated myocardium The usual measures designed to control heart failure cardiac pain or cardiac arrhythmias should also be instituted

Chapter 45

CARDIAC TUMORS

Tumors of the heart and pericardium have evoked an extensive literature out of all proportion to their uncommon incidence and their relative unimportance as a cause of clinical heart disease This unusual interest has been aroused by four aspects of the subject

(1) Uncertainty as to the nature and pathogenesis of cardiac myxoma and rhabdomyoma

(2) The occurrence of clinical features which may simulate those of common forms of heart disease

(3) The ability to diagnose cardiac tumors during life

(4) The possibility of surgical removal and cure of certain cardiac tumors

INCIDENCE

There have been many reviews of the literature on cardiac neoplasms [60, 111, 59, 85, [illegible], 28, 31, 38] Lymburner[55] encountered only 4 primary tumors of the heart (0 05 per cent) and 52 secondary tumors (0 6 per cent) in a series of 8500 autopsies at the Mayo Clinic Similarly Pollia and Gogol[71] discovered only 29 secondary tumors (0 25 per cent) in 12,000 autopsies and Scott and Garvin[88] 118 metastatic neoplasms of the heart and pericardium (1 0 per cent) in a series of 11 100 postmortem examinations Malignant neoplasms of the heart and pericardium compose [illegible] to 11 per cent of malignant tumors of all kinds throughout the body [106, 85, [illegible]] According to Prichard,[73] a metastatic cardiac neoplasm was discovered at autopsy in 326 (3 9 per cent) of 8414 cases in which death was due to cancer A higher incidence was reported by Young and Goldman [112] and by Bisel et al [illegible] (21 per cent of 500 cases of neoplastic disease)

CLASSIFICATION

Cardiac tumors may be classified as follows

(I) Primary tumors of the heart
- (A) Benign
  - (1) Myxoma
  - (2) Rhabdomyoma
  - (3) Other rarer tumors
    - Fibroma lipoma angioma papilloma teratoma leiomyoma xanthoma
- (B) Malignant
  - (1) Sarcoma—various types
  - (2) Other rarer malignant tumors
    - Mesothelioma or mesothelial sarcoma of the pericardium rhabdomyosarcoma epicardial epitheliomas

(II) Secondary (malignant) tumors
- (A) Carcinoma and occasional sarcoma by direct invasion
- (B) Carcinoma or sarcoma by metastasis
- (C) Systemic neoplastic disease with cardiac involvement
  - (1) Hodgkin s disease
  - (2) Lymphosarcoma
  - (3) Leukemia
  - (4) Kaposi s sarcoma
  - (5) Neurofibromatosis (von Recklinghausen s disease)

PATHOLOGY

PRIMARY TUMORS

Lymburner[44] was able to collect 226 instances of primary cardiac tumors from the literature in 1934 but by 1951 Prichard[73] found 415 such reported cases Approximately three fourths of the primary tumors were benign Myxoma, sarcoma and rhabdomyoma are the commonest primary tumors in the given order of frequency The myxoma the polypoid fibroma and sarcoma arise from the endocardium Rhabdomyoma and fibroma arise from the myocardium while mesothelioma or mesothelial sarcoma lipoma fibroma angioma are among the tumors of pericardial origin

Benign Primary Tumors

Myxoma The myxoma is a solitary globular or polypoid tumor varying in size from that of a cherry to a large peach It is semi translucent, yellowish gray in appearance and elastic and gelatinous in consistency Its cut surface is mucinous or gelatinous and may be more or less hemorrhagic The myxoma occurs chiefly in the left atrium arising usually from the atrial septum near the rim of the fossa ovalis to which it is attached by a short stalk From this pedicle the myxoma extends to fill some or most of the atrial cavity and may even occlude the mitral orifice and produce all the disturbances of a mitral stenosis including right ventricular hypertrophy and pulmonary vascular changes The myxoma may be the source of coronary and cerebral embolism [11] The myxoma may also arise near the margin of the left atrial appendage or less often from the right atrium or ventricles A myxoma of the left ventricle with occlusion of the abdominal aorta and renal arteries by tumor embolus was reported by Young and Hunter [113] In another case myxomatous embolic occlusion of the abdominal aorta was responsible for the earliest clinical symptoms [illegible]

Microscopically the myxoma is seen to be composed of an amorphous or mucoid matrix with characteristic stellate or spindle shaped cells acini of large polyhedral cells, delicate scanty blood vessels, occasional lymphocytes and plasma cells small hemorrhages or blood pigments (hemosiderin or hematoidin) and very small amounts of collagenous and elastic fibers Variations in the appearance and predominance of these individual microscopic elements of myxoma account for other names applied to this tumor, e g hemangio or fibro-myxoelastoma,[14] lymphangioendothelioma [66] fibromyxoma, fibroma, hemangio myxoma

The weight of evidence appears to favor the concept that the myxoma is a true neoplasm,[111, illegible] as maintained by Ribbert [78] The neoplasm may arise in rests of embryonic mucoid tissue or it may represent an endothelioma with myxomatous degeneration [66] However, following the interpretation of Thorel,[101] many writers view the myxoma as a thrombus which has swollen by imbibition and undergone organization [illegible] In the case reported by Dexter and Work [27] the authors suggested that rheumatic inflammation of the left atrium predisposed to the formation of the myxoma, but rheumatic lesions have not been reported in other cases of myxoma

Myxomata of the cardiac valves have been described as distinctive shaggy tumor masses which are probably true tumors but have also been interpreted as exaggerated Lamblian excrescences Fibroma of the valves has been described [95] This occurs as a solitary round or oval, broad or pedunculated solid tumor with a slight predilection for the tricuspid valve It is probably a true tumor arising from the valvular subendothelium but it has also been interpreted as an organized thrombus

Rhabdomyoma The rhabdomyoma is a congenital glycogen-containing tumor which occurs as multiple or solitary nodules or as a diffuse infiltration of the myocardium [30, 4] There is a difference of opinion as to whether the tumors actually contain glycogen Most frequently there are multiple gray or purplish nodules lying within the myocardium bulging externally on the epicardial surface, or projecting into the lumen of the cardiac chambers They occur oftenest in the left ventricle but may affect any portion of the heart including the valvular leaflets Less often there are solitary nodules which are usually located in the region of the apex Solitary tumors on the valve may produce murmurs or a tumor of the conduction system may cause heart block or an arrhythmia Occasionally there is diffuse cardiac involvement and enlargement without distinctive tumor formation, this type of case may be a form of glycogen storage disease [60] Sudden death, or death within a few hours after onset of dyspnea and cyanosis, may occur

According to Batchelor and Maun [4] 63 authentic cases of rhabdomyoma had been described since the first case reported by von Recklinghausen[74] in 1862 In most instances death occurs in the first year of life and in 85 per cent before puberty A striking feature is the usual association of multiple cardiac rhabdomyoma with tuberous sclerosis of the brain, multiple tumors of the kidney and adenoma sebaceum of the skin [4] The solitary cardiac rhabdomyoma is not accompanied by such lesions This combination of tumor like deformities in several organs simultaneously has cast doubt on the concept of Wolbach[109] and others that rhabdomyoma is a true tumor of embryonal cardiac muscle cells Instead the teratogenetic character of the tumorlike

lesions suggests that they represent simultaneous tissue malformations in the various organs The term hamartoma[2] has been applied to these tumor like formations caused by errors in tissue development[34] Occasionally fibrosis and calcification occur in a rhabdomyoma features which have led Olsen and Cooper[6] to interpret the nodules as resulting from congenital glycogenic degeneration of the myocardium

Microscopic examination of cardiac rhabdomyoma discloses a spongy tissue containing many large stellate cells which form peculiar vacuolated structures These vacuoles lie within the cell body of large embryonic like muscle fibers[48] and have been said to contain glycogen as may be demonstrated by Best s carmine stain[1]

Other benign primary tumors have been described in solitary case reports *Fibroma* of the valves has been mentioned Fibroma may also occur as a solid gray or white polypoid tumor of the left or right atrium or as a more or less circumscribed mass within the myocardium of the ventricles or ventricular septum *Lipoma or fibrolipoma* occur occasionally as a single tumor of great size or in the form of multiple fatty tumors Cases of lymph angioendothelioma reported by Armstrong and Monckeberg[1] and by Lloyd[58] are of special interest because they involved the atrioventricular node and caused heart block Teratoma arising in the mediastinum may rarely involve the pericardium[48, 107] and cause symptoms of acute or chronic cardiac compression or may become infected and produce symptoms of purulent pericarditis[6]

Malignant Primary Tumors

Primary Sarcoma Sarcoma of the heart is the almost exclusive representative of primary malignancy of this organ Many varieties have been described including fibrosarcoma spindle cell sarcoma round cell giant cell myxosarcoma rhabdomyosarcoma[54, 9] and mesothelioma (mesothelial sarcoma endothelial sarcoma) Kaposi s sarcoma of the heart[105] has sometimes been reported under the heading of angiosarcoma[104] angioendothelioma[41] and angioreticuloendothelioma[19] The sarcoma may arise from the endocardium or pericardium or more rarely from the myocardial layer (rhabdomyosarcoma)

According to Prichard[73] 113 cases of primary sarcoma of the heart and pericardium had been reported by 1951 In about 50 per cent of the cases in which the site was mentioned the malignant tumor arose from the right atrium[104] This contrasts with the commonest benign tumor (myxoma) which arises usually from the left atrium Primary sarcoma may also originate in the pericardium[93] but only 22 cases had been reported up to 1947[75] Isolated instances of sarcoma of the left atrium[47] or other portions of the heart have also been noted Mahaim[59] has described cases of mesothelioma arising from epicardial inclusions in the septum near the a v node

The primary cardiac sarcoma metastasizes most commonly to the pleura and lung but also to the mediastinal tracheobronchial or retroperitoneal lymph nodes to the adrenals to other parts of the heart or to the brain Haythorn et al[45] described a case of primary fibromyxosarcoma of the heart and pulmonary artery with extensive metastasis along the pulmonary arterial tree bronchi and lungs The roentgenologic appearance resembled that of carcinoma or Hodgkin s disease of the lungs

The primary sarcoma arising from the right atrium is usually a large firm gray or yellowish papillary tumor which may fill most of the atrial cavity it may extend toward the right ventricle to occlude the tricuspid orifice or it may invade or occlude the venae cavae

Pericardial sarcoma forms a more diffuse white or yellowish tumor mass often of massive thickness (1 to 5 cm) and extent which deforms or obliterates the cardiac contours and partially or completely glues the pericardial layers[93, 67] The tumor itself reveals many areas of hemorrhage and necrosis It may be confined entirely to the pericardium it may compress the myocardium from without or it may actually invade the heart muscle and replace more or less extensive portions The base of the pulmonary artery and aorta may be incorporated in the dense tumor mass and rendered relatively fixed The pericardial cavity often contains a serofibrinous or serohemorrhagic effusion which occasionally becomes infected Pleural effusions sometimes bloody may be associated either due to direct neoplastic invasion of the pleura or secondary to cardiac compression and heart failure

SECONDARY (METASTATIC) CARDIAC NEOPLASMS

Secondary tumors occur with much greater frequency than primary tumors of the

heart[73, illegible, illegible, 39] In a recent series of 2547 consecutive cases studied at necropsy at the Walter Reed Army hospital including 980 cases of malignant disease the incidence of metastatic neoplasms of the heart was 5 3 per cent of the entire series and 13 9 per cent of the malignant cases[25] Cohen and associates[21] encountered 65 tumors metastatic to the heart or pericardium among 315 malignant tumors, an incidence of 20 6 per cent Most of the secondary tumors are carcinomata but metastatic sarcomata also occur Carcinoma usually appears as single or multiple discrete small white firm nodules but it may occur as a more diffuse infiltration and occasionally as a single metastasis Carcinoma of the heart may also present as miliary infarction without gross metastases Carcinomatous emboli may be observed in branches of the coronary arteries A carcinomatous lymphangitis may occur Sarcoma occurs chiefly as diffuse infiltrating masses in the pericardium and myocardium They may broaden the cardiac walls and may encroach on the cardiac cavities or protrude externally Like primary sarcoma secondary sarcoma of the pericardium may produce massive thickening of the pericardium a serofibrinous or fibrinopurulent effusion which is often hemorrhagic, or a completely adherent pericardium Malignant melanoma and leukemia are particularly likely to spread to the heart or pericardium [illegible] Bisel et al[10] found the over all incidence of cardiac infiltration in 119 patients with leukemia to be 44 per cent

Metastatic neoplasms may invade any part of the heart including the pericardium the ventricles atria ventricular septum and occasionally the conduction system[19] The endocardium and valves are very rarely involved[2] but I have seen carcinomatous implants on the *mitral valve secondary to a* carcinoma of the uterus and on the tricuspid valve secondary to carcinoma of the gallbladder In general the right side is involved more often than the left side of the heart but the experience of Burnett and Shimkin[18] and of Gassman et al[36] does not accord with this Pericardial effusion is common[14]

Most of the secondary cardiac neoplasms have their primary origin in malignant tumors of the bronchi lungs and breast[85, 21] But the primary neoplasm may be situated in the esophagus mediastinum thyroid uterus genitourinary tract and many other organs[79] Melanosarcoma and carcinoma of the skin not *infrequently metastasize to the heart*[63, 20] I have observed a case of Ewing's sarcoma of bone which had given rise to a cherry sized polypoid metastasis of the left ventricle near the apex

Invasion of the heart by secondary tumors has been said to occur by direct extension from neighboring intrathoracic organs (chiefly bronchi, lungs pleura, thymus, mediastinal glands and tissues) But in the series of cases reported by Prichard,[73] spread by the lymphatic route, retrograde from the tracheobronchial lymph nodes, occurred more frequently than direct invasion, even from carcinoma of the lung The malignant tissue infiltrates the pericardium and may also invade and replace the myocardium Intrathoracic neoplasms may also break into a pulmonary vein, and by passage through the left atrium, left ventricle aorta and coronary arteries reach the cardiac tissues Direct invasion of the heart may result from extension of tumor masses through the inferior vena cava to the right atrium This may be the mechanism in cases of renal hypernephroma and in occasional instances of testicular teratoma, hepatic malignancies and chondrosarcoma Less often cardiac metastases are secondary to malignant tumors in distant organs The malignant cells reach the heart by passage through the blood stream Tumor cells have actually been found in the circulating blood and endocardial vegetations Least commonly secondary neoplasms of the heart result from retrograde lymphatic extension from neighboring intrathoracic organs or lymph nodes

A variety of systemic neoplastic diseases rarely involve the heart in these instances the pericardium is usually involved *The most common of these* are Hodgkin's disease[39, 43, 82] lymphosarcoma[94, illegible] and reticulum *cell* sarcoma[16, 10] and malignant lymphoma[illegible] Invasion of the heart usually follows direct extension, or retrograde lymphatic spread from involved mediastinal lymph nodes I have also observed a thymic lymphosarcoma which infiltrated the parietal and visceral pericardium Like other pericardial sarcomata the lymphomatous lesions of the pericardium are often associated with pericardial effusions which may be hemorrhagic *Occasionally* leukemic infiltrations are found in the pericardium or myocardium Adhesive peri

carditis or pericarditis with effusion occurs frequently when myelogenous or lymphatic leukemia involve the heart ■ Kaposi s sarcoma involving the heart[105] and neurofibromatosis with cardiac involvement have also been reported [74]

CLINICAL MANIFESTATIONS OF CARDIAC TUMORS

Most cardiac tumors produce no clinical symptoms and are discovered only at post mortem examination In some cases of secondary cardiac tumors the symptoms referable to the cardiac metastases are obscured or overshadowed by those of the primary disease Occasionally however both primary and secondary tumors give rise to distinctive clinical features which permit an accurate diagnosis In the latter group symptoms are dependent on the location and to some extent on the size of the tumor Symptoms result from interference with the passage of blood through the heart impaired transmission of the cardiac impulse through the conduction system pericardial reaction or rarely from extensive myocardial damage Somewhat characteristic clinical syndromes may be associated with a few of the individual cardiac tumors

Congestive Heart Failure Symptoms of congestive heart failure are generally regarded as the most common manifestations of cardiac neoplasms These include dyspnea and orthopnea and venous engorgement with or without peripheral edema and serous effusions Careful analysis discloses that these symptoms do not usually represent heart failure caused by extensive neoplastic myocardial damage In some instances the dyspnea results from the primary pulmonary neoplasm while the venous engorgement is the consequence of metastatic involvement of lymph nodes and mediastinal tissues with obstruction of the superior vena cava In others symptoms indistinguishable from heart failure are due to subacute or chronic compression (tamponade) by extensive malignant pericardial involvement with or without effusion [3, 90] But typical manifestations of congestive heart failure may be caused by longstanding functional mitral stenosis due to a myxoma or other polypoid tumor of the left atrium which occludes the mitral orifice Progressive heart failure and sudden death in a case of myxoma of the left atrium have been attributed to pressure on the pulmonary veins [100] Only occasionally is heart failure produced by extensive sarcomatous destruction of the myocardium The heart failure due to cardiac tumors ■ characterized by its intractable rapidly progressive course and its failure to respond to all therapy Its sudden and unexplained development has also been remarked

Chronic cardiac tamponade and superior caval syndrome result from lymphomatous, metastatic or primary malignant neoplasms of the pericardium In some of these cases the onset with cough malaise and fever suggests ■ diagnosis of grippe Later the full clinical picture develops with increasing dyspnea engorgement of the cervical veins enlargement of the liver and small rapid pulse

Weller[105] associated Kaposi s sarcoma of the right atrium with a distinctive syndrome which he believed permitted clinical recognition The onset resembled that of an acute upper respiratory disease which became protracted (cough malaise weakness night sweats and occasional hemoptysis) Edema of the face at first transitory was later striking and permanent Other features were cyanosis fever between 100 F and 101 F and roentgen ray shadow of a mass along the right atrial border with or without evidence of pericardial effusion When a ardiac murmur is present the clinical picture may resemble bacterial endocarditis However these symptoms and signs are not specific and may be encountered with any malignant tumor of the right atrium and with pericardial malignancies which eventually obstruct the superior vena cava

Acute circulatory failure with a shock like syndrome is apt to result from a ball valve tumor of the left atrium which intermittently and increasingly obstructs the mitral valve [65, 49] Transient obstruction of the circulation sometimes associated with change of position in bed may cause attacks of faintness or syncope cold extremities and cyanosis [77] Peripheral cyanosis, localized necrosis of the tip of the nose fingertips and toes or gangrene may result from prolonged intense circulatory obstruction

A huge ball valve thrombus of the *right* atrium in a patient with mitral stenosis and atrial fibrillation was reported to produce dusky cyanosis of the face and neck engorgement and systolic pulsation of the cervical

veins enlargement and systolic pulsation of the liver, air hunger without pulmonary congestion pronounced enlargement of the right heart, especially the right atrium, and rapid variations in the severity of the clinical features [110]

Acute malignant pericarditis or pericarditis with effusion may be evidenced by a friction rub over the precordium or by physical and roentgenologic signs of diffuse water bottle type of cardiac enlargement In several cases of malignant pericarditis that I have observed, a pericardial rub persisted for more than thirty days Symptoms and signs of cardiac tamponade may develop rapidly only after many months Pericardial aspiration may yield a serofibrinous exudate or a sero sanguineous effusion but a 'dry tap' may be encountered because of complete pericardial adhesion When pericardial effusions due to malignancy are aspirated there is a tendency to rapid refilling of the sac Temporary spontaneous resorption of a pericardial effusion may be associated with misleading, transient clinical improvement [13] Pleural effusions, also frequently hemorrhagic, are likely to accompany pericardial effusions because of direct extension of the malignancy to the pleura

Arrhythmias are relatively common The most characteristic are atrial fibrillation and flutter which may appear as transient paroxysms but later persist [33, 4] Paroxysmal tachycardia, frequent premature beats and occasionally heart block or bundle branch block have also been reported Unexplained tachycardia has often been noted The arrhythmias are usually encountered in cases with metastatic neoplasms of the atria especially the right atrium Heart block has been associated with lymphangioendothelioma [3, 56] and hemangioendothelioma[40] of the atrioventricular node with multiple rhabdomyomata and with leukemic infiltration of the interventricular septum [3] Perry and Rogers[70] reported a case of Adams Stokes syndrome with heart block due to cardiac lymphangioendothelioma

Signs of valvular disease usually those of mitral stenosis[57, 3] and occasionally of tricuspid stenosis [96] may be present in cases of polypoid tumor of the atria [5, 34a] Myxoma of the left atrium is the commonest cause of this form of functional valvular stenosis[99] but less commonly a pedunculated sarcoma[47] or metastatic sarcoma is responsible In 1933 Ludwig[57] assembled 21 cases including one of his own in which tumors of the left atrium had caused a functional mitral stenosis Wainwright[10] reported a case of metastatic sarcoma which reached the left atrium and mitral valve and produced signs of mitral valvular disease Cardiac catheterization in cases of right and left atrial myxomata have disclosed elevation of right atrial pressure in the former and of the pulmonary "capillary pressures in the cases of left atrial tumor [6, 55, 44] The cardiac output was diminished at rest or upon exercise

The murmurs may be typical of mitral (or of tricuspid) stenosis or they may be bizarre in quality, location and variability Occasionally in cases of ball-valve neoplasms the murmur varies or disappears with change in the patient's position [52] Syncope on standing or with change of position, periods of coldness and cyanosis of the extremities peripheral embolization, epileptiform convulsions with gangrene of the nose and extremities [5] progressive heart failure unresponsive to treatment, and sudden unexpected death are among the clinical features in these cases notably of myxoma or sarcoma

Sudden death is relatively frequent, especially in primary tumors of the heart This was the mode of exitus in one third of the cases of myxoma or fibroma of the atria and in about three quarters of the rare cases of lymphangioendothelioma It is also common with cardiac rhabdomyomata Sudden death may follow a period of intermittent or persistent circulatory failure, but it also occurs without preliminary circulatory symptoms

A variety of other clinical manifestations may owe their genesis to cardiac tumors *Angina pectoris* and typical manifestations of *coronary artery occlusion* may result from neoplastic involvement or obstruction of the coronary vessels In one of Fishberg's [3] cases continuous cardiac pain for sixteen days was due to a tumor encircling the left circumflex artery Non specific chest pain occurs in cases of pericardial neoplasm Primary or secondary pericardial sarcoma may cause rapid death by rupturing into the pleural cavity I have seen a perforation of the inferior vena cava by a mediastinal chorioepithelioma I have also observed the clinical picture of Laennec's cirrhosis with ascites edema of the lower extremities and dilatation of the veins of the abdominal wall, caused by an adenoma of the

left kidney which extended into the inferior vena cava and up to the right atrium. Post mortem examination revealed also an adherent fibrous pericardium and thrombosis of the hepatic veins. Rarely a myxoma of the left atrium causes embolization and infarction of various organs.[17] Convulsions in cases of cardiac tumor may be due to heart block (Adams Stokes syndrome) or to tuberous sclerosis of the brain associated with cardiac rhabdomyomata. *Congenital rhabdomyomata* may produce cardiac murmurs when the tumors are situated on the valvular leaflets and arrhythmias are not uncommon due to atrial involvement.[103] In addition these cases are characterized by cyanosis at birth and indifference to surroundings; later there is delay in walking and in mental development, epileptiform seizures and sudden death during an apparently minor ailment.

Roentgenologic examination may disclose bizarre irregular protuberances or advanced universal enlargement of the cardiac silhouette with obliteration of the normal cardiac curves. The appearance may resemble that of a pericardial effusion or localized bulges may simulate ventricular aneurysm or pericardial cyst.[[illegible], 34] Immobility of the right border of the heart on fluoroscopy and irregular or unusual cardiac borders may be noted.

Angiocardiography has disclosed filling defects in enlarged atria in cases of atrial myxomata.[6, 91] It may also be helpful in the differential diagnosis of pericardial neoplasms.[4, 18] Polypoid tumors of the left atrium may effect "mitralization" of the cardiac shadow with straightening of the left border and prominence of the left pulmonary salient.

The **electrocardiogram** is not usually distinctive.[89] It may depict atrial fibrillation or flutter due to atrial involvement[33] or rarely heart block[56, 44] or bundle branch block[103] and P wave abnormalities in atrial neoplasms.[97] Elevation of the RS T segments and inversion of T waves in leads I and II were documented by Boman[12] in a case of primary sarcoma of the pericardium. In a case of carcinoma of the esophagus with massive metastases and extensive destruction of the heart muscle, Rosenbaum[81] et al observed persistent upward displacements of the RS T segments in leads II, III, V_F and in unipolar leads. They interpreted these findings which resembled those seen following combined anterior and posterior infarction as being due to continuous acute myocardial injury by invading neoplasm. Although the electrocardiogram in occasional cases of cardiac neoplasm has been mistaken for that of anterior or posterior wall infarction, the characteristic discordant ST elevation and depression of the latter in leads I and III have not been described.

DIAGNOSIS

More than twenty reports have been made of correct antemortem diagnosis, most of them in recent years and usually in cases of secondary (malignant) tumors of the heart.[33, 3, 18, 38] Primary tumors have also been recognized during life by Barnes et al,[7] Popp,[72] Shelburne,[87] Lange and Christiansen,[53] Goldberg et al,[37] Bahnson and Newman,[6] Steinberg et al[[illegible]] and others. Because of the possibility of surgical removal, the recognition of benign tumors is especially important.

As with other rare forms of heart disease, diagnosis depends on alert awareness that cardiac neoplasm may be responsible for cardiac manifestations, especially when the clinical course is atypical. In the presence of a malignant neoplasm elsewhere in the body, especially in the neighboring thoracic organs, certain clinical features should suggest the occurrence of cardiac metastases. These diagnostic features are:

(1) The rapid onset of congestive heart failure without apparent cause and its unabated progression despite treatment.

(2) The development of signs of fibrinous pericarditis or pericarditis without other apparent cause. The pericardial rub, if present, persists for many days or weeks. A blood tinged pericardial tap is confirmatory[67] and the finding of tumor cells is diagnostic.[[illegible], 89]

(3) The occurrence of paroxysmal or persistent atrial fibrillation or of heart block in the absence of the usual causes of these disturbances.

(4) The development of cardiac tamponade as indicated by dyspnea, engorged veins, hepatic enlargement, falling blood pressure and pulse pressure, tachycardia and pulsus paradoxus.

The *diagnosis of primary tumors* is more difficult. Signs of mitral stenosis in the absence of a history of rheumatic fever together with symptoms and signs of ball valve

obstruction of the mitral valve (p 656), should suggest the possibility of a polypoid myxoma fibroma or sarcoma of the left atrium Episodes of syncope, dyspnea or cyanosis which are unexplained except for their relation to change of position may suggest the diagnosis Occasionally an atrial tumor is discovered during an operation for mitral stenosis or constrictive pericarditis Similarly the presence of right atrial tumor may be suggested by a tricuspid murmur intractable congestive right sided heart failure without apparent cardiac or pulmonary disease or evidence of superior vena caval obstruction (edema and cyanosis of the neck and face and venous engorgement with or without dilated collateral veins on the chest wall) Differential diagnosis may require angiocardiography to demonstrate or exclude the presence of a tumor

Primary tumors of the pericardium (teratoma sarcoma) may be recognized by physical signs of pericarditis or pericardial effusion, especially hemopericardium, or by bizarre, localized bulges of the roentgenologic silhouette of the heart Angiocardiography, fluoroscopy and kymography may differentiate these tumors from aneurysms, since the tumors do not fill with Diodrast and pulsation is absent or only transmitted, the latter is not an absolute distinction *Rhabdomyoma* may be suggested by the association of cardiac enlargement cardiac irregularity, and convulsive seizures with or without Adams-Stokes syndrome in backward, mentally deficient infants or children, who may have adenoma sebaceum

Examination of the pericardial fluid in cases associated with pericarditis with effusion may disclose the presence of tumor cells

TREATMENT

Treatment of the secondary neoplasms of the heart is essentially symptomatic Acute cardiac tamponade due to rapidly accumulating pericardial effusion may require frequent paracentesis of the pericardium Rapid relief of alarming circulatory deficiency followed the aspiration once of 340 cc and again of 300 cc of extremely hemorrhagic fluid in a case of metastatic carcinoma of the pericardium reported by Barnes Beaver and Snell[7] Deep roentgen ray therapy may temporarily destroy pericardial neoplasms or lymphomata and effect more or less symptomatic relief as in the case of pericardial metastasis reported by Shelburne and Aronson,[33] and as in the case of Hodgkin s disease of the pericardium reported by Garvin[25] Nitrogen mustard, radioactive P^{32} or urethane therapy may be tried The instillation of radioactive gold (Au^{198}), with a physical half life of 2 7 days, into the pericardial cavity of a patient with massive, recurrent pericardial effusion secondary to carcinoma of the breast was followed by temporary diminution of the effusion, relief of symptoms, and a radiation effect on the neoplasm without significant injury to the myocardium[4]

Hope for surgical removal of primary tumors was engendered by Beck's[9] report of a case of an intrapericardial teratoma and one of tumor of the heart in which the lesions were successfully extirpated and the patients cured Maurer[6] reported the successful removal of a primary lipoma of the heart, weighing 3½ pounds Several attempts have been made at surgical removal of a right or left atrial myxoma diagnosed during life, but almost invariably these attempts have been failures[11 38] But Scannell and associates[6] reported the successful removal of a myxoma from the left atrium, with the aid of hypothermia

Chapter 46

FUNCTIONAL MANIFESTATIONS REFERRED TO THE HEART

The physician is confronted more often with functional disturbances which the patient refers to his heart than with organic cardiac abnormalities.[3, 11] Proper treatment requires the ability not only to differentiate these functional disorders from organic heart disease but also to recognize them when superimposed on organic heart disease. These functional problems will be discussed under the following headings:

1. Neurocirculatory asthenia or cardiac neurosis
2. Isolated and transient functional cardiac symptoms
3. Objective functional cardiac signs
4. Phobias regarding heart disease
5. Fainting or syncope

NEUROCIRCULATORY ASTHENIA OR CARDIAC NEUROSIS

DEFINITION

Neurocirculatory asthenia (NCA) refers to an ill defined syndrome of psychogenic or neurogenic origin, often mistaken for organic heart disease and characterized by dyspnea, precordial pain, palpitation, exhaustion and a general incapacity or inefficiency in adjusting *to physical or emotional strain.*

Despite the distinctive titles given to this syndrome it is not a nosologic entity. It is nothing more than a moiety of the more general picture of psychoneurosis which in the cases under discussion chances to assume entirely or predominantly the garb of cardiac or circulatory symptoms.[34] Hence the term "cardiac neurosis." DaCosta[10] in 1871 applied the title "irritable heart" but recognized that the manifestations were due to a functional cardiac disorder. "Disordered action of the heart" (DAH) and "soldiers heart"[32] were popular terms during World War I. Parkinson[39] and Lewis[31] employed the synonym "effort syndrome" because the symptoms were readily induced by minor exertion.[2] Oppenheimer and associates[37] first employed the label "neurocirculatory asthenia" to denote a generalized weakness of the circulatory system due more particularly to its innervation but they clearly recognized the importance of the psychoneurotic factor in its causation.

ETIOLOGY AND PATHOGENESIS

Underlying Cause: Psychologic Disturbances

The underlying cause appears to be a fundamental ego insecurity arising from psychologic problems which began in infancy and childhood. In the vast majority of cases a careful history discloses previous serious maladjustments or nervous breakdowns, long absences from school or work, or unexplained prolonged illnesses.[13, 11, 7, 9] The relative importance of constitutional (genogenic) factors and of psychic factors in producing neurocirculatory asthenia is undetermined.

That psychologic disturbances frequently present their "somatic" extension into the cardiac sphere is not surprising. The heart is the traditional center of emotional expression. *There is an early awareness of* changes in cardiac activity with the strain of physical and emotional activities.[5] Literally and figuratively life and its emotions are symbolized in the beat of the heart and death in its stoppage. Death fears and death wishes are psychologically interwoven in the maladjusted person and the heart is an appropriate site for their somatic expression. Finally, accidental factors often determine the cardiac localization of psychoneurotic disturbances, e.g., the inadvertent remark of a physician, rejection of an application for life insurance, news of cardiac disease or of the cardiac death

of a relative, friend, neighbor or prominent person or the experience of palpitation or precordial discomfort

Physiologic Mechanism

In recent years physiologic methods have been applied to the study of functional disorders of the heart and an effort has been made to interpret these disorders in terms of pathologic physiology [5, 1] The similarity of the manifestations of neurocirculatory asthenia to those associated with stimulation or inhibition of the sympathetic and vagal nervous system suggested that the syndrome was due to autonomic imbalance "[29] On the basis of clinical and experimental data a more primary origin of the "autonomic imbalance" is postulated in the hypothalamic region and the latter is conceived as being functionally disturbed by abnormalities in cortico hypothalamic control [III] Since the hypothalamus is a center for the mediation of numerous endocrine and metabolic as well as autonomic nervous functions the concept of an hypothalamic origin of neurocirculatory asthenia is at best a non specific one A hypothalamic disturbance can be assumed with equal propriety for gastrointestinal and other visceral functional disturbances as well as for a host of so-called psychosomatic diseases

NCA and Hyperventilation The Hyperventilation Syndrome

The similarity of certain symptoms of NCA to those of hyperventilation [3] suggested that the latter was a major factor in the production of functional cardiac manifestations [40] However it has been amply demonstrated that these symptoms usually appear in the absence *of hyperventilation, and the latter is merely* one and only an occasional one of the manifestations of the underlying psychologic or neural disturbance [50]

Conversely hyperventilation may produce a clinical syndrome characterized by neurovascular, muscular respiratory, gastrointestinal and psychic, as well as cardiac manifestations [III] The cardiac and respiratory manifestations of the hyperventilation syndrome, viz palpitation, tachycardia atypical chest pain together with fatigability, faintness and breathlessness have certain resemblances to those of neurocirculatory asthenia but other features due to hyperventilation are lacking in the latter

NCA and Graves Disease

Because of a resemblance of functional cardiac symptoms to some of the symptoms of hyperthyroidism, NCA has been interpreted as an earlier and larval form of Graves' disease [35] This relationship has not been demonstrated for any significant number of cases

Extrinsic Factors—Relation of War and Strain

Neurocirculatory asthenia is predominantly a disorder of civil life, but it appears in a more striking form and has been studied most extensively among soldiers during war As in previous wars the outbreak of World War II was soon followed by the publication of numerous studies of NCA [31, 41, III] I have indicated that the fundamental cause of NCA is a psychologic insecurity and maladjustment but the onset of overt symptoms, as with all psychoneurosis, is usually precipitated by some extrinsic environmental strain War presents a particularly intense life strain with removal from family and friends dislocation of environment and activity new competitive situations close exposure to severe physical exertion intense anxiety and fear as well as risk of death In civilian life the symptoms of neurocirculatory asthenia are likewise precipitated by stress producing life situations associated with fear anxiety anger, frustration and despair [49, 4] However, these are rarely as intense as those presented by intimate and prolonged exposure to the actual hazards of war The more serious the intrinsic psychiatric difficulty the less severe is the external factor needed to precipitate symptoms Conversely even the so-called normal individual may exhibit functional cardiovascular symptoms if the environmental strain is extremely intense and prolonged

Age

In its overt form neurocirculatory asthenia is said to occur most commonly between the ages of 20 to 40 but this is largely a matter of terminology It may occur at any age

Sex

In civilian life it is much more common among females than among males

Heredity

Functional cardiovascular or other psychoneurotic symptoms are common among the parents and siblings of patients with neurocirculatory asthenia There appears to be a high family incidence of neurocirculatory asthenia

Infections

Acute infections have often been arraigned

as precipitating causes of NCA. Although this relationship is possible not only physical factors but complex psychologic ones may be involved. Sometimes maternal or familial overprotection and overanxiety during a childhood illness set up a pleasant subconscious association with ego importance and exaggerated parental attention. Often this initiates abnormal anxieties regarding illness and a withdrawal from physical exercise, especially active sports. With subsequent illnesses the pattern both of anxiety and prolongation of disability tends to recur.

CLINICAL FEATURES

Symptoms

Dyspnea is usually the commonest and most distressing symptom. It generally occurs at rest and is described as an inability to take a deep breath and not as a panting such as follows exertion. There is often an irregular sighing which is readily demonstrable in the curve of a basal metabolism test. The incidence and severity of the dyspnea are disproportionate to the degree of exercise and to the objective disturbances in ventilation.[3]

There are occasionally spontaneous attacks of dyspnea and tachypnea which have been described as the hyperventilation syndrome. They have been interpreted as a psychogenic expression of the fear of suffocation, especially in patients with claustrophobia.[48] These outbursts are often associated with tachycardia, giddiness, axillary and palmar sweating, and anxiety and may culminate in frank tetany.[illegible] Patients with NCA and respiratory symptoms exhibit a diminished capacity for breath holding.[50]

Pain in the precordium is usually distinctive from that of angina pectoris. It may be a dull continuous ache or soreness or may be sharp, intermittent and dartlike. The pain is usually localized to the region of the apex of the heart, the nipple or inframammary area. It is either unrelated to effort or occurs some time *after* a tiring exertion. Unlike the pain of angina pectoris it does not compel the patient to stop activity nor is it rapidly relieved by rest. Occasionally there is an associated local precordial tenderness which may be abolished by the infiltration of procaine. The precordial pain of NCA has been attributed to excessive use and tonic spasm of the intercostal muscles.[50] This explanation is based on the observation that patients with functional cardiovascular disturbances tend to breathe almost exclusively with their chest wall and not with their diaphragm.[50, 18]

Palpitation occurs commonly. As a rule there is an uncomfortable awareness of the heart beat in the absence of any arrhythmia. But tachycardia and a forceful cardiac pulsation are often present. Occasionally premature beats or paroxysmal tachycardia account for distressing cardiac discomfort, pain and intense anxiety.

Fatigability is a characteristic feature of neurocirculatory asthenia. It takes two forms. One is a sense of great fatigue on arising in the morning which gradually diminishes in the course of the day's activity. The other is a profound exhaustion following relatively minor physical exertion. In severe cases of NCA the patient spends many hours in bed during the day as well as at night.

Psychic symptoms characterized by phobic, depressive and hypochondrial elements have been described by Badal.[4]

Fever of mild degree is not uncommon in civilian practice; it often presents great difficulty in diagnosis and management. The temperature rarely exceeds 100.5 and is often discovered after a mild sinusitis or respiratory infection. Often it is the physician who initiates cardiac symptoms by diagnosing rheumatic fever and advising prolonged bed rest.

Other symptoms which are included in the syndrome of NCA are dizziness, sweating, cold clammy palms, nervousness, tremor, headache, flushing, frequency of micturition, insomnia, paresthesia, faintness, diarrhea, difficulty in concentration, indecision, impairment of memory and a tendency to mental, emotional and physical apathy.

Objective Signs

There are no objective signs of organic cardiac disease as a rule. But patients with NCA may independently experience rheumatic, coronary (atherosclerotic) or other cardiac disease. Furthermore the discovery of such organic heart disease may be the factor which precipitates overt symptoms of NCA.

The electrocardiogram is usually normal.[47] In some patients there is a depression or inversion of the T wave in leads II and III and in precordial leads.[3] More often the T waves are normal when the patient is recumbent and abnormal when he sits or stands. The fact that

these postural electrocardiographic changes may be minimized or abolished by ergotamine suggested that they are due to sympathetic stimulation [illegible] The heart tends to be small, but it is normal when related to the size of the thorax and body [15, 6]

Tachycardia is common not as a result of effort but because of emotional attitudes [27] Following exercise the pulse rate increases more than normally and its return to the original level is abnormally delayed The blood lactate concentration is significantly higher in NCA during moderate exercise than in control subjects [7] The vital capacity is normal but there is an increase in minute respiratory volume [8]

DIAGNOSIS

The diagnosis of NCA is based on the general appearance and behavior of the patient, on an analysis of the above mentioned symptoms and on the exclusion of organic heart disease But the diagnosis should also be made when NCA is combined with organic heart disease by a similar analysis of the symptoms and by recognition of the lack of relationship to the type and severity of the organic disease The diagnosis of neurocirculatory asthenia should be made not only by exclusion of organic cardiac disease but also by positive data supporting the psychologic basis of the symptomatology

A *hyperventilation test has been suggested* to aid in diagnosis [17] The duration of breath holding after hyperventilation, divided by the duration of breathholding before forced breathing is termed the hyperventilation index Normally it exceeds 1 3 In patients with NCA who have respiratory symptoms it is less than 1 3 Its value remains to be assessed

DIFFERENTIAL DIAGNOSIS

Neurocirculatory asthenia is not infrequently treated as rheumatic fever, sinusitis, undulant fever, tuberculosis and hyperthyroidism It is especially important not to misinterpret the symptoms as being due to organic heart disease

PROGNOSIS

The outlook for disappearance of symptoms and for efficient work is poor when there is a serious psychiatric background a long history of symptoms and when the syndrome of NCA appears after relatively brief and minor strain On the other hand a good symptomatic result may be anticipated if the syndrome appears acutely, after a prolonged and very intense emotional and physical strain in an individual without previous significant psychomotor or personality derangement If the precipitating cause can be discovered and abolished, it is probable that the symptoms can be alleviated

Follow up studies of cases of NCA are difficult to evaluate and compare because cases are not analyzed according to the above mentioned factors and because of differences in criteria of improvement or cure Grant [1] studied 601 former soldiers with NCA about seven years after discharge Approximately 15 per cent were free of symptoms another 15 per cent improved, and over 50 per cent unchanged or worse Relatively poor results were reported by Parkinson [illegible] and by Jones and Lewis [27] whereas others reported remarkable therapeutic results as measured by the percentage of patients returned to military duty [43, 19, 26]

TREATMENT

Winning and retaining the patient's confidence and cooperation are essential This is usually accomplished by a careful and detailed history and physical examination and the demonstration of a complete understanding of and interest in the patient's symptoms Reassurance as to the absence of organic heart disease is invaluable The recommendation of rest is to be avoided While it may provide the solace that comes from the avoidance or escape from life's situations, it usually fosters *the very factors responsible* for the disorder

Specific treatment should be directed toward the underlying psychologic abnormality and toward the extrinsic factors which appeared to precipitate the syndrome [illegible] When the latter occurs acutely as a result of an obvious extreme harrowing experience reassurance as to the circulatory status and elimination of the precipitating cause are usually curative In other acute cases without previous profound psychologic difficulties the precipitating factor is less obvious and must be sought by repeated discussions or by narcohypnosis if necessary Elimination of the precipitating factor when possible and guidance of the patient in management of his problem or in his adjustment to it often yield a favorable result

In chronic cases the discovery and control or removal of the precipitating factor are likewise helpful but it is desirable and often essential that the total life situation of the patient and his attitudes and emotional reactions be analyzed A revision in the patient s standards and goals which are retained from infancy and childhood is often valuable An effort should be made to enhance his ego security by lowering his exaggerated and anachronistic standards by increasing his self evaluation and by promoting his physical and intellectual capacities and his social relationships

Treatment of individual symptoms is secondary but important Beneficial results have been attributed to the judicious use of sedatives vitamins sex hormones and occupational therapy as well as to reassurance and reeducation Reeducation should involve the formulation of and guidance in a program of physical mental and social activity best suited to the individual s particular problems capacities and needs

ISOLATED AND TRANSIENT FUNCTIONAL CARDIAC SYMPTOMS

Under this heading are included cases in which isolated functional symptoms such as difficulty in taking a deep breath precordial pain or palpitation occur in an individual without apparent psychologic difficulties As a rule he is annoyed by the symptom and may be worried about the presence of heart disease but his efficiency at work and his interpersonal social relationships appear unimpaired

In such cases reassurance as to the normalcy of the heart and the functional nature of the symptom often suffices to alleviate it or to render the patient unconcerned Sometimes a change in hygiene including more sleep and relaxation a holiday a bland diet and regular bowel habit and elimination of tobacco alcohol and coffee are helpful especially for palpitation or submammary pain Local infiltration with procaine may eliminate pain at least temporarily and convince the patient that it arises in the chest wall and not in the heart Physical exercise including training in abdominal (diaphragmatic) breathing is valuable in patients with functional dyspnea If the symptom is severe and persists despite these measures a more fundamental psychiatric investigation and treatment are necessary

OBJECTIVE FUNCTIONAL CARDIAC SIGNS

Under this heading are included systolic murmurs arrhythmias tachycardia or minor electrocardiographic abnormalities which cannot be related to any underlying organic disease Tachycardia [illegible] paroxysmal tachycardia[4] and heart block[4, 11] have been related to precipitating emotional factors These have been discussed in connection with the above mentioned individual conditions Careful cardiac investigations and follow up examinations are essential to exclude organic disease If evidence of organic disease is absent it is best to emphasize this to the patient, to reassure him and to avoid restriction of activity On the other hand insurance examiners are often compelled to reject such individuals for insurance or to increase their premium rates on the purely statistical basis of a greater than expected mortality rate

HEART PHOBIAS

This includes three types of cases (1) fear of cardiac death although there are neither symptoms nor signs of cardiac disease[9] (2) fear of cardiac death because of functional symptoms or signs or (3) fear of cardiac death because of actual organic heart disease Sometimes symptoms referable to the heart or a fear of heart disease are the result in part or in toto of words or actions of the physician Such an anxiety neurosis has been termed *iatrogenic heart disease*[15] However the iatrogenic factor should not be overemphasized since there are usually more fundamental constitutional and/or psychologic underlying causes[illegible]

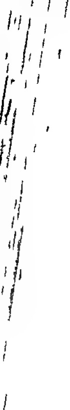
The first group presents a purely psychiatric problem and should be so handled In the second and third groups the therapeutic mainstay is reassurance as to either the absence of heart disease in group (2) or as to the favorable outlook if the patient in group (3) follows the physician s instructions In all groups avoidance of unnecessary restrictions as to physical activity supports the physician s verbal reassurance

FAINTING AND SYNCOPE

These have been discussed in Chapter 12 They are mentioned here because many people associate fainting with cardiac disease However cardiac disease is responsible for only a small minority of cases e g , Adams-

Stokes syndrome Although emotional factors, especially fear and anxiety may induce the common type of vasodepressor faint, there is often no profound psychologic difficulty If the stimulus such as the sight of blood or an operation is repeated several times, the syncopal response may no longer occur In many of the patients subject to occasional faints of the vasodepressor type there appears to be a defect of vasomotor regulation

Hysterical fainting has been distinguished by the absence of objective changes in blood pressure pulse or electroencephalogram The fainting is due to a deep seated psychologic disturbance



Hyperventilation may produce giddiness and a faint feeling but no syncope except indirectly by inducing anxiety and a vasodepressor reflex [12]

PART VII

SPECIAL PROBLEMS IN HEART DISEASE

Chapter 47

PREGNANCY AND HEART DISEASE

Pregnancy is a physiologic process which imposes a functional load on the heart and circulation. Pregnancy is well borne by the normal heart, which calls upon its substantial reserve to supply the increased demands of the growing embryo. The response of the diseased heart, on the other hand, is not always adequate and varies with the degree of cardiac compensation before pregnancy. The well compensated heart may tolerate the increased circulatory demands of pregnancy essentially as well as the normal heart under the same circumstances; hearts with limited reserve fail with significant frequency. Thus pregnancy is not responsible for a specific etiologic type of heart disease. But in the presence of a previously diseased heart, pregnancy may represent an intolerable circulatory burden which induces cardiac failure and death.

Preexisting heart disease has been generally regarded as the most important complicating factor likely to endanger the otherwise smooth course of normal pregnancy and labor, but this may no longer be accurate since cardiac complications are being avoided or treated more effectively.[illegible] According to Hamilton,[42] *heart disease was present in 1.8 per cent of 76,125 pregnancies* treated at the Boston Lying-In Hospital in the past twenty-five years. In other studies the incidence of heart disease in pregnant women varied between 1 and 7 per cent.[44, 84, illegible, 42, 1] Heart disease in pregnancy almost always means rheumatic heart disease. The latter is encountered in over 90 per cent of pregnant cardiac patients; congenital cardiovascular lesions occur in 1.5 to 5 per cent, whereas syphilitic, hypertensive and other types of heart disease are observed only occasionally.[6, illegible, 42, 11, 56] Among the rheumatic cardiac cases, mitral stenosis alone or in combination with aortic valvular disease occurs in at least 75 per cent

PATHOLOGIC PHYSIOLOGY OF THE CIRCULATION IN PREGNANCY

Oxygen Consumption and Basal Metabolism. The circulation in pregnancy provides an increased volume of blood necessitated by the growing embryo. The latter augments the total metabolism of the body and consequently the *consumption of oxygen*. According to Cohen and Thomson[30] the *consumption of oxygen* increases between 15 and 25 per cent, owing almost entirely to the uterus and its contents.[17] But since this approximates the average weight change during pregnancy, they concluded that the *basal metabolic rate* was essentially unchanged. On the other hand, Clute and Daniels[28] stated that the *basal metabolic rate* in normal pregnancy was elevated as much as 25 to 30 per cent. Watrous and Blakely[67] found a slight progressive rise in basal metabolism during pregnancy and a maximal increase of 5 to 25 per cent at the tenth month.

Cardiac Output. The cardiac output (minute volume) increases progressively *from the third or fourth month to the twenty-fifth to the thirtieth week, at which time it is usually about 30 to 50 per cent above normal.*[37, 8, 20, 71, 45, 2, 8] In the last 8 to 10 weeks of pregnancy there is a moderate fall in the cardiac output from these maximal levels. The cardiac output falls to prepregnancy levels about two weeks post partum. In part, the augmented output is mediated by a slight acceleration of the pulse rate (10 to 20 beats per minute), but in large measure it is due to a greater output per beat (elevated stroke output). The increase in cardiac output is greater than the increase in oxygen consumption. The arteriovenous oxygen difference is diminished.

Work of the Heart. The work of the heart is proportional to the product of the cardiac output and the mean arterial blood pressure

Since the latter [redacted] not usually altered during pregnancy[47, 3] the work of the heart per beat and per minute are increased by as much as the cardiac output namely up to about 50 per cent[87] This additional work may represent the extent of the cardiac load of pregnancy

Circulation Time The augmented cardiac output reflects a similar enhancement of the venous return to the heart The latter is accomplished in part by an acceleration of the speed of the circulation and in part by an enlargement of the circulating blood volume There [redacted] a progressive acceleration of circulatory speed (reduced circulation time) from the third to the ninth month of pregnancy This acceleration diminishes moderately in the last weeks before term[29] While there are discordant reports regarding the circulation time[88, 60, 28] the findings of Cohen and Thomson[29] have been confirmed by those of Manchester and Loube[redacted] whose determinations in 48 pregnant women disclosed a progressive circulatory acceleration from an average circulation time of 12 4 seconds in the first trimester to 10 2 seconds in the third trimester

Blood Volume Recent studies using T 1824 dye[2] radio-iron[24] or P^{32} labeled red cells[7] have yielded results somewhat at variance with those previously reported[94] Nevertheless, there appears to be a progressive rise in blood and plasma volume beginning about the thirteenth week of pregnancy reaching a maximum about the thirty second week, and diminishing thereafter The peak increase in blood volume is about 30 per cent, in plasma volume about 40 per cent and in erythrocytes about 20 per cent The red cell volume may continue to increase to term[24]

Since the plasma volume increases proportionately more than the cell volume there is a diminished viscosity and hematocrit which may account for an apparent slight anemia

Total body water like plasma volume increases progressively but unlike the latter its volume rises until the end of pregnancy[41, 53]

Sodium retention is an important feature in pregnancy The normal total exchangeable sodium was found to average 39 3 milliequivalents per kilogram There was an average absolute increase of 20 mEq per week or a total of 500 mEq during the second and third trimesters The increment in exchangeable sodium could be accounted for by the uterus and its contents and the expanded blood volume[40] The retention of sodium and water in pregnancy has been related to the increased activity of the adrenocortical sodium retaining hormone, aldosterone Its secretion rises sharply after the third month of pregnancy and remains at a high level up to term[95] Following delivery it declines speedily to pre pregnancy levels

SIGNIFICANCE OF CIRCULATORY CHANGES

The circulatory changes in pregnancy have been interpreted [redacted] similar to those of an arteriovenous fistula[16] There is an almost direct connection between arteries and veins in the placenta[85] The consequent blood shunt from the arterial to the venous side results in an acceleration of blood flow, of venous return and of cardiac output Some support for this concept was found in observations of the circulatory dynamics during and after labor by Brown and her associates[redacted] but there are many gaps in the analogy between the circulatory changes in pregnancy and those in cases of arteriovenous fistula

The circulatory adaptations in pregnancy may be likened also to those of hyperthyroidism in that in both they are designed to satisfy increased metabolic demands—local demands in pregnancy generalized in hyperthyroidism In both increased metabolism results in accelerated velocity of blood flow, which is, however, much less pronounced in pregnancy The increased speed of circulation is insufficient to maintain the required cardiac output in pregnancy and the progressive augmentation of blood volume may be regarded as a compensatory mechanism to provide a needed increase in cardiac output The cardiac output increases substantially more than the oxygen consumption[19] because of a subnormal arteriovenous oxygen difference, the latter [redacted] probable consequence of the accelerated speed of circulation

While the increased circulating blood volume and the augmented venous return are thus viewed as adaptive mechanisms their disadvantages must also be considered Like exercise, saline infusions and other factors which enhance the venous return, the load of pregnancy imposes no serious strain on the normal or well compensated heart The diseased heart with diminished functional reserve, may be unable to maintain an adequate cardiac output despite the enlarged blood volume Further increases in blood

volume cannot be normally propelled by low-reserve hearts The consequence is a congestion of the lungs viscera and other tissues behind the failing chambers Since the accelerated blood flow the augmented blood volume venous return cardiac output and work of the heart all become significantly greater after the third or fourth month and reach their maximum in the eighth lunar month the intervening period represents the span of increasing danger to the cardiac patient There is in fact a close correlation between the time of onset of heart failure and the severity of the circulatory load [84]

CIRCULATORY DYNAMICS OF LABOR

As compared with the prolonged and increasing strain of pregnancy that of labor is relatively well tolerated Nevertheless it does represent a strain comparable to that of muscular exercise The oxygen consumption rises during labor [81] Slight tachycardia occurs during the actual delivery and bradycardia post partum Labor is associated with a moderate transient elevation in arterial blood pressure and a corresponding increase in the work of the heart [81] It has been noted that the blood volume cardiac output and work of the heart diminish significantly in the eight weeks before term whereas the fetus continues to enlarge and the oxygen consumption red cell mass and total body water continue to increase up to term After labor there is a further reduction in blood volume and a considerable fall in body water associated with marked diuresis A rise in venous pressure in the first 24 hours after delivery has been attributed to the effects of Ergotrate [13] That the strain of normal labor is less than that of pregnancy is supported by the infrequency of heart failure beginning during or immediately after delivery On the other hand if heart failure is present when labor starts there is a great risk of intensifying the myocardial insufficiency This is particularly likely to occur in the first 24 to 48 hours post partum

CARDIOVASCULAR MANIFESTATIONS DURING PREGNANCY

An evaluation of the cardiac status should take into account the frequency of cardiac symptoms and signs in pregnant women even without heart disease These may simulate the manifestations of organic heart disease and heart failure [84]

Dyspnea at rest and on exertion and orthopnea are common complaints especially in the latter half of pregnancy The dyspnea may be due to increased respiratory effort to ventilate the deflated lung of pregnancy Often the dyspnea of pregnancy takes the form of sighing respiration or of inability to take a deep breath a disturbance of psychic origin In any event neither exertional dyspnea nor orthopnea is to be regarded as certain evidence of heart failure without careful evaluation

Ventilation and Lung Volumes Careful studies have disclosed that the vital capacity remains unchanged or increases slightly during the course of pregnancy [93] The inspiratory reserve is increased the expiratory reserve and residual volume slightly decreased [17] Breathing is performed with the lungs chiefly in the expiratory position However although the vital capacity is normal or only slightly increased the minute volume ventilation is greatly increased [4] According to Cugell et al [4] ventilation increases somewhat in the first trimester and progressively thereafter to a maximum increase of about 42 per cent at the tenth month The increment in ventilation exceeds that of oxygen consumption indicating that the pregnant woman hyperventilates at rest This inefficiency may be due to increased work necessary to ventilate the deflated restricted lung of pregnancy

Palpitation and tachycardia are frequent with or without associated dyspnea Respiratory distress choking sensations and palpitation occurring at night may simulate an attack of paroxysmal nocturnal dyspnea But cough with frothy or blood stained sputum and pulmonary rales are not noted There may be transient basal rales due to compression of the lung by the elevated diaphragm but these disappear after cough or a few deep respirations

Edema of the legs develops in about 25 per cent of non cardiac pregnant women especially during the last two months of pregnancy The association of dyspnea and edema is likely to suggest the possibility of heart failure But the edema is a local phenomenon confined to the lower extremities It is due to compression of the iliac veins by the enlarged uterus and its contents While an extremely high venous pressure in the lower extremities is probably the chief cause of the dependent edema the enlarged circulating blood volume

a diminished concentration of blood proteins and of osmotic pressure, and local tissue changes may be contributory factors That the edema is not due to heart failure may be perceived from the absence of venous engorgement in the cervical veins and from the normal venous pressure in the upper half of the body

Cardiac enlargement may be diagnosed because the apical impulse is displaced to the left and upward by the elevated diaphragm Roentgenologic observations disclose displacement of the heart upward laterally and forward as pregnancy advances, owing chiefly to elevation of the diaphragm and to lordosis The transverse diameter of the heart may thereby be increased These findings suggest cardiac enlargement but the area and volume of the heart increase only in proportion to an increase in the corresponding dimensions of the chest [9] Allowance should be made for the tendency to overestimate the size of the heart on physical examination and the difficulties of such examination due to the enlarged breasts Hollander and Crawford [9] were impressed by the cardiac indentation of the anterior wall of the esophagus

A *systolic murmur* is audible at some time during pregnancy in most women Usually it is in the pulmonic or apical regions Diastolic murmurs should be considered as evidence of organic heart disease unless proven otherwise A third heart sound is frequently audible and may simulate the gallop rhythm of heart failure The second pulmonic sound is often loud and may be accentuated and reduplicated especially in the third trimester A slight tachycardia is the rule with the highest cardiac rate in the eighth month Premature beats are not uncommon and may be associated with palpitation Paroxysmal atrial tachycardia is being reported with increasing frequency during normal pregnancy [9, 91] The *arterial blood pressure* is often unchanged during pregnancy, or there may be a reduction in the diastolic blood pressure with a consequent increase in pulse pressure A collapsing pulse and capillary pulsation may accompany a wide pulse pressure in the absence of aortic valvular disease

The *electrocardiogram*[93] usually shows a left axis deviation and an inversion of T_3[22] in the first two trimesters These are due to the transverse position of the heart and resemble the findings in the electrocardiogram of obesity A deep Q_3 as well as the inverted T_3 is encountered in a small percentage of cases and is probably due also to the altered position of the heart [22, 60] *Vectorcardiographic changes* in pregnancy[15] are similarly related to positional changes

DIAGNOSIS OF CARDIAC DISEASE IN PREGNANCY

The recognition of organic heart disease when present, is essential for the proper management of the pregnant woman Due care must be taken not to mistake the above-mentioned findings in pregnancy for cardiac disease

Often a careful history will reveal that the patient has some organic cardiac lesion and simple physical and fluoroscopic examination readily confirms this information But occasionally a previous diagnosis of heart disease may be found to be inaccurate On the other hand, the absence of a history of rheumatic fever or the failure of previous routine examinations to disclose a cardiac disease should not be accepted as proof that the heart is normal

Since the common heart disease of pregnancy is rheumatic heart disease careful search should be made for evidence of mitral or aortic valvular disease The crescendo presystolic murmur of mitral stenosis may be overlooked unless the patient is examined *in* the left lateral (decubitus) position preferably after exercise The murmur may be sharply localized to the apex The diastolic murmur of aortic insufficiency is often best heard along the left sternal border with the patient standing and with the breath held in expiration A loud systolic murmur may be due to rheumatic aortic stenosis a systolic thrill should be sought carefully *In its absence* pulse tracings may confirm the diagnosis

Fluoroscopic examination may provide the first clue or the confirmatory evidence of heart disease Cardiac enlargement *should* be unequivocal to be diagnostic in itself The localization of the enlargement *may* be especially significant, e g , the left atrium and the pulmonary salient in mitral stenosis and the left ventricle in association *with* dynamic pulsations of *the ventricle* and aorta in cases of aortic insufficiency

The possibility of *congenital heart disease* should be considered The machinery like

murmur of a patent ductus arteriosus is distinctive Coarctation of the aorta may be suggested by the presence of hypertension or an unexplained loud systolic murmur especially in the left posterior chest Subaortic stenosis may be suggested by a loud aortic or pulmonic systolic murmur and thrill since infancy and by left axis deviation in the electrocardiogram Tetralogy of Fallot has rarely been encountered in pregnancy, but more patients with this condition may live to maturity and become pregnant following the Blalock or Potts operation

In summary the recognition of cardiac disease in pregnancy requires a careful physical, fluoroscopic and electrocardiographic examination A diastolic murmur and distinct cardiac enlargement are the chief diagnostic features The cardiac enlargement is most suggestive if it involves distinct contours of the heart which can then be related to corresponding valvular lesions and murmurs In the presence of loud systolic murmurs, a diagnosis of organic heart disease depends on confirmatory findings such as thrills, unequivocal cardiac enlargement or collateral evidence of congenital heart disease

DIAGNOSIS OF HEART FAILURE

Having distinguished the cardiac patient in pregnancy, the physician must evaluate the functional capacity of the heart and make careful observations to recognize promptly the development of heart failure

In practice a careful history of the patient's exercise tolerance as determined by her response to various activities in her daily life is a useful guide to the functional capacity of the heart Her ability to consummate a previous pregnancy and labor successfully is an important index of cardiac capacity Since dyspnea and orthopnea occur during pregnancy without heart disease their usual merit as early clues of heart failure is somewhat vitiated Nevertheless, by careful history and observation the physician may justly conclude that the dyspnea is out of proportion to that attributable to pregnancy and is in fact caused by heart failure Unexplained cough especially that which occurs on effort is also a valuable early clue to the possible occurrence of heart failure Breathlessness may awaken the patient from sleep or may occur after intercourse The association of cough with frothy or blood tinged sputum and with persistent rhonchi or moist râles in the chest denotes that the dyspnea and cough are due to left sided heart failure Relief of the dyspnea and the cough following extreme restriction of salt and one or two injections of mercurial diuretics is a valuable diagnostic test to confirm the diagnosis of heart failure

Objectively heart failure may be first discovered by serial determinations of vital capacity which is normal in uncomplicated pregnancy In the presence of pulmonary congestion due to left sided heart failure there is usually an unequivocal reduction in vital capacity Although the determination of vital capacity has many limitations it is of value if the patient is intelligent and cooperative and has been taught to perform the test and if successive tests are compared at regular intervals Nevertheless it is not a practical routine procedure As a rule the earliest sign of congestive heart failure is the development of persistent rales at the bases of the lungs The lungs should therefore be examined regularly and carefully in all cardiac patients throughout pregnancy *Prolongation of the circulation time* with or without elevation of the venous pressure is a valuable indication of the presence of heart failure

Of course there is usually no difficulty in determining the presence of heart failure when the complete clinical picture is unfolded The patient is dyspneic on the slightest exertion or at rest Complete recumbency is intolerable because of respiratory distress Mild or moderate cyanosis is common in patients with mitral stenosis and heart failure Râles are readily audible throughout the lower portions of the lungs Hydrothorax may be present The cervical veins become engorged The liver is enlarged and tender Edema of the lower extremities is pronounced

PROGNOSIS OF CARDIAC DISEASE ASSOCIATED WITH PREGNANCY

Rheumatic Heart Disease

The prognosis of heart disease in pregnancy is essentially that of rheumatic heart disease Pregnancy involves a greater risk for the cardiac patient than for the normal individual However with increasing knowledge and attention to the problems of the cardiac patient the mortality rate during pregnancy has been substantially reduced From quoted figures

of 40 to 55 per cent mortality at the turn of the century, the rate dropped to 15 per cent in the first three years after the formation of the Heart Clinic at the Boston Lying In Hospital in 1921, to 5 per cent between 1925 and 1927 and to 2 or 3 per cent between 1937 and 1939 [44] The over all maternal death rate among cardiac patients in the past twenty five years was 3 9 per cent There were 17 deaths (4 8 per cent) among 352 cardiac patients carried through pregnancy and for two years post partum by Jones,[46] and only 29 deaths among 3000 pregnant cardiacs reported by Mendelson [57] These mortality figures apply essentially to rheumatic heart disease which accounts for 90 per cent or more of heart disease in pregnancy

Although the maternal death rate is still about five times as high as among non cardiacs it is perhaps as important to emphasize the 97 or 98 per cent chance of survival among cardiac patients who are pregnant as to stress the greater risk among these patients Furthermore the mortality rate among pregnant cardiacs should be compared with that of non pregnant cardiacs in the same age range for the expected mortality among cardiacs is higher than that of non-cardiacs, independent of pregnancy It appears likely that if the obviously decompensated patient is restricted from becoming pregnant and if the compensated cardiac patient is carefully managed to avoid heart failure during the course of pregnancy or is properly and promptly treated if heart failure does develop, then the maternal mortality rate among pregnant cardiacs need not significantly exceed that among non cardiac pregnant individuals nor that among comparable cardiac patients who are not pregnant [84]

The prognosis among cardiac patients during pregnancy conforms remarkably with that anticipated on the basis of cardiac functional classifications made at the onset of pregnancy Utilizing the functional classification of the New York Heart Association, Pardee[72] observed the following mortality in the various classes

Class I Patients with organic heart disease who suffer no limitation of activity There were no deaths among 157 patients in this category

Class II A (now Class II) Patients with heart disease who suffer slight or moderate limitation of activity There was 1 death among 180 patients in this group

Class II B (now Class III) Patients with heart disease who experience moderate to great limitation of physical activity Less than ordinary physical activity causes discomfort There were 8 deaths among 169 such patients

Class III (now Class IV) Patients with heart disease who are unable to carry on any physical activity without discomfort There were 16 deaths among 40 such patients

These and other observations indicate that pregnancy is tolerated without significant additional risk by the well compensated patient with heart disease but that the mortality rate increases as the degree of compensation diminishes Carr and Hamilton[21] and Hamilton and Thomson[44] found that an unfavorable outcome might be anticipated among those cardiac patients who present (1) signs of heart failure or a history of heart failure (2) a serious disorder of the heart beat such as atrial fibrillation, (3) a complicating serious disease such as diabetes pulmonary tuberculosis, nephritis Among 95 cases classified as "unfavorable' on the basis of these criteria, when first seen the maternal mortality rate was 16 7 per cent in contrast with a mortality rate of 2 3 per cent among 655 cases which were classified as "favorable because they did not satisfy these criteria Patients with atrial fibrillation suffered the notably high mortality rate of 33⅓ per cent However, it is doubtful whether atrial fibrillation per se is necessarily associated with a high mortality rate in pregnancy Atrial fibrillation denotes a late stage in the life history of rheumatic heart disease and is usually a precursor of or is accompanied by, heart failure The outlook in patients with atrial fibrillation is determined chiefly by the *functional capacity* of the heart and the absence or presence of heart failure It is chiefly because of pregnancies among cardiac patients with poor cardiac reserve or actual heart failure that the maternal mortality is relatively high among subjects with heart disease

If the patients who develop congestive heart failure during pregnancy labor or the puerperium are omitted from consideration it is doubtful whether pregnancy has any ultimate deleterious effects on longevity or mortality rates [84, 10] The studies of Friedberg and Tartakower[35] and of Reid[77] indicate that

if the pregnancy itself is well tolerated there is no shortening of the life of cardiac patients even after bearing many children

Congestive heart failure is the commonest serious complication of pregnancy in cardiac patients and the most frequent cause of death[11, 44] [illegible] Its likelihood of occurrence is greater the less the cardiac reserve of the patient as evaluated at the onset of pregnancy Cardiac failure occurs more frequently in cardiac patients who become pregnant after the age of 35 than in those below that age level The incidence of heart failure increases sharply after the fifth month of pregnancy and progressively thereafter to the eighth or ninth month corresponding to the similar increase in physiologic strain as described above With the reduction in circulating blood volume and cardiac output in the last eight weeks of pregnancy there is a corresponding diminution in the occurrence of heart failure According to Gorenberg and McGleary[37] 80 per cent of 77 cases of heart failure developed before the last month of pregnancy Acute heart failure beginning during the course of labor is uncommon but heart failure that is already present may be intensified The majority of deaths from heart failure occur during the puerperium but careful history and observation disclose that the onset of heart failure in such instances usually occurred during the course of pregnancy

Of the other complications of pregnancy in cardiac patients *subacute bacterial endocarditis* is one of the most important[33, 46] The early use of penicillin or penicillin and streptomycin in adequate dosage should minimize the mortality from this disease The maternal mortality during pregnancy in 85 patients with healed bacterial endocarditis and 35 patients cured of this disease during pregnancy was 6 6 per cent[72] Following recovery from bacterial endocarditis the outlook during a subsequent pregnancy is dependent on the functional status of the heart without regard to the history of the endocarditis But it is generally advised that at least six months should elapse following cure before childbearing is again undertaken

Pulmonary embolism infection toxemia and hemorrhage are complications in non cardiac as well as cardiac patients although embolism may occur more frequently in the latter With the inauguration of early ambulation and the use of anticoagulants the frequency of and mortality from pulmonary embolism may be sharply reduced Postpartum infection has already diminished as a cause of death since the use of antibiotics

About half of the cases of *dissecting aneurysm of the aorta* in women under 40 occur during the course of pregnancy

The importance and frequency of *activation of rheumatic fever* in pregnancy[37, 3, 51] has been greatly exaggerated There are no reliable data to indicate that pregnancy activates rheumatic fever Clinically active rheumatic fever is very rare during pregnancy although febrile episodes in the pregnant woman with rheumatic heart disease are erroneously attributed to rheumatic fever Rheumatic fever may be observed occasionally in pregnant women in their teens particularly when there has been rheumatic activity within the preceding two years

Congenital Cardiac Disease

Pregnancy and labor have been successful in many patients with congenital heart disease[64, 3] including those with interatrial or interventricular septal defects[80] congenital heart block[6, 74] patent ductus arteriosus[48] pulmonary stenosis coarctation of the aorta[47, 73, 79] tetralogy of Fallot[3, 4] and truncus arteriosus communis [illegible] There are insufficient data to permit a detailed discussion of each lesion in pregnancy In patients with septal defects or a patent ductus with left to right shunt there may be a dangerous or fatal reversal of shunt after the uterus is emptied The functional capacity of the heart and the presence or absence of cyanosis and heart failure rather than the specific lesion are generally the determining factors in the outlook for pregnancy and labor in women with congenital cardiac lesions In cases of coarctation of the aorta there is a particular *danger of vascular accident (ruptured cerebral aneurysm)* or dissection of the aorta attributed to a rise in blood pressure during pregnancy and labor[34, 63, 78] Miller and Falor[67] recommend that the coarctation be corrected surgically early in pregnancy But if the patient is first seen late in pregnancy a cesarean section should be performed and surgery undertaken subsequently Pregnancy may be undertaken safely after the coarctation is corrected Of some interest is the probability that the woman with congenital heart disease

is somewhat more likely to bear an infant with a congenital cardiac lesion than the mother with acquired heart disease

Hypertension and Nephritis Myocardial Infarction

Patients with chronic glomerulonephritis without azotemia and patients with mild essential hypertension assume only a slight risk with pregnancy Patients with severe hypertension and significant cardiac enlargement and those with azotemia assume a risk equivalent to that of patients with unfavorable rheumatic cardiac disease [5, 80] In addition there is some evidence that hypertensive patients have a higher than normal incidence of preeclampsia and eclampsia and that the progress of hypertension is hastened by pregnancy [48, ■] (See also Toxemias of Pregnancy on p 952) Attacks of paroxysmal dyspnea or pulmonary edema with extreme rise in blood pressure may necessitate an interruption of pregnancy but extreme restriction of sodium and fluids the administration of morphine, rest digitalization and diuretics may prevent or control the attacks

Cases of coronary occlusion followed by pregnancy with successful termination have been reported by Horwitz and associates [53] and others [12, 65] Coronary occlusion is a rare event during pregnancy, but 15 cases have been reported with survival in 13 [62] The two patients who developed myocardial infarction in the third trimester died

Arrhythmias

In the presence of persistent or frequent and annoying arrhythmias, quinidine or procaine amide may be administered, without any additional risk because of the pregnancy

FETAL MORTALITY

Among the hazards that cardiac disease adds to pregnancy is the *higher fetal mortality* than among normal pregnant women In the Boston Lying In Hospital the fetal mortality among favorable cases in ten years[42] was 8 6 per cent However among unfavorable cardiac cases the infant mortality was still relatively high at 31 per cent while among patients with atrial fibrillation the infant mortality was about 50 per cent According to Stromme and Kuder,[89] maternal heart disease does not adversely affect infant mortality but no detailed analyses are presented But Bunim and Rubricius[14] found that the infant mortality rate for their group of patients with congestive heart failure was three times ■ high as for patients with compensated heart disease and four times as high as for normal pregnant women delivered on the same obstetrical service Fetal death was found to be significantly increased among mothers with hypertension [98] The chief cause of infant mortality among cardiac patients is prematurity and stillbirth Some of this is due to the unwise practice of interrupting or inducing labor before the thirty fifth week From the viewpoint of the child as well as the mother the risk of labor diminishes in the last month of pregnancy There ■ evidence also that infant mortality ■ less when delivery occurs through the pelvis than when cesarean section is performed [27] The use of low forceps instead of entirely spontaneous delivery may also diminish the risk to the infant [9]

THE MANAGEMENT OF HEART DISEASE AND HEART FAILURE IN PREGNANCY

The major problem in the treatment of the cardiac patient during pregnancy is the prevention and control of heart failure [■] To this end it is essential that the presence of cardiac disease be recognized early The subject with such disease must be registered with her physician early in pregnancy and regular visits at one- or two week intervals should be made depending on her cardiac status and symptoms Cooperation with a cardiologist or with an internist interested in the problems of cardiac disease in pregnancy is desirable Cardiac patients should enter the hospital one to two weeks before the expected date of delivery for proper appraisal of the cardiac status planning of delivery procedure and for *the institution of* treatment of incipient heart failure if necessary

The precipitating causes of heart failure include acute infections especially those of the upper respiratory tract, overexertion and excessive sodium intake These should be avoided as far as possible Antibiotics should be administered promptly at the onset of infections If excessive anemia is discovered it should be corrected Arrhythmias should be treated speedily Sudden weight gain should be regarded as probably due to excessive water retention, and should be treated by more rigid restriction of sodium intake and by mercurial diuretics

The well compensated cardiac patient (Class I and some in Class II) requires little

restriction in activity except for severe and unusual physical exertions A rigid restriction in sodium intake appears desirable especially after the fourth calendar month A moderate restraint in weight gain also appears advantageous Digitalis is not given as a prophylactic measure in this group of patients In these as in all other cardiac patients excellent hygienic care including adequate periods of rest and of sleep attention to proper dietary intake and especially the avoidance of upper respiratory and other infections should be stressed A supplementary intake of vitamin B_1 may be necessary because of the added requirements of pregnancy and the possible contributory role of thiamine deficiency in heart failure

Cardiac patients whose outlook is less favorable because of a poorer cardiac reserve (Class III and some in Class II of the New York Heart Association) or those with a previous history of congestive heart failure require greater restrictions as to physical activity and more rigid regulation In some instances modified bed rest most of the day or rest in a chair or chaise longue may be necessary throughout pregnancy The intake of sodium should be reduced to 500 mg or less daily if possible Digitalis should be continued if started during a previous episode of heart failure Patients in this group of limited cardiac reserve should be hospitalized at least two weeks before term according to the requirements of the individual case Patients in Class III or IV usually require digitalization

If heart failure develops in any patient or is already present when the patient is first seen active treatment should be instituted as described above (Chapter 11) Bed rest at home or preferably in the hospital is necessary Digitalization should be effected and maintained Sodium intake should be restricted to 200 to 500 mg daily Mercurial diuretics should be administered every two to seven days according to the need and response If there is evidence of infection thiamine deficiency anemia or hypoproteinemia which might contribute to the development of heart failure these factors should be eliminated or corrected by appropriate measures The intravenous introduction of fluids containing sodium (saline plasma blood) should be avoided

In the presence of heart failure during the first three months of pregnancy the patient should be aborted by dilatation and curettage after treatment to control the heart failure In cases of heart failure noted later in pregnancy labor should not be induced until after seven calendar months have elapsed i e until after the fall from the peak of the circulatory burden It is unnecessary to terminate pregnancy before term in order to avoid the strain of labor since heart failure rarely begins in labor and since the strain of labor is less than that of pregnancy in the seventh calendar month Cesarean section may be desirable at term in patients with coarctation of the aorta

CARDIOVASCULAR CORRECTIVE SURGERY DURING PREGNANCY

Mitral Commissurotomy

This procedure has been performed in pregnant women with mitral stenosis and has been followed by a successful outcome of the pregnancy[4, 31, [illegible], 35, 44] It would be difficult to prove that the course of pregnancy would have been less favorable with proper medical treatment but without the operation Patients in Class I or II in whom the operative risk of mitral commissurotomy [illegible] low are the patients who are subject to minimal risk from the pregnancy itself and therefore require no prophylactic surgery Patients in Class III and IV in whom pregnancy may be associated with significant mortality are the ones in whom there is a substantial operative risk from mitral commissurotomy It remains to be proved that this operative risk is justified by the reduction in mortality from pregnancy itself effected by the operation If mitral commissurotomy is eventually desirable it is probable that it can be performed with less danger after the stress of pregnancy is over Furthermore it is uncertain how soon after the mitral commissurotomy sufficient clinical improvement will ensue and whether this will occur early enough to be of benefit during the pregnancy The frequent occurrence of the post-commissurotomy syndrome (p 675) points to the probable risk that this will develop before the completion of pregnancy and hamper its course If there is an error in the evaluation of the degree of associated mitral regurgitation the patient will be subjected to an operation which endangers rather than benefits the pregnant woman with cardiac disease

The question of performing a mitral com

missurotomy for mitral stenosis during pregnancy is most likely to arise when there are frequent recurrent attacks of pulmonary edema or refractory congestive heart failure If these conditions are present during the first trimester despite expert treatment, it is best to interrupt the pregnancy and perform a mitral commissurotomy some weeks or months later If these conditions develop after the third month or if the patient with these complications is first seen after that period vigorous medical treatment should be carried out and almost always will permit completion of the pregnancy without operation But if these manifestations of heart failure do not respond to meticulous treatment, a mitral commissurotomy may have to be performed if the evidence indicates that there is a very tight mitral stenosis[67] If pregnancy is interrupted during the first trimester because of severe heart failure, sterilization by tubal ligation is not necessarily indicated because a mitral commissurotomy may be performed later with a good chance of a subsequent successful pregnancy

Correction of Congenital Cardiovascular Lesions

As in cases of mitral stenosis pregnancy proceeds favorably in cases of congenital heart disease which are properly managed, and correction of the lesion should be deferred if possible until after pregnancy is completed Occasionally correction of a coarctation of the aorta has been performed during pregnancy for fear of a dangerous rise in arterial blood pressure during pregnancy or labor Section of a patent ductus arteriosus during pregnancy has been suggested for fear of a reversal of shunt after delivery But except in the presence of heart failure patients with a patent ductus do well during pregnancy A Blalock procedure may be performed in the pregnant patient with tetralogy of Fallot[70]

CONDUCT OF LABOR

Labor should be permitted to proceed normally in the cardiac patient During labor and delivery the patient should be propped up as high as is necessary and feasible Vaginal delivery is allowed even in patients with serious heart disease unless there are non cardiac indications for cesarean section Even in the presence of heart failure it is uncertain that a cesarean section with sterilization should be preferred to delivery from below with sterilization at a later date if desirable The present trend is definitely against interruption of pregnancy in the later months of pregnancy and against cesarean section during labor, for both the maternal and fetal mortality rates are significantly less when normal delivery by the vaginal route is permitted[64, 33] However it is desirable to avoid a prolonged second stage by the use of the low forceps procedure The pulse and respiratory rate and blood pressure should be followed continuously during labor According to Mendelson and Pardee,[48] the elevation of the pulse rate above 110 and of the respiratory rate above 24 during the first stage of labor provide usually reliable clues to impending heart failure and the need for appropriate therapeutic measures, such as digitalization and oxygen therapy Intravenous fluids should be given very cautiously and slowly, if at all during labor The fluid should contain no sodium The patient should be adequately sedated with barbiturates, morphine or Demerol

The competent administration of anesthesia by an experienced anesthetist is important in minimizing the strain of labor Ether is generally regarded as one of the safest anesthetics and is well tolerated by cardiac patients Maximal concentrations of oxygen should be given with it Ethylene and oxygen may be employed only for the preliminary induction of anesthesia but even then the most diligent care should be taken to avoid asphyxia Cyclopropane with oxygen and chloroform have been shunned by many Low spinal or continuous caudal anesthesia have come to be preferred by many especially in patients with actual or impending heart failure

Careful observation should not be relaxed immediately after delivery The rapid onset of acute pulmonary edema or more gradual congestive heart failure may occur during the third stage or at any time in the first 24 hours after delivery Some physicians apply tourniquets prophylactically during the third stage of labor on all patients who have shown previous evidence of heart failure Penicillin 600 000 units and streptomycin 2 gm daily, should be given prophylactically during the third stage and continued for three days postpartum to avoid bacterial endocarditis Ergotrate should not be given Pituitrin should be avoided, but, if essential, only the oxytocic

fraction (Pitocin) should be administered intramuscularly. After delivery an adequate period of bed rest should follow with care as to sodium intake and necessary medication.

Acute pulmonary edema is a sudden and sometimes startling incident which occurs sufficiently often during pregnancy or labor to require special mention. It is usually a complication of mitral stenosis and may occur in apparently well compensated patients and without apparent cause. But often it is induced by the intravenous administration of fluids.[74] Acute and terrifying dyspnea with or without cyanosis, cough, frothy sputum and hemoptysis are the outstanding manifestations. Recurrences during the course of pregnancy are not uncommon.

The prompt administration of morphine may in itself control the attack. The slow intravenous administration of 0.25 to 0.5 gm. (3¾ to 7½ grains) of aminophylline in 10 to 20 cc. of 5 per cent glucose in distilled water may also abort the attack. Digitalis or ouabain should be given intravenously (p. 262). Venous tourniquets should be applied to all four extremities and if this is ineffective a venesection should be performed. Oxygen should be administered by mask or tent under positive pressure if there is no evidence of shock. Antifoaming agents such as ethanol administered by oxygen aerosol may be beneficial.[88] Rarely a rapid venesection is necessary if other measures fail to control the pulmonary edema. If shock occurs, Wyamine (mephentermine) may be given at once intravenously and intramuscularly (p. 564) and a continuous infusion of Levophed set up (p. 563).

To prevent recurrences of pulmonary edema sodium intake should be curtailed drastically, digitalization should be maintained, aminophylline rectal suppositories (0.5 gm. aminophylline) should be inserted before retiring and mercurial diuretics administered at appropriate intervals. The prophylactic use of morphine in the twelve hours following labor may prevent the occurrence of post partum pulmonary edema.

INDICATIONS FOR DISCOURAGING PREGNANCY AND FOR PERFORMING THERAPEUTIC ABORTION

The physician is frequently confronted with the question of advising women with heart disease whether they may safely undertake pregnancy and childbearing or whether they may continue if already pregnant. Often there are associated religious, socioeconomic and personal factors which may be decisive regardless of medical considerations. The physician's advice should consist chiefly in providing his patient with the known data as to prognosis, especially as applied to her own cardiac status. Having been apprised of the facts, she herself must decide whether her desire for a child outweighs the probable risk.

In summary, pregnancy may be undertaken by the well compensated cardiac patient with only slightly more risk than by the normal woman. The mortality risk during the childbearing age is essentially identical for the compensated cardiac patient whether she becomes pregnant or not. In borderline cases she is more justified in undertaking pregnancy if it is the first or second than if there are already two or three children. Pregnancy should be undertaken and the family completed relatively early in life since the diseased heart becomes less capable of tolerating the load of pregnancy with advancing years. However, the woman with rheumatic heart disease who marries before she is 21 might advantageously delay pregnancy for two or three years since the risk of activation of a quiescent rheumatic infection diminishes progressively after the age of 21.

Patients whose outlook is relatively unfavorable (i.e., those in Classes III and IV of the New York Heart Association Classification, or those with signs or a history of heart failure, atrial fibrillation or a complicating serious disease) should be impressed with the considerable risk of pregnancy: maternal mortality of 15 to 18 per cent, fetal mortality of 30 per cent according to data which were accumulated prior to the more effective management of heart failure in recent years. If pregnancy is nevertheless undertaken, the importance of early and constant cardiac supervision and of rigid adherence to a prophylactic and therapeutic regimen must be stressed.

If the problem is one of terminating rather than of undertaking pregnancy, advice varies according to the duration of pregnancy and to religious and legal considerations, as well as the clinical status of the patient. The number of cardiac patients in whom the interruption of pregnancy is clearly indicated is growing progressively smaller. Although the risk to life among well compensated patients is

only slightly enhanced by pregnancy, under special circumstances abortion by cervical dilatation and curettage is permissible during the first two months if the patient desires to terminate the pregnancy This is particularly advisable if there are already three or more children or if the responsibilities involved in raising a family are likely to endanger the patient's health After the first two or three months of gestation the risk of artificial termination of the pregnancy is probably greater in the well compensated cardiac patient than is the completion of term and delivery

Among 'unfavorable' cases i e, with evidence of cardiac failure, termination of pregnancy should be encouraged if the patient is seen in the first three months of pregnancy and a satisfactory control of heart failure cannot be rapidly effected Interruption can be done from below in the first two months or by abdominal hysterotomy if absolutely necessary from the third to the fifth month Thereafter the risk is less if the patient is treated for her cardiac disability and allowed to go to term But even in this unfavorable group, the religious ethical or personal beliefs of the patient may be such that pregnancy is continued despite the risks entailed

Chapter 48

SURGICAL PROCEDURES IN THE CARDIAC PATIENT

FUNCTIONS OF THE CARDIOLOGIST

An evaluation of the cardiovascular status is a traditional prerequisite to a contemplated major surgical procedure involving a general anesthetic. Implicit in such precaution is the belief that a major surgical operation and general anesthesia impose an unusual strain on the circulation, and that the diseased heart is more vulnerable to this strain than the normal heart. The internist or cardiologist is therefore frequently called preoperatively, not only to determine the cardiac status and whether the patient actually has heart disease but also if a cardiac lesion is present, to advise whether this lesion alters the decision to operate. If an operation is undertaken, the cardiologist may participate in the management of the patient preoperatively, during the operation and postoperatively.

Primarily the surgeon and the patient are interested in the ability of the diseased heart to withstand the proposed operation. An estimate of this ability requires a knowledge of the risk added by the cardiac disease to the usual risk of the operation itself. The cardiologist must also estimate the general outlook and life expectancy of the patient in terms of his cardiac disease. For a substantial surgical risk cannot be justified if the cardiac condition precludes a sufficient survival period to enjoy the benefits of the surgical procedure.

The cardiologist must give consideration to the surgical condition as well as to the cardiac status, for occasionally he will discover that the so-called "surgical condition" is actually a "medical" manifestation of the diseased heart, e.g. abdominal manifestations of myocardial infarction, rheumatic fever or subacute bacterial endocarditis. The dangers of the disease for which operation is being proposed and the disability due to the disease must also be carefully assessed, for an evaluation of surgical risk to a cardiac patient assumes significance only by balancing this risk against the risk and disability if operation is withheld. Finally, aside from the surgical condition itself, the particular procedure which is contemplated, the available facilities and the skill of the surgeon and anesthetist are variable factors which must be estimated before the surgical risk to a cardiac patient can be properly evaluated. Small differences in morbidity and mortality rates with different surgeons or operative procedures on the noncardiac patient may become strikingly exaggerated in the patient with heart disease.

When the decision to operate on a cardiac patient has been made, the cardiologist may be helpful in reducing the surgical risk by the correction or alleviation of heart failure or by other preoperative measures. He may also be consulted on the choice of anesthetic agents and on circulatory problems which arise in the course of operation and postoperatively. In many operations, particularly those on the heart, his presence and cooperation during the surgical procedure and recovery are highly desirable or essential.

In general it may be stated that the cogency of the surgical indication is usually more important than the cardiac status in determining whether an operation should be performed. In the vast majority of cases the cardiac lesion is no contraindication to a necessary operation. For practical purposes the compensated heart which permits a reasonably normal if somewhat restricted way of life is virtually as capable of handling a major operation and a general anesthetic as a normal heart and the surgical mortality rate is *not* substantially higher.[66, 15] In the presence of heart failure or other serious manifestations of heart disease

however the evaluation of the surgical indication as against the surgical risk often presents a difficult problem

CIRCULATORY RISKS IMPOSED BY SURGICAL PROCEDURES

The commonest surgical risks which may adversely affect the diseased circulation are hemorrhage and shock infection and thromboembolism When these complications are severe and uncontrolled they are equally fatal in the cardiac and non cardiac patient In borderline cases however the presence of cardiac disease may turn the tide against recovery

Cardiac hypertrophy is the usual compensation for many forms of cardiac disease The effectiveness of this compensation depends on the maintenance of an increased supply of oxygen and nutriments to the enlarged heart by way of the coronary vessels Hemorrhage is a serious threat to this compensatory mechanism because it may adversely compromise cardiac nutrition and oxygenation Degrees of myocardial anemia which could be tolerated by the normal heart might result in irreversible and serious myocardial damage or in fatal cardiac disturbance when the heart is already enlarged or suffering from advanced coronary artery disease Furthermore hemorrhage is a common cause of surgical shock with its attendant hypotension The hypotension reduces the coronary blood flow an occurrence which is distinctly less well tolerated by the diseased and enlarged heart than by the normal heart Similarly shock due to other surgical causes besides hemorrhage (p 305) poses a greater hazard for the heart with valvular coronary or myocardial disease

Aseptic technique and the availability of modern chemotherapeutic and antibiotic measures have greatly reduced the incidence and dangers of postoperative infection but such infection has not been entirely eliminated, and the cardiac patient is more apt to suffer or succumb than the patient with a normal heart Infection is one of the common precipitating causes of heart failure in the cardiac patient

Thromboembolic disease following operations is a serious hazard to all patients but it occurs with much greater frequency among those with heart disease than among non cardiac patients (p 959) Furthermore theoretical considerations and clinical experience indicate that thromboembolic complications are more apt to cause serious circulatory disturbances or death in the cardiac patient

Despite the greater hazard of these surgical complications to the cardiac patient it must be emphasized that their incidence is relatively low and not much higher in the cardiac than in the non cardiac patient The severity of the complication itself rather than the presence or absence of heart disease usually determines its clinical outcome For these reasons when proper care and skill are employed the additional cardiac strain imposed by a surgical operation is only infrequently of decisive importance

CARDIAC RISKS IMPOSED BY ANESTHESIA

Only when chloroform was used was the danger of anesthesia dependent in part on the possibility of cardiac damage by direct action of the anesthetic on the heart muscle As a rule however the risk of anesthesia is related to the danger of hypoxemia cardiac (vagal) reflexes accumulation of carbon dioxide (hypercarbia) sharp changes in blood pressure and the induction of cardiac arrhythmias [43]

Hypoxemia may result from the low oxygen concentration in the anesthetic mixture or from chemical or mechanical causes interfering with respiration or the respiratory airway The damaged enlarged heart especially the heart with diminished coronary reserve is particularly susceptible to hypoxemia which may induce myocardial necrosis or predispose to ventricular fibrillation and cardiac arrest

Cardiac standstill or ventricular fibrillation may occur during the induction of anesthesia or during the operative procedure Tachycardia bradycardia extrasystoles and other arrhythmias may be associated with anesthesia (infra) These complications are more likely to occur in patients with certain types of cardiac disease especially those with severe coronary atherosclerosis calcific aortic stenosis or syphilitic coronary ostial stenosis

A sharp reduction in blood pressure such as often accompanies spinal anesthesia may seriously impair the coronary blood flow in susceptible cardiac or hypertensive patients Hypotension may result from large doses of barbiturates or from the inhalation of anesthetics if the anesthesia is deep since

these agents cause marked peripheral vasodilatation The excitement and struggling associated with the induction of anesthesia may increase the work of the heart not only by elevating the blood pressure but also by causing an increased outpouring of nor epinephrine The latter may be especially detrimental to patients with low coronary reserve Hypertension may be due to improper depth of anesthesia, to hypoxia or to abnormal accumulation of carbon dioxide, caused by airway obstruction, improper pulmonary ventilation or inadequate absorption by soda lime

THE TYPE OF OPERATION

There are insufficient data to permit statistically valid generalizations as to the added risk of associated heart disease in various individual operative procedures However the reported observations in relatively small series of cases as well as personal clinical experience are the bases for the following impressions and opinions

Minor Procedures

Such procedures as are usually performed with local procaine anesthesia on ambulant patients in the physician s office or in the outpatient department of a hospital can usually be performed on cardiac patients of all types without significantly greater risk than on noncardiac patients Most dental extractions are included under this heading provided that multiple extractions are not performed at one sitting Even multiple simultaneous extractions may be permissible under certain circumstances in well compensated cardiac patients But in the patient with valvular lesions multiple extractions at one time predispose to bacterial endocarditis

Operable Malignant Neoplasms

These almost always demand early surgical intervention if there is a chance of cure and the cardiac condition is not in a terminal stage

Emergency Operations

Operation is essential regardless of the presence of heart disease if the surgical condition is one which is otherwise rapidly fatal Such conditions include certain forms of acute and massive hemorrhage, perforation of a viscus cases of acute cardiac tamponade not relieved by medical means, strangulated hernia, acute phlegmonous appendicitis, ovarian cyst with torsion of the pedicle, and certain mechanical forms of acute intestinal obstruction

Acute suppurative or gangrenous cholecystitis may also be included in this category of emergency operations but conservative treatment is sometimes warranted if careful observation discloses regression of clinical features The use of antibiotics may eliminate some of these cases from the category of surgical emergencies, especially when there is associated cardiac disease

Peripheral embolism usually denotes underlying cardiac disease Despite the added risk due to the latter, a surgical attempt to remove the embolus is indicated if it involves a major artery and threatens gangrene or death

Elective Operations

It is not always certain whether a contemplated operative procedure is essential or elective When it is elective the ordinary risk of the operation plus the added risk due to associated cardiac disease must be weighed against the risks and discomforts of conservative treatment and the disability due to the unoperated surgical condition

Urinary obstruction due to prostatic hypertrophy and other urologic diseases are among the commonest conditions in cardiac patients for which operation is performed[81] The surgical and cardiac risks are further complicated by the relatively advanced age of these patients which averages between 65 and 70 years Coronary (atherosclerotic) heart disease is very frequent in these patients Postoperative coronary occlusion is relatively common In a series reported by Morrison[72] the mortality rate for various forms of prostatectomy or suprapubic cystotomy averaged 19 per cent in 125 operations on cardiac patients as against 7 5 per cent in 823 such operations on non cardiac patients

As a rule prostatectomy for prostatism is indicated in cardiac patients only if there are episodes of complete obstruction if there is severe retention with secondary infection or impairment of renal function or if frequency, nocturia or overflow incontinence is intolerable Transurethral resection appears to be the operation of choice when the surgeon is skilled in this procedure and the estimated weight of the prostate does not substantially exceed 50 gm In patients with advanced heart failure or minimal outlook for life repeated catheterization or an indwelling

catheter and the use of antibiotics may be preferable to operation But when the surgical indications are clear cut the surgical risk must be considered relatively moderate in most cardiac patients Among other urologic conditions occasionally demanding operative intervention despite coexisting cardiac disease special mention may be made of urinary calculus with obstruction

Operations on the Biliary Tract The urgent surgical indication in most cases of acute suppurative or gangrenous cholecystitis has been mentioned Obstructive jaundice due to a common duct stone almost always demands surgical intervention but delay is sometimes justified either to confirm the diagnosis or in patients with serious cardiac disease to await the possibility of spontaneous passage of the offending calculus or calculi

Cholelithiasis and chronic cholecystitis which are only discovered by roentgenologic examination and are virtually asymptomatic are probably best treated by moderate dietary restriction If there are severe persistent symptoms especially frequent attacks of biliary colic despite medical treatment cholecystectomy is usually clearly indicated even in the presence of cardiac disease If the patient is relatively young and the cardiac disease well compensated a cholecystectomy may be desirable even if the symptoms are fairly well controlled by onerous dietary restrictions Under such circumstances the risk of early cholecystectomy may be less than that of delaying the operation and being forced to do it when the patient is much older and the cardiac status much less favorable In a study of 100 patients with coronary heart disease subjected to cholecystectomy the surgical procedure was well tolerated and there were no deaths or other serious complications on the operating table There were 3 postoperative deaths 2 of which were due to pancreatitis or pancreatic necrosis

Other common elective operations in cardiac patients include hernioplasty and hemorrhoidectomy These operations are usually well tolerated by cardiac patients unless there are serious cardiac complications Therefore if the disability of the hernia hemorrhoids or other elective surgical condition is great the operation should be performed before advancing age and the progress of the cardiac disease greatly enhance the risk If the cardiac status is poor and the operative indication is not compelling conservative therapeutic measures should be employed

Thyroidectomy for hyperthyroidism has hitherto been essential in cardiac patients even in the presence of heart failure Although the results were usually brilliant the operative mortality was substantially greater than in non cardiac patients with hyperthyroidism (p 1012) Therefore at the present time treatment should be carried out with radioactive iodine followed by a brief period of lugolization until the radioactive iodine becomes effective Similarly in cases of fibroid uterus with excessive bleeding radiotherapy should be employed instead of hysterectomy if there is serious heart disease

Cardiac operations have been discussed in connection with the individual lesions The safe conduct of the patient through cardiac surgery has been discussed by Black and Harken[51] Poor cardiac function or congestive heart failure is no contraindication if the operative procedure is designed to diminish cardiac strain or promote aeration of the blood This applies to release of the heart in constrictive pericarditis to correction of a patent ductus arteriosus or arteriovenous aneurysm or to the amelioration of tetralogy of Fallot or advanced mitral stenosis or other such conditions Correction of such lesions as coarctation of the aorta patent ductus or arteriovenous aneurysm is justified by the unfavorable natural course of these conditions

THE TYPE OF CARDIAC DISEASE AND FUNCTIONAL CARDIAC STATUS

The surgical indication is usually a more important factor than the presence or absence of heart disease in deciding upon an operative procedure But insofar as cardiac disease adds to the surgical risk both the status of cardiac function and the etiologic type of heart disease are determining factors In general there is statistical evidence to indicate that rheumatic heart disease is associated with a lower mortality than coronary heart disease or syphilitic cardiovascular disease[13, 71]

Rheumatic Heart Disease

The risk of surgical procedures in rheumatic patients resembles that of pregnancy in such patients in that there is a close correlation to the functional state of the heart (p 1092) The well compensated rheumatic cardiac patient tolerates surgical operations virtually as well as the normal individual[64] The risk

rises substantially in those who have experienced an attack of heart failure or those who are suffering from heart failure at the time of operation [72] A careful clinical history with special reference to dyspnea, cardiac asthma and orthopnea, exercise tolerance and previous episodes of heart failure is essential for a satisfactory evaluation of cardiac function Cardiac operations are being performed regularly and successfully in patients with heart failure, e g, in patients with mitral stenosis Nevertheless although the indication justifies the risk, the mortality does increase in cases of moderately severe or advanced heart failure

Patients with calcific aortic stenosis are susceptible to sudden death a danger which may be increased by a general anesthetic or surgical procedure The risk is greatest in those patients who have experienced dizziness, syncope or angina pectoris The surgical mortality rate also rises in cases of rheumatic heart disease when the patient passes the age of 35 for developing coronary atherosclerosis often impairs the blood supply required to maintain compensation by the enlarged heart Rheumatic cardiac patients are susceptible not only to the more general risks of surgical operations but also to a complicating bacterial endocarditis The latter is most likely to follow dental operations and operations on the genitourinary tract

Hypertension

Operative procedures are tolerated virtually as well by patients with uncomplicated hypertension as those with normal blood pressure Among other evidence to support this opinion is the minimal operative mortality associated with extensive sympathectomies even in cases of malignant hypertension However, the surgical risk in most major operative procedures on hypertensive patients increases when there is evidence of cardiac insufficiency, severe coronary disease, renal impairment or a previous cerebral accident In the presence of these complications operation is permissible only when the surgical indication is absolute

Coronary Heart Disease

The surgical risk is somewhat higher with coronary artery disease than with other cardiac diseases Therefore it is especially important that the surgical indication be unequivocal However, it is important to emphasize that major surgical operations are well tolerated by the great majority of patients with clinical coronary disease provided adequate measures are taken to prevent myocardial ischemia [■] Preoperative emotional anxiety and excitement, hypoxia shock and deep anesthesia must be avoided Brumm and Willius[14] reported only 11 cardiac deaths (4 3 per cent) among 257 patients with severe coronary artery disease undergoing major operations The mean age of these patients was 60 years There was a history of previous myocardial infarction in 32 and a history of angina pectoris in the remainder In another series of 517 patients with coronary heart disease subjected to major and minor operative procedures, there was a mortality of 2 9 per cent in comparison with a mortality of 2 0 per cent among a control group of non cardiac patients who underwent similar procedures [■] Cardiac disease was responsible for a mortality of 1 2 per cent among the coronary patients and only 0 1 per cent among the non cardiac patients However patients with previous myocardial infarction may experience a relatively high incidence of cardiorespiratory complications, such as fresh myocardial infarction, bronchopneumonia, pulmonary embolism or congestive heart failure Such complications are most likely to occur in patients with prolonged operations marked cardiac enlargement or previous or present heart failure [41]

Frank heart failure increases the surgical risk in patients with coronary disease as it does in rheumatic patients but the close correlation with degree of functional impairment is absent The risk of myocardial ischemia and the danger of postoperative myocardial infarction or of sudden death due to ventricular fibrillation or other cause are complicating factors

Surgical risk is greatly enhanced if operation is performed in the course of a recent myocardial infarction Therefore an electrocardiogram should always be taken preoperatively to exclude recent myocardial infarction On occasion, I have observed such routine electrocardiograms to reveal that myocardial infarction was responsible for the acute abdominal symptoms which were interpreted as due to an acute abdominal surgical complication Unless there is an acute emergency demanding immediate operation, surgical procedures should be delayed at least three months following the acute myocardial in

farction. If there is a history of increasing frequency of angina pectoris or of its occurrence with less and less provocation, an impending coronary occlusion is probable and operation should be avoided or delayed if possible.

Bundle Branch Block and Heart Block

These conditions in themselves are not contraindications to a surgical operation, but the underlying cardiac disease and associated manifestations must be evaluated.[73] *In 51 major and 107 minor operations on 56* patients with an average age of 67 years whose electrocardiograms showed bundle branch block, there were no fatalities, but postoperative shock occurred in 16.[86] The association of *Adams-Stokes syndrome* with heart block adds greatly to the risk of operation and the latter should be performed only for emergencies. Patients with asymptomatic fixed heart block usually tolerate surgical *procedures. But patients with first degree* heart block may be more susceptible than normal subjects to the hazard of complete atrioventricular dissociation and ventricular standstill during anesthesia or surgical stress.[84]

Chronic Atrial Fibrillation

Surgical procedures do not significantly increase the morbidity and mortality in patients with chronic atrial fibrillation if the underlying cardiac disease is adequately compensated. Finkbeiner and associates[35] reported an operative mortality of 5 per cent in 60 patients with cardiovascular disease associated with chronic atrial fibrillation who underwent 76 major operative procedures. But there were cardiovascular complications during operation in 71 per cent of the 76 procedures and cardiopulmonary complications in *22 per cent. Only 23 per cent* were uncomplicated. A high incidence of complications was related to inadequate digitalization, recent congestive heart failure, angina pectoris, poor cardiac function, pulmonary *emphysema, azotemia and obesity.*

Syphilitic Cardiovascular Disease

In asymptomatic cases operation is usually well tolerated. In the presence of angina pectoris or heart failure the surgical risk increases considerably.

THE CHOICE OF ANESTHESIA

The anesthetic agent administered by a skillful anesthetist is rarely a significant factor in surgical risk, either in the cardiac or non-cardiac patient.[8] However, the diseased heart is usually more sensitive to myocardial anoxia and therefore to deficient oxygen in the anesthetic mixture. This applies particularly in cases of advanced coronary atherosclerosis, aortic steno[illegible] *syphilitic coronary ostial stenosis* and those with Adams-Stokes syndrome. Sudden and severe reductions in arterial pressure are also particularly dangerous to these patient[illegible] diminished coronary reserve. In the above-*mentioned groups of cases* there is a tendency to sudden death and factors [illegible] coronary blood flow or myocardial oxygen[illegible]tion increase that tendency. The p[illegible]logic effects of anesthesia on the hea[illegible] been *reviewed* by Meek.[87]

The oft-stated rule that the ch[illegible] skilled anesthetist is more importa[illegible] type of anesthetic agent bears rep[illegible] corollary it may be said that in [illegible] *cardiac patients the anesthet*[illegible] the anesthetic with which he [illegible] familiarity and skill rather tha[illegible] preferable one with which h[illegible] experience.

During induction and the [illegible] thesia, emotional exciteme[illegible] ertion by the patient, hypo[illegible] significant changes in blood [illegible] ished coronary flow or incre[illegible] of the cardiac muscle *should* [illegible] liberal supply of oxygen is [illegible] less of the anesthetic. The [illegible] thetic must be made with re[illegible] problems of the surg[illegible] operation.

Local anesthesia or reg[illegible] caine or similar prepara[illegible] when possible for minor [illegible] rine is best avoided in all [illegible] is contraindicated in pa[illegible] artery disease. Barbitura[illegible] istered before the us[illegible] anesthesia appears inad[illegible] Pentothal sodium in 2 [illegible] may be given intrave[illegible] tions or for extraperi[illegible] are not very long and [illegible] great abdominal relax[illegible] per cent oxygen and [illegible] are important adj[illegible] thesia. Intravenou[illegible] combined with a [illegible] nitrous oxide and [illegible] tube to maintain [illegible]

both in children and adults for all transpleural operations and should be inserted when the patient is well anesthetized

The most reliable inhalation anesthetic for major operations in cardiac patients is *ether* because of maximal experience with this agent and because of the absence of serious disadvantages Ether is administered by means of the carbon dioxide absorption technique Nitrous oxide with at least 50 per cent oxygen may be used for induction A combination of cyclopropane with ether and oxygen may give a smoother induction with pleasanter awakening and less nausea or vomiting [6]

Cyclopropane without ether, is undesirable because of the risk of inducing serious cardiac arrhythmias especially in patients with coronary artery insufficiency [30] It is therefore permissible only for induction of anesthesia and then in combination with high concentrations of oxygen Induction of anesthesia with cyclopropane has been recommended for cardiac patients because of the smoothness and rapidity of induction and its prompt controllability [30] Nitrous oxide and ethylene have been regarded by some as undesirable in cardiac patients because they are not combined with sufficient oxygen when the concentration of these agents is high enough to produce adequate anesthesia But adequate oxygenation can be provided, and under such circumstances ethylene reinforced with small amounts of ether has been used successfully in rheumatic cardiac patients undergoing mitral commissurotomy Chloroform should not be used in cardiac patients because of direct toxic effect on the heart Epinephrine should not be administered during general anesthesia and especially with cyclopropane because of the danger of causing ventricular fibrillation and cardiac arrest

Spinal anesthesia is usually avoided in cardiac patients (except low spinal or caudal anesthesia in vaginal or rectal operations) because of the danger of a sharp reduction in diastolic pressure The contraindication applies particularly to patients with a high diastolic blood pressure However this objection may be overcome by the proper use of vasopressor drugs such as Neosynephrine and the concomitant administration of 100 per cent oxygen Pituitrin should not be used for its vasopressor effect because of its pronounced coronary constrictor action In some patients with congestive heart failure inhalation anesthesia may be entirely undesirable and the most satisfactory anesthesia may be obtained with low spinal or caudal anesthesia in combination with 100 per cent oxygen and a continuous intravenous drip of Pentothal sodium Low spinal anesthesia may be particularly satisfactory in heart failure, since it causes pooling of blood in the lower extremities and viscera and prevents further pulmonary congestion and edema Hypotension is avoided by a preceding injection of 1 per cent Neosynephrine, 5 to 15 mg (0 5 to 1 5 cc) intramuscularly or 2 mg (0 2 cc) in an intravenous drip

MANAGEMENT OF THE SURGICAL CARDIAC PATIENT

In general the same rules of good surgical practice apply to cardiac as to non cardiac patients Only special points referable to the cardiac patient are briefly considered in the following discussion

PREOPERATIVE MANAGEMENT

See also sections on the individual cardiac lesions which are treated surgically, especially pp 671, 672

Preoperative sedation is effected in infants by morphine in doses of 1 to 2 mg and in older children either by morphine or seconal combined with scopolamine In adults morphine and scopolamine (0 3 to 0 4 mg) or atropine are usually administered Every effort is made to avoid apprehension or excitement and to allay anxiety

The intravenous administration of sodium containing fluids including blood, plasma or amino acid infusions *should be avoided*, or if essential, must be conducted with special caution as to quantity and rate of infusion The advisability of giving packed red blood cells instead of whole blood should be considered when transfusion is indicated because of preoperative anemia or because of blood loss during the operation The patient's head and shoulders should be elevated during the infusion Frequent examinations of the chest determinations of vital capacity, circulation time and venous pressure, and questioning as to dyspnea and orthopnea may help to avoid pulmonary edema and right sided heart failure by early discontinuation of the infusion

If heart failure is present preoperatively it should be controlled by reasonable bed rest by

digitalization of the patient by restriction of sodium intake and if necessary by the administration of mercurial diuretics The method and speed of digitalization (Chapter 11) depend on the urgency of the operative procedure If the patient has been previously digitalized maintenance doses of digitalis should be continued preoperatively and thereafter Patients with atrial fibrillation and rapid ventricular rate should be given adequate amounts of digitalis to slow the ventricular rate to normal When heart failure is due in part to loss of blood or to anemia of other origin it may be most readily controlled by correction of the anemia Similarly the parenteral administration of thiamine chloride and the correction of a protein deficiency are sometimes essential measures in the preoperative control of heart failure

If possible therapy of heart failure including intelligent bed rest (with the patient s head elevated) should be maintained for at least two or three weeks after the heart failure is controlled before the operation is performed But an operation should not be deferred until heart failure is controlled if the heart failure is due chiefly to a condition which the operation is designed to correct e g a constrictive pericarditis or arteriovenous aneurysm If an operation is performed for a surgical emergency despite the presence of heart failure 0 25 mg of ouabain may be administered intravenously and repeated in a half hour and again in two to four hours if necessary provided that the patient has not received digitalis in the preceding two weeks The effectiveness of preoperative control of heart failure is indicated by the experience of Hamilton[49] who *reported 144 cases of overt* heart failure on admission in which a major surgical operation performed after satisfactory preoperative treatment was associated with a mortality of only 5 5 per cent

In patients with angina pectoris the frequent sublingual administration of nitroglycerin preoperatively may be beneficial

In patients who are to have an operation on the genitourinary tract as in patients having dental extraction 0 5 gm tetracycline (Achromycin) 500 000 units of aqueous penicillin 600 000 units of penicillin procaine and 1 gm of streptomycin should be given intramuscularly one half hour before the procedure because of the risk of bacterial endocarditis This should be repeated every 12 hours for two or three days postoperatively If there has been any history of bronchopulmonary disease bronchodilators should be given in addition to the antibiotics

Insulin must be given with extreme caution preoperatively to diabetic patients with coronary artery disease lest a resulting hypoglycemia induce a myocardial infarction Epinephrine pituitrin and ergot are drugs to be avoided preoperatively during or after the operative procedure

MANAGEMENT DURING OPERATION

The normal body temperature should be maintained Prolonged narcosis should be avoided and to this end the operation should be limited to the essential minimal procedures The special vulnerability of the cardiac patient enhances the importance of minimal handling of tissues skillful technique proper hemostasis and adherence to all other good surgical principles Loss of blood due to avoidable surgical trauma or improper hemostasis because of its deleterious anoxic effect on the diseased heart is especially inexcusable Such blood loss should be corrected promptly by the cautious transfusion of blood or of packed red blood cells If there is a history of or danger of left heart failure the operation should be conducted whenever possible with the patient s head and shoulders elevated

The occurrence of heart failure during operation may be indicated by acute pulmonary edema The patient should be placed in Fowler s position the anesthetic discontinued and oxygen administered in high concentration by mask under positive pressure of 5 to 10 mm Hg *Rotating tourniquets should* be applied to the extremities If these measures are ineffective morphine sulfate aminophylline intravenously and Cedilanid intravenously may be administered in succession at appropriate intervals (p 263) If the heart failure is due to an arrhythmia appropriate corrective measures should be instituted (infra)

Shock during operation (p 309) is treated according to the cause Blood replacement adequate oxygen supply and ventilation and the use of vasopressor drugs (p 502) may be indicated

Cardiac Arrhythmias During Operation

The relative frequency of cardiac arrhythmias during operation especially during

cardiac surgery,[14, illegible] and the importance of prompt diagnosis and treatment indicate the need for constant monitoring of the cardiac rate, rhythm and conduction by means of the oscilloscope and the use of a direct writing electrocardiogram for a permanent record. Electrocardiographic abnormalities were described in about 80 per cent of a series of 109 patients under anesthesia with a variety of anesthetic.[illegible] Eisaman et al.[illegible] observed arrhythmias in 62 per cent of 113 patients who received cyclopropane, chiefly multiple and multifocal ventricular premature beats. The intravenous administration of 1 per cent procaine was beneficial in 93 per cent of the cases, but this drug was avoided in cardiac arrest. On the other hand, arrhythmias, most commonly of atrial origin, were observed in only 9 per cent of 221 patients who had received Pentothal for induction and nitrous oxide and ether anesthesia. The arrhythmias during operation have been attributed to direct manipulation of the heart or adjacent structures, to reflex effects of the surgical procedure on the heart, to the induction or the depth of anesthesia, to hypoxia, hypercapnia, metabolic changes or hemorrhage.

In general, proper management of the arrhythmias should stress prevention and elimination of the cause. Whenever feasible, correction of all possible contributing causes of the arrhythmia should be carried out before the addition of cardiac drugs is undertaken. Cardiac arrest is discussed separately (infra).

Sinus tachycardia usually requires no treatment except to check that there is an optimal supply of oxygen and efficient ventilation. During ether anesthesia it may be an indication to diminish the depth of anesthesia or as some have recommended, to administer small amounts of cyclopropane. For severe tachycardia, occasionally neostigmine (1 mg intramuscularly) or Tensilon (edrophonium) (10 to 20 mg intravenously) may be given.

Sinus bradycardia may be due to vagal reflexes initiated by the anesthetic or the surgical procedure. If severe, it may be treated by the intravenous administration of atropine (0.4 to 1.0 mg). The patient should be well oxygenated and hyperventilated first and atropine injected only if severe bradycardia persists.

Supraventricular tachycardias which persist may be treated by the intravenous administration of neostigmine methylsulfate (0.5 to 1.0 mg). Procaine 1 per cent (100 mg) and procaine amide 10 per cent solution (100 to 500 mg) have also been used successfully.

Paroxysmal atrial flutter and fibrillation may be treated by Cedilanid, 4 cc (0.8 mg) intravenously, and this is repeated if necessary provided the patient has had no digitalis. Otherwise, procaine amide 100 to 500 mg may be given intravenously.

Ventricular premature beats, when very frequent, and *ventricular tachycardia* may be controlled by 100 to 500 mg of procaine amide administered intravenously. This should be given cautiously with electrocardiographic control, and vigilance for the possible development of hypotension or convulsions.

The appearance of severe *conduction disturbances* is an indication to withdraw the anesthetic and administer oxygen. Atropine may be administered.

Cardiac Arrest in Surgery

Incidence. Cardiac arrest denotes the sudden stoppage of the heart and circulation. It may be due to cardiac (ventricular) standstill or ventricular fibrillation. Its frequency in the course of surgery has been variously reported as 1 in 3673,[39] 1 in 2382[82] and 1 in 1200 cases.[89] But in cardiac surgery it was observed as often as once per 41 cases in one series.[39] It may occur during induction of anesthesia, during endotracheal intubation, during the course of an operation and in 14 per cent of 1200 cases of cardiac arrest reported in various countries it occurred after the patient had left the operating room.[89]

Etiology of Cardiac Arrest. *Myocardial anoxia or hypoxia* is the major and commonest cause of cardiac arrest.[81, 83, illegible, 179] This results usually from impairment of the airway or of the ventilatory exchange or from insufficient administration of oxygen. Other causative mechanisms include vagal reflexes,[81, 74] hypercapnia[89, illegible] and hyperkalemia,[79] excessive anesthesia or sensitivity to the anesthetic and direct manipulation of the heart and great vessels.[89] Pentothal sodium is especially suspect. Often multiple factors appear to be involved, but hypoxia and vagal reflexes are the ones which are almost always directly or indirectly concerned. In cardiac operations direct manipulation of the heart or torsion of contiguous structures may be contributory to

if not entirely responsible for cardiac arrest, but this is most likely to occur in the presence of myocardial hypoxia.

Prevention of Cardiac Arrest. The prevention of cardiac arrest is stressed.[49] Avoidance of anoxia is the primary means of preventing cardiac arrest and this depends chiefly on the anesthetist with due cooperation of the surgeon. Maintenance of an airway at all times, adequate oxygen concentration in the anesthetic mixture and avoidance of excessive depth of anesthesia are essential. The surgeon can minimize anoxia by careful hemostasis, prompt blood replacement if necessary, minimal traction on abdominal or thoracic viscera to prevent vagal reflexes and minimal manipulation and distortion of the heart and great vessels in cardiac surgery. The use of atropine or scopolamine in children and adults has been recommended to minimize vagal reflexes.[4, 41] Procaine and procaine amide have been administered intravenously by some surgeons to prevent ventricular fibrillation and procaine has been instilled into the pericardium or cardiac cavity before actual cardiac surgery. The prophylactic value of drugs is unproven.

Prompt Diagnosis of Cardiac Arrest. Early diagnosis of cardiac arrest is essential for successful treatment. Restoration of an effective heart beat must be accomplished within a maximum of three to five minutes because this is the usual maximum period of anoxia which the brain will tolerate before death or serious irreversible damage occurs. The early diagnosis of cardiac arrest depends primarily on the anesthetist who is making continuous observation of the patient's vital signs. Sudden absence of the pulse and blood pressure denotes cardiac arrest. This should be promptly announced and action taken without confirmation by prolonged auscultation, electrocardiography, etc. In thoracic and especially in cardiac operations, the diagnosis of cardiac arrest may be made by the surgeon or by the physician who is monitoring the cardiac action by an oscilloscope. The anesthetist, physician or nurse in attendance should continue to watch for the possibility of cardiac arrest even after the patient leaves the operating room until he reacts from the anesthetic.

Treatment of Cardiac Arrest. Successful treatment of cardiac arrest requires prompt recognition and previously organized preparation with a set plan of action and readily available equipment.[53, 55] The heart beat must be restored and respiration maintained, preferably with the aid of administered oxygen. A cardiac resuscitation kit should be available at critical locations. This should contain a scalpel and a few other dissecting instruments, a costotome, endotracheal tube, syringes and 4 inch long 22 gauge needles and solutions of 10 per cent calcium chloride, epinephrine 1:1000, 2 per cent procaine, procaine amide and sterile saline.[43, 53] A defibrillation apparatus should also be readily available.[35, 9, 46, 65, 77]

One may begin attempted resuscitation by striking a sharp blow over the precordium which is occasionally effective.[74] If cardiac arrest occurs in the course of an abdominal operation, a few seconds only may be used in an attempt to restore the heart beat by cardiac massage by way of the diaphragm. If the patient is out of the operating room and there is any delay in procuring a knife, a long needle introduced through the fourth left intercostal space may be used to prick the heart once.[22] If a knife is still unavailable, 0.5 mg. atropine sulfate, 2 to 4 cc. of 10 per cent calcium chloride[5] and 0.3 cc. of 1:1000 epinephrine may be injected intracardially. Three patients who suffered cardiac arrest during surgical procedures were resuscitated by the intravenous infusion of molar lactate solution.[7] But these drugs should not be employed if a thoracotomy and direct cardiac massage can be instituted within a few minutes.

An external electrical stimulator[17, 82, 83] (p. 394) has served successfully as a cardiac pacemaker in certain cases of cardiac standstill. Zoll and associates[84] reported 8 successful cases of cardiac resuscitation from unexpected arrest during surgery in 7 and pericardiocentesis in 1. Cardiac arrest was terminated in each case by means of the electric pacemaker without resorting to thoracotomy or cardiac massage. This apparatus is ineffective when cardiac arrest is due to ventricular fibrillation or when treatment is delayed. If the cardiac arrest is due to ventricular fibrillation, it may be terminated by externally applied electric countershock.[85] The 120-volt line current must be converted to a range of 0 to 720 volts by a special 6:1 isolation step-up transformer and a variable autotransformer. Usually 240 to 720 volts were required. The current was

applied for a fixed period of 0 15 second at the second intervals When ventricular standstill follows defibrillation, an external cardiac pacemaker is employed to stimulate the heart If the external pacemaker and the apparatus for application of external countershock are not immediately available or effective, a thoracotomy should be performed promptly

As soon as a knife is available an incision is made in the fourth or fifth intercostal space from the left border of the sternum to the axilla Sterile facilities should be used only if immediately available The costal cartilages above and below may be cut to improve exposure The pericardium is incised, the ribs spread and both hands introduced to compress the heart between them Cardiac compression should be continued at the rate of at least 60 to 80 per minute, although experiments suggest that rates up to 120 per minute are even more effective[11, 10] Cardiac massage should be continued for at least an hour since resuscitation has followed even after periods up to approximately two hours Sometimes cardiac massage is supplemented by placing the patient in the Trendelenburg position and blood is infused rapidly intravenously or intraarterially If cardiac massage is ineffective after a few minutes atropine, calcium chloride and epinephrine may be injected intracardially as indicated above but massage should then be continued To obtain more uniform cardiac compression and avoid the fatigue of prolonged manual massage, a set-up has been devised to obtain regular cardiac compression by rhythmic insufflation of oxygen into the pericardial cavity ("pneumo massage" of the heart)[7b]

While efforts are undertaken to restore the heart beat artificial respiration must be maintained The tongue should be pulled forward and a pharyngeal airway inserted Artificial respiration may be accomplished by mouth to mouth or mouth to-mask[33] breathing initially but the use of an anesthesia machine and face mask to deliver 100 per cent oxygen under pressure should be instituted as soon as possible As soon as an endotracheal tube is available this should be inserted and oxygen administered intratracheally

Treatment of Ventricular Fibrillation When thoracotomy is first performed, an effort should be made to distinguish ventricular fibrillation from standstill and the diagnosis should be confirmed by oscilloscopic or electrocardiographic examination In the presence of ventricular fibrillation, cardiac massage is undertaken as above until the defibrillator is available[55, 5, 9, 46, 65, 77]

Defibrillation is designed to restore the normal cardiac rhythm, after producing momentary standstill, by passage of an electric current through the heart[90, 4] A single shock, lasting 0 1 second may be effective If not, several shocks are repeated at intervals of 0 5 to 1 0 second Usually 110 to 130 volts at 1 5 to 2 5 amperes are administered, but recently voltages of 220 to 250 have been employed for large hearts For children, a variable resistance is inserted into the circuit For protection from electric shock, the surgeon should wear two pairs of gloves, manage the electrodes with the aid of wooden handles, stand on a wooden stool or similar non conductive platform and avoid contact with the operating table when the shock is applied Risk is diminished also by an isolation transformer in the circuit Successful defibrillation should be controlled by observing the cardiac rhythm with an oscilloscope or direct-writing electrocardiogram Resuscitation has been accomplished as long as 1 hour and 50 minutes after the onset of ventricular fibrillation[1] The physician undertaking cardiac resuscitation should be aware that serious myocardial tears[47] have been caused by rough massage and myocardial burns by excessive voltage of the defibrillating current

If no defibrillation is promptly available or if defibrillation appears unsuccessful, 5 cc of 2 per cent procaine or 1 to 3 cc (100 to 300 mg) of a 10 per cent solution of procaine amide may be introduced directly into the right atrium or ventricle The intravenous administration of molar sodium lactate may also be tried[7] (p 393)

Various educational programs have led to an increase in early diagnosis of cardiac arrest and probable improvement in the incidence of successful resuscitation Nevertheless, the mortality has been approximately 70 per cent[25] in large series of collected cases and 25 to 30 per cent in recent small series[65, 14]

POSTOPERATIVE CARE

Attention is directed again to the need for caution in the intravenous administration of blood plasma or sodium-containing fluid as discussed above (p *1106*) If fluids must be

given parenterally because of postoperative nausea 5 per cent glucose in distilled water should be administered instead of saline Postoperative distention may be controlled by the inhalation of 100 per cent oxygen by gastric aspiration with a Levin tube and by control of any postoperative infection but pituitrin should not be given

If heart failure develops the appropriate measures mentioned under preoperative care should be instituted The excessive parenteral administration of fluids excessive blood loss during operation and infection are among the common causes of postoperative heart failure in cardiac patients The particular danger of infection for cardiac patients demands prompt and adequate administration of antibiotics if there is any doubt as to its presence

The special frequency of phlebothrombosis and pulmonary embolism among patients with heart disease suggests the importance of using anticoagulants postoperatively as well as other prophylactic measures These have been discussed in detail (p 576)

Cardiac arrhythmias following operation usually subside spontaneously in a few hours or days They may be controlled if necessary by the administration of appropriate drugs usually digitalis quinidine or both

DIRECT VISION CARDIAC SURGERY

Cardiac surgery by direct vision has been accomplished by the aid of (1) cross-circulation techniques (2) hypothermia and (3) mechanical techniques for by passing the heart Lillehei[62] reported successful curative open cardiotomies performed under direct vision on 101 of 138 patients Of these 49 patients with atrial septal defects were operated on under hypothermia The others with atrioventricular defects ventricular septal defects pulmonary stenosis and tetralogy of Fallot were operated on with the aid of cross circulation in 45 instances a reservoir in 5 a biologic oxygenator in 12 and an artificial mechanical oxygenator in 27

CROSS CIRCULATION TECHNIQUES

Direct vision surgery has been made possible by means of controlled cross circulation using a living human donor or by means of continuous perfusion from an arterial reservoir[63 64] These techniques involving venous inflow occlusion (of the venae cavae) for 5 to 40 minutes have been made possible by the use of the azygos vein or low flow concept[3] It was noted that dogs survived long periods of vena caval occlusion without sequelae if only the blood flow from their azygos veins amounting to less than 10 per cent of the cardiac output was permitted to enter the heart Accordingly during the period of cardiac and pulmonary by pass perfusion of the patient can be accomplished at rates of flow which are only one eighth to one fourth of the resting cardiac output without cerebral renal hepatic or other serious organ disturbance With these low rates of flow there has been a relatively low coronary sinus blood loss and great improvement in cardiac visibility in contrast with the conditions associated with large perfusion flows

A suitable donor is carefully chosen with respect to previous health and compatibility of blood with that of the patient Donor and patient are given a single intravenous dose of heparin (0 75 mg per pound of body weight) and a similar amount of protamine may be given to the patient at the conclusion of the intracardiac operation Both donor and patient are anesthetized the former with Pentothal curare the patient with combinations of nitrous oxide or cyclopropane for induction and Pentothal-curare for maintenance The patient s body temperature is carefully maintained at normal levels

Arterial blood from the donor is supplied to the patient by way of a cannula inserted through the superficial femoral artery with its tip lying in the abdominal aorta Venous blood returns from the patient to the donor by way of a cannula threaded into the saphenous vein with its tip lying in the iliac vein or inferior vena cava Tapes are placed about the venae cavae to obtain inflow stasis during the actual intracardiac procedure A tape with Rumel tourniquet attached is placed around the ascending aorta Thereby the root of the aorta is occluded briefly when necessary to obtain a bloodless field and then released momentarily to restore the coronary flow thus alternating until the procedure is completed A pump assembly controls the reciprocal exchange of blood between patient and donor A venous reservoir serves to maintain a free flow of blood and as an effective air bubble trap The donor does not lose blood during the procedure but the patient s blood loss

from the operative wound and from the interior of the heart are replaced during the procedure by equal volumes of citrated bank blood introduced through a cannula in the patient's saphenous vein

A related technique of cross circulation involves a similar perfusion set-up, but instead of the human donor, a reservoir of arterial blood collected from donors and a reservoir to collect the venous blood returning from the patient are used These reservoirs are standard siliconized blood collection bottles from which the air has been exhausted Arterialized blood is obtained by applying heat to the arms of the donors before performing phlebotomy Warden et al [58a] reported the successful repair of a high interventricular septal defect in an infant by means of this method

Results

Lillehei and associates[61] reported the use of cross circulation in intracardiac operations, by direct vision in 30 patients with a variety of congenital lesions including interventricular septal defects tetralogy of Fallot, atrioventricularis communis and isolated infundibular stenosis Suture closure of the ventricular defect with resection of the infundibular stenosis was performed in the tetralogy of Fallot with survival of 6 of 10 patients In one case of isolated infundibular stenosis the infundibular pulmonic muscle was resected and the preoperative right ventricular pressure of 136 mm Hg was reduced four months postoperatively to normal (25/0 mm Hg)

No donor mortality resulted in 39 operations and only one serious but temporary complication, before the technique was improved Ventricular fibrillation and conduction defects have not been a problem in the operated patients, presumably because of maintenance of normal body temperature and adequate myocardial oxygenation during inflow stasis During the latter the myocardium is relieved of its pumping action and requires only a fraction of the normal coronary flow No air embolism, hemolysis or postoperative hemorrhage has been reported

This technique is one of the most dramatic recent advances in cardiac surgery Nevertheless, possible risk to the healthy donor represents a theoretical hazard which will lead to hesitancy in adopting the procedure The amount of blood needed for young children is sufficiently small to permit the substitution of a reservoir of arterialized blood and a collection reservoir for venous blood, to replace the living donor *It is probable that* a mechanical heart lung by pass will ultimately serve in place of the human donor cross circulation technique (infra)

HYPOTHERMIA

The induction of hypothermia has also been used to permit cardiac surgery under direct visual control with a relatively bloodless field [80, 85, 31, 8, 3, 11, 29, 75] The oxygen requirement of the body is substantially reduced by general body hypothermia, permitting the surgeon to interrupt the circulation for a longer period of time than at normal body temperature The circulation through the heart is interrupted by clamping the superior and inferior venae cavae and azygos veins Such interruption may be safely maintained at normal body temperature for 2 to 3 minutes or slightly longer But at 28° C (83° F) the circulation may be thus interrupted safely for 15 to 20 minutes, which is adequate for the correction of certain cardiac lesions under direct vision with a relatively dry field Operations under hypothermia are usually conducted at a body temperature of 30 to 31° C (86° to 88° F) or slightly higher or lower On the other hand hypothermia is associated with the risk of inducing ventricular fibrillation, cardiac arrest and cardiac failure Ventricular fibrillation is particularly likely to occur when the body temperature is reduced below 26° Hyperthermia is better tolerated by infants and very young children than by older children and adults There is experimental evidence that ventricular fibrillation may be prevented by procaine infiltration of the sinoatrial node,[30] by coronary artery perfusion with neostigmine solution,[71] and by the use of a mixture of 5 per cent carbon dioxide and 95 per cent oxygen in artificial respiration The cardiac rhythm should be controlled throughout hypothermia by electrocardiography, and a defibrillator should be available

Various techniques have been employed to induce hypothermia Preanesthetic medication is first administered, e g Demerol and scopolamine and succinyl choline or d tubocurarine to prevent shivering The combination of phenergan Thorazine and Demerol has also been used [57] Anesthesia is induced by cyclopropane or small doses of Pentothal and maintained by ether and oxygen until

hypothermia is effected Positive pressure respiration is administered with sufficient hyperventilation to induce mild respiratory alkalosis

Infants and children have been cooled by placing them in a cold water bath cooled by ice cubes to a temperature of 6° C Adults have been cooled by wrapping them in refrigerated blankets through which a pump circulates refrigerant fluids while a rectal thermocouple records the rectal temperature Some surgeons have preferred to induce hypothermia by cooling the blood itself[73, 13] Venous blood drawn out through a catheter inserted in the superior vena cava by way of the external jugular vein is conducted through a cooling coil—a plastic tubing immersed in a refrigerant—and returned to the body by way of the femoral vein Or the blood can be cooled after opening the chest and withdrawing blood through a cannula inserted into the superior vena cava through the right atrial appendage and returning it to the inferior vena cava through another catheter through the right atrial appendage Hypothermia has also been induced with the aid of brain cooling by irrigation of the carotid blood[42]

Cooling to 30 C usually requires 20 to 30 minutes in children But the time may vary from 10 minutes for an 8 lb baby to one or two hours for an adult The patient is rewarmed to normal body temperature at the conclusion of the operation by placing him in a bed with warm water bottles or in a warm water bath or by means of a diathermy device Whatever method is employed final warming is completed by placing the patient in a bed with warm blankets

Hypothermia combined with inflow circulatory occlusion has been successfully employed in cardiac surgery for interatrial septal defects of the secundum type for total anomalous venous occlusion transarterial correction of pulmonary stenosis and in the resection and homologous graft replacement of the thoracic aorta[4] It has also been used in closed heart surgery in which circulatory occlusion is unnecessary but in which the lower metabolic needs associated with hypothermia permit better tissue oxygenation especially in poor risk cases or when cyanosis is present e g tetralogy of Fallot tricuspid atresia

PUMP-OXYGENATORS (ARTIFICIAL HEART MECHANICAL HEART)

Ultimately the performance of cardiac surgery under direct vision without haste will be performed with the aid of some form of mechanical pump or pump-oxygenator which diverts the circulation from the heart[■, 34, ■, 38, 44, 37, 41] Many such devices are now available Some pumps have served to bypass only the right side of the heart or only the left side but a complete cardiac bypass necessitates also a mechanical oxygenator to perform the function of the lungs The patient s lungs may be cannulated and employed as the oxygenator in combination with mechanical pumps Biologic oxygenators such as an autologous or homologous pulmonary lobe have also been employed together with a mechanical pump[13a]

The problems involved in the use of a mechanical pump oxygenator include not only the construction of a suitable type of pump which can be cleaned and autoclaved and an efficient oxygenator but also the avoidance of clotting hemolysis of erythrocytes and infection[31] In addition all open cardiac operations are beset with the danger of air embolism Clotting has been controlled by coating the apparatus with silicone and by the use of intravenous heparin but the latter has been responsible for annoying oozing of blood during the operative procedure Hemolysis has been minimized by improved pumps designed to reduce damage to erythrocytes

Mechanical oxygenators have been constructed to expose successive thin films of blood to an atmosphere of oxygen[42] The spinning disk oxygenator of Bjork[10] consisted of a series of disks which were mounted on and rotated about a common horizontal shaft dipping into a pool of blood and forming a changing film of blood at the periphery of the disk The spinning screen oxygenator of Dennis[5] consisted of a series of rotating wire mesh disks near the centers of which blood was distributed, it was then spread into thin films over the entire disk by gravity and centrifugation These oxygenated blood by dispersing it in oxygen Other oxygenators such as the small bubble gas dispersion oxygenators of Clark et al[■, 44] and the large bubble oxygenator of Thomas and Beaudoin[47] disperse bubbles of oxygen into blood The

residual gas was then separated by defoaming facilities or by buoyancy In the foam oxygenator of Gimbel and Engelberg[38] the blood was oxygenated as it cascaded down a densely packed column of foam Two valve less rotary pumps were used, a venous pump to supply the oxygenator with blood and an arterial pump to deliver oxygenated blood to the patient The speed of the pumps was controlled electrically by signals from manometers which measure the volume of blood in the oxygenator and the pressure in the arterial and venous parts of the circuit

An apparatus to by pass the right side of the heart, and its use in animals, has been described by various investigators Dodrill[27] reported its successful use to perform a pulmonary valvuloplasty in a 16 year old boy with isolated pulmonic stenosis and intact septa A by pass of the left side of the heart especially useful for the surgical treatment of mitral and aortic valvular lesions has been utilized experimentally and in humans by Dodrill et al[28, 7] Blood was withdrawn from the pulmonary veins or left atrium passed through the mechanical pump and returned to the aorta by retrograde passage through the left subclavian artery Thus the left atrium, mitral valve area and left ventricle are full of blood and may be operated under direct vision provided there is no aortic regurgitation Dodrill[27] has reported the use of a mechanical by pass of both sides of the heart while the patient's lungs continued to function in an 18 year old girl operated on for pulmonic stenosis with possible ventricular septal defect

Kirklin et al[84] reported the performance of precise unhurried intracardiac surgery with a mechanical pump oxygenator system of the Gibbon type[51] in 8 patients with very severe congenital heart disease The period of cardiotomy varied from 20 to 73 minutes In 4 of the patients there was a ventricular septal defect, in 2 a persistent common atrioventricular canal and in one each an atrial septal defect and the tetralogy of Fallot Increased pulmonary vascularity, severe pulmonary hypertension and right ventricular hypertrophy were present in 7 of the patients Four of the 8 survived and are well In a subsequent publication DuShane et al[30a] reported the repair of ventricular septal defects in 20 children, under direct vision with the aid of this mechanical pump oxygenator (see p 1113)

Cannulae within the superior and inferior venae cavae diverted the patient s venous blood to the apparatus The output of venous blood from patient to machine was kept constant by gentle controlled suction Arterialized blood from the apparatus was returned to the patient through a filter to a cannula in the left subclavian or innominate artery The oxygenator consisted of 14 wire mesh screens, 12 by 18 inches each enclosed in a Lucite case Flows of 100 to 200 cc per kilogram per minute were obtained The oxygen saturation was 100 per cent in the blood returning to the patient 60 to 85 per cent in the venous blood Hemolysis was minimal Heparin was administered pre operatively to diminish the coagulability of the blood and protamine was administered after the operation to restore normal coagulability

Lillehei et al[6] have reported the performance of intracardiac surgery under direct vision in 36 patients whose hearts and lungs were totally by passed for periods of up to 50 minutes, by using a simple pump-oxygenator system The pumps employed were those used in their cross circulation technique The oxygenator, of the large bubble dispersion type, represents an effective ingenious improvement over previous devices It is simple in construction, without moving parts, and is assembled from commercially available plastic (pure polyvinyl) tubing and can be sterilized by autoclaving Since the cost of the oxygenator is only a few dollars Lillehei et al[6] have preferred to dispose of it after each clinical use rather than to clean and use it again

Oxygenation was accomplished by direct introduction of humidified, 100 per cent oxygen in the form of large bubbles which enter near the base of a vertical plastic mixing tube through multiple circumferential No 2? intravenous needles with their hubs cut off The needles are inserted circumferentially through an ordinary laboratory rubber stopper As the bubbles rise in the column of venous blood which also enters and circulates in the vertical mixing tube the blood-oxygen contact at the surface offers the large surface area necessary for efficient oxygen uptake and elimination of carbon dioxide, without need

of a foreign substance (such as disks or meshes) to produce blood films Momentary contact with a potent non toxic silicone anti foam substance sprayed or painted on the distal (U shaped) portion of the walls of the mixing tube and a smaller connecting tube dissipates the bubbles Because of their large size any remaining bubbles rapidly rise to the surface and are eliminated carrying off the carbon dioxide The oxygenated blood de scends by gravity in a spiral plastic settling tube and enters the central collecting reser voir an ordinary Kelly flask lined with a polyethylene bag from which it is perfused through the patient after passing through standard blood filters The flow of oxygenated blood from the pump-oxygenator system dur ing the interval of total heart lung by pass varied from 172 cc per minute to 600 per minute The patient s plasma hemoglobin in blood drawn immediately after perfu sion was not excessive varying between 17 and 45 mg per cent

Twenty five of the 36 patients had curative surgery for ventricular septal defects as sociated with pulmonary hypertension with 7 deaths Of 6 patients with the tetralogy of Fallot who underwent corrective surgery 2 died The other 5 survived intracardiac opera tions for atrial septal defect atrioventricularis communis or complete transposition of the great vessels In the last 10 operations all performed on seriously ill patients with ven tricular septal defects or tetralogy of Fallot there were 2 deaths

EXTERNAL SHUNTS

External plastic shunts have been used to by pass the circulation around the aortic and pulmonic valves and the proximal great vessels[16 24] Cross et al[24] showed that such shunts could carry the entire cardiac output for periods of 30 to 80 minutes in 26 dogs thus obviating the need for hypothermia or mechanical pump oxygenators

Chapter 49

INSURANCE AND MEDICOLEGAL PROBLEMS IN CARDIAC DISEASE

The facts of cardiology are no different when applied to insurance and medicolegal problems from those of ordinary clinical practice as described in previous chapters of this book. Unfortunately this is not always apparent in the statements of physicians engaged in forensic medicine or in the decisions of judicial referees or courts. There is great need for reorientation of physicians, lawyers, judges and legislators with respect to the medicolegal aspects of cardiology in order to direct their opinions and judgments into greater harmony with the available body of scientific fact. This applies with particular emphasis to the physician who should not compromise with or distort established facts in order to abet legal interpretations based on erroneous interpretations of medical concepts. Neither should his scientific opinions be prejudiced by economic, emotional, sociologic or political bias.

The following pages include brief mention or discussion of some of the more frequent cardiac problems encountered in insurance and forensic medicine. The cardiac facts which should enable the physician to cope with these problems have already been presented in previous chapters.

CARDIOVASCULAR EXAMINATION AND ACCEPTANCE FOR INSURANCE

The medical examiner for an insurance company or for an industrial plant is often handicapped in making an evaluation of the cardiac status of an insurance applicant. An accurate or complete history is often unobtainable and facilities for roentgen ray and electrocardiographic examination and sometimes even for complete physical examination are often unavailable, especially when the applicant is examined at his place of employment. Thus moderate grades of cardiac enlargement are undiscovered. In the absence of electrocardiograms severe coronary disease may be overlooked, for the physical examination may be negative and a history of clinical symptoms may be concealed by the applicant. If there are no facilities for examining the subject in the left lateral recumbent position, an apical presystolic murmur of mitral stenosis may not be discovered.

On the other hand, a private physician may tell his patient after careful examination, that he is entirely normal only to have his application for life insurance rejected because of a cardiovascular abnormality. Or else the applicant is first rejected because of cardiovascular disease but subsequent examination by his private physician fails to disclose a significant abnormality. In such instances the discrepancy between private and insurance examinations is due to the wide range of normal values and differences in interpretation of borderline findings.

Among the commoner borderline findings responsible for insurance rejection are a systolic murmur, a slightly elevated blood pressure and a rapid pulse rate. The problem of differentiating the insignificant functional from the organic systolic murmur has been discussed (p. 617). The applicant's personal physician, with a complete and reliable history and every needed diagnostic aid, may reasonably conclude that a given systolic murmur is functional and not due to cardiac disease. Without these advantages of accurate history and complete diagnostic facilities the insurance examiner may be inclined to interpret the murmur as being more significant. Not infrequently individuals with an inconsequential systolic murmur are rejected for life insurance because of the greater than standard risk associated with any large *group*

Chapter 49

INSURANCE AND MEDICOLEGAL PROBLEMS IN CARDIAC DISEASE

The facts of cardiology are no different when applied to insurance and medicolegal problems from those of ordinary clinical practice as described in previous chapters of this book. Unfortunately this is not always apparent in the statements of physicians engaged in forensic medicine or in the decisions of judicial referees or courts. There is great need for reorientation of physicians, lawyers, judges and legislators with respect to the medicolegal aspects of cardiology in order to direct their opinions and judgments into greater harmony with the available body of scientific fact. This applies with particular emphasis to the physician who should not compromise with or distort established facts in order to abet legal interpretations based on erroneous interpretations of medical concepts. Neither should his scientific opinions be prejudiced by economic, emotional, sociologic or political bias.

The following pages include brief mention or discussion of some of the more frequent cardiac problems encountered in insurance and forensic medicine. The cardiac facts which should enable the physician to cope with these problems have already been presented in previous chapters.

CARDIOVASCULAR EXAMINATION AND ACCEPTANCE FOR INSURANCE

The medical examiner for an insurance company or for an industrial plant is often handicapped in making an evaluation of the cardiac status of an insurance applicant. An accurate or complete history is often unobtainable, and facilities for roentgen ray and electrocardiographic examination and sometimes even for complete physical examination are often unavailable, especially when the applicant is examined at his place of employment. Thus moderate grades of cardiac enlargement are undiscovered. In the absence of electrocardiograms severe coronary disease may be overlooked, for the physical examination may be negative and a history of clinical symptoms may be concealed by the applicant. If there are no facilities for examining the subject in the left lateral recumbent position, an apical presystolic murmur of mitral stenosis may not be discovered.

On the other hand, a private physician may tell his patient after careful examination, that he is entirely normal only to have his application for life insurance rejected because of a cardiovascular abnormality. Or else the applicant is first rejected because of cardiovascular disease but subsequent examination by his private physician fails to disclose a significant abnormality. In such instances the discrepancy between private and insurance examinations is due to the wide range of normal values and differences in interpretation of borderline findings.

Among the commoner borderline findings responsible for insurance rejection are a systolic murmur, a slightly elevated blood pressure and a rapid pulse rate. The problem of differentiating the insignificant functional from the organic systolic murmur has been discussed (p. 647). The applicant's personal physician, with a complete and reliable history and every needed diagnostic aid, may reasonably conclude that a given systolic murmur is functional and not due to cardiac disease. Without these advantages of accurate history and complete diagnostic facilities the insurance examiner may be inclined to interpret the murmur as being more significant. Not infrequently individuals with an inconsequential systolic murmur are rejected for life insurance because of the greater than standard risk associated with any large group

of persons with a systolic murmur Reversal of this judgment may follow appeal to and more detailed reexamination by physicians at the home office of the company

The range of normal blood pressure is not sharply defined If 140 and 90 mm Hg are chosen as the upper limits of normal systolic and diastolic pressures respectively, many normal individuals may be refused insurance or compelled to pay increased rates On the other hand more liberal interpretations of normal would result in the insurance of many individuals with a higher average death rate than that of more rigidly normal controls Even when a definite elevation of blood pressure is found to be transient, the applicant may be considered less than a standard risk from the actuarial viewpoint For there is evidence that persons with transient hypertension are much more prone to the later occurrence of sustained hypertension and cardiorenal disease than normal controls A tachycardia, even if transient, may likewise be associated with increased life insurance risk, since individuals with transient tachycardia are also found to develop sustained hypertension and cardiorenal disease more often than normal controls

Other borderline cardiac findings sometimes responsible for increased insurance rates or rejection of individuals whose hearts are probably normal include premature beats, pronounced bradycardia, and T wave abnormalities in the electrocardiogram due to rotation or other positional changes of the heart It is, therefore, often helpful and desirable for the applicant's physician and the insurance medical examiner to cooperate in determining as accurately as possible the significance of these minor deviations in the particular individual in question It is unfair to apply the less favorable prognosis of a heterogeneous group with a given cardiac finding to every individual with that finding when it may be possible to demonstrate its insignificance in a given instance

WORKMEN S COMPENSATION AND HEART DISEASE

Most of the medicolegal problems involving cardiac disease arise in connection with claims for workmen's compensation based on cardiac disability or death attributed to an unusual strain or injury suffered unexpectedly in the course of the claimant's employment

Preexisting Heart Disease

When direct penetrating or non penetrating injuries affect the precordial region, cardiac disability may occur whether the heart was previously well or diseased On the other hand, there is virtually no substantial evidence that strenuous exertion can damage the normal heart Yet most of the claims for compensation are based on cardiac disability attributed not to direct trauma but to unusual exertion, lifting or other physical strain In such cases it follows from the above that a causal relation between the strain and the cardiac disability appears more probable in the presence of preexisting cardiac disease than in its absence

Since cardiac disability is the usual natural consequence of organic cardiac disease, it would appear illogical, in the presence of preexisting disease, to attribute such disability to some extraneous exertion with any high degree of probability But according to most compensation laws preexisting cardiac disease is no bar to compensation if the actual disability or death is deemed to arise from some unusual and extraordinary exertion connected with an individual s employment This exertion or strain is interpreted as the determining cause of disability if it aggravates or accelerates the course of the underlying disease and thereby leads to cardiac disability or a fatal end sooner than would otherwise have occurred Furthermore most workmen's compensation decisions have failed to apportion responsibility between the underlying cardiac disease and the strain When cardiac disability was held to result from such strain, the latter was deemed totally responsible

From the medical, as contrasted with the legal, viewpoint the physician must attempt to assess the probable natural course of the underlying cardiac disease on the basis both of known data concerning the disease and of its history in the individual in question Then he must estimate whether the underlying disease was unusually and unexpectedly aggravated or accelerated, and if so, whether the alleged strain was the probable cause of this unfavorable acceleration This decision is particularly difficult because coronary thrombosis, serious arrhythmia and heart failure often appear suddenly and unexpectedly in the natural course of the preexisting disease without unusual exertion or other apparent cause Furthermore medical

testimony in workmen's compensation cases is often not supported by any strong significant evidence relating the onset of symptoms to some particular incident during employment. Certain diseases such as coronary atherosclerosis with angina pectoris, coronary occlusion, calcific aortic stenosis and syphilitic aortitis with coronary ostial stenosis are likely to terminate in sudden unexpected death independently of any physical strain. There is rarely a scientific medical basis for deciding whether sudden death in the presence of these diseases was precipitated by physical strain arising in the course of employment or was a natural phenomenon of the disease. When an individual suffers from preexistent calcific aortic stenosis or heart block he may experience attacks of dizziness or syncope which may be fatal. In the course of such an attack he may suffer an injury which is the result of the fatal cardiac episode rather than the cause.

The Relation of Strain to Cardiac Disability

In actual medicolegal practice the physician is queried much less about the pathology, symptomatology or natural course of the preexisting disease than about the role of some physical strain or "accident" in producing angina pectoris, coronary occlusion, myocardial infarction, a disabling arrhythmia, heart failure or unexpected death. Unfortunately the answers to this latter question are rarely strongly buttressed by scientific factual data. They are often determined by personal estimates of probability and reasonableness with emphasis on a post hoc propter hoc type of logic. Frequently the physician is called upon to give his answer in a "yes" or "no" form to an hypothetical question when neither the question nor the answer fully encompasses a just consideration of all the facts and all the gaps in our medical knowledge.

The physician must first determine the presence and degree of cardiac disability following the alleged injury and whether this differs from any disability present prior to the injury. The most frequent manifestations attributed to cardiac strain include more or less immediate cardiac pain, acute dyspnea, faintness, dizziness, syncope or collapse, cold sweat, palpitation and cardiac irregularity followed by subsequent recurrent angina pectoris or evidence of myocardial infarction or congestive heart failure. Confirmation of a change in the cardiac status may be supplied by serial electrocardiograms following the injury, especially if they can be compared with electrocardiograms taken previous to it.

The physician must then determine whether the given strain was adequate to produce the cardiac disturbance and whether, considering the complete history and findings, the strain in all probability did cause the disability. Various criteria have been proposed as a basis for relating cardiac disability to a physical strain, among which the following may be mentioned: (1) the physical exertion is of unusual severity and more intense or involving greater strain than that previously regularly performed by the affected person; (2) the onset of symptoms of cardiac strain is relatively sudden and follows immediately or very soon after the alleged causative exertion; (3) physical exertions perviously executed without difficulty cannot be undertaken or endured. It must be apparent that since preexistent heart disease is usually present, satisfaction of these criteria does not exclude the possibility of coincidence rather than causal relationship.

According to most workmen's compensation decisions involving the heart, compensation is awarded for an "accidental injury" sustained in the course of and arising out of an individual's employment which causes disability of the heart, aggravates or accelerates preexisting disease or causes sudden death. An accident is interpreted as an unforeseen and unexpected occurrence and includes extraordinary physical strain which is not usual to the employment. In addition to lifting, straining and other physical exertions, accidental injuries causing coronary insufficiency or heart failure have been ascribed to "nervous shock," exposure to toxic gases including carbon monoxide and sulfur dioxide, infections sustained in the course of employment, electric shock and even to an injection of tetanus for a wound received in the course of work. The development of heart failure in association with lower nephron nephrosis due to carbon tetrachloride exposure may be an additional basis for workmen's compensation claims.

Degree of Disability: Total and Permanent Disability

Having stated that in his opinion there is cardiac disability due to some accidental extraordinary exertion, the physician may be

asked to assess the degree of disability sustained and to state whether this disability is temporary or permanent From the medical viewpoint it should be emphasized that neither the existence of clinical manifestations of coronary sclerosis including those of myocardial infarction, nor the presence of electrocardiographic abnormalities nor even the mild grades of cardiac failure denotes total and permanent disability A substantial percentage of individuals return to gainful employment following recovery from an acute myocardial infarction Because of differences in individual response to disease the evaluation of partial or total disability should be made individually in each case and not on the basis of the general etiologic or pathologic diagnosis Evaluation of "permanent" disability is often equally difficult because of the well known hazard of prognostication The word 'permanent" must be used with the reservation that it may be subject to revision after continued observation

Workmen s compensation decisions interpret 'permanent and "total disability" very liberally It is unnecessary for the claimant to be entirely incapacitated or inert It suffices to prove that his disability prevents him from performing in his usual manner all the essential duties of his occupation which his age, training, experience and physical condition would permit if not for the accidentally induced cardiac infirmity Thus disability is interpreted in terms of the employe s particular occupation, business or profession and not in terms of other forms of employment or of general physical capacity

Coronary Heart Disease

Most claims of compensation for cardiac disability allege the production of angina pectoris coronary thrombosis or myocardial infarction by unusual physical strain or less often by toxic agents infections or emotional shock A causal relationship between penetrating or non penetrating chest trauma and coronary and myocardial injury is well established by scientific medical evidence (Chapter 44) But the evidence linking physical strain to coronary thrombosis is tenuous

Our present medical knowledge indicates clearly that coronary thrombosis and myocardial infarction almost always occur on the basis of preexisting severe coronary atherosclerosis, whether or not there was manifest clinical evidence The thrombosis or occlusion is a common inherent incident in the natural life history of the progressive coronary atherosclerotic process, and in 95 per cent or more of cases it appears without causal relation to any unusual physical strain It occurs at least as often among sedentary as among manual workers and at rest or sleep as often as during activity

In occasional instances coronary occlusion is preceded by such an intense and extraordinary physical strain the previous history is so apparently free from cardiac abnormality, and the onset of cardiac manifestations occurs so promptly after the strain that it is difficult to avoid the conclusion that the strain actually produced or precipitated the coronary occlusion or myocardial infarction Since intimal hemorrhage in an atherosclerotic plaque may lead to occlusion (p 500), it has been hypothesized that an unusual physical strain may raise the blood pressure and cause an intimal hemorrhage It has also been suggested that a severe physical strain, by increasing the work of the heart and its need for blood, intensifies a preexisting relative myocardial ischemia to the point of necrosis (infarction)

The difficulty of relating a coronary occlusion and myocardial infarction to a physical strain increases when distinctive clinical manifestations appear only after an interval of many hours, days or weeks Yet there is evidence that such an interval may actually elapse between the onset and the full development of coronary occlusion and cardiac infarction Occasionally a transient minor or severe clinical symptom occurring immediately after an unusual exertion appears to be followed by complete recovery Only days or weeks later is the evidence of recent myocardial infarction discovered and the claim is made that the initial immediate symptom represented the onset of a coronary occlusion due to physical strain This type of case stresses the value of routine and repeated electrocardiograms promptly after any unusual effort which is suspected of having caused cardiac injury

Sometimes a traumatic injury is followed by infection and prolonged invalidism and culminated by a disabling or fatal coronary occlusion Even in such cases courts or

referees have affirmed a causal relation between the infection and physical and mental suffering and the coronary occlusion even though much more hypothesis than medical fact is adduced to support such an interpretation Rarely a myocardial infarct has been attributed to a coronary embolism arising in a venous thrombus at the site of injury of an extremity In the absence of cardiac septal defects this could not occur and even in their presence there is no evidence that coronary embolism and cardiac infarction do occur In this connection the section on fat embolism should also be reviewed (p 966)

Valvular Disease, Arrhythmias and Heart Failure

Penetrating and non penetrating injuries of the chest may cause myocardial contusion pericarditis or hemopericardium arrhythmias rupture of valves or heart wall and heart failure or rapid death In some instances of non penetrating chest trauma it is difficult to prove the actual occurrence of cardiac injury, but this difficulty can usually be avoided if careful physical roentgenologic and electrocardiographic examinations are made promptly and repeatedly after the trauma

An unusual physical strain may rarely rupture the chordae tendineae or cusps of a diseased valve, but extremely rarely if ever is a normal cusp so ruptured Since rupture of the chordae may occur spontaneously the extraordinary nature of the alleged strain must be carefully evaluated before it is credited as the causative factor

Bacterial Endocarditis

This has been attributed to trauma and infection occurring in the course of employment A decision as to causal relationship may be aided by bacteriologic study of the blood and if possible, by comparison of the organism obtained on blood culture with that of the organism responsible for the infection in the traumatized area

Cardiac Neurosis

Not infrequently the persistence of symptoms such as precordial pain dyspnea and fatigability following a chest trauma or an unusual physical strain are due to a cardiac neurosis and not to organic damage to the heart In this as in other forms of traumatic neurosis early settlement of litigation is often an effective prophylactic against prolonged invalidism

LIFE HEALTH AND ACCIDENT INSURANCE

Total and Permanent Disability

The difficulties of evaluating the presence of total and permanent disability in connection with benefits provided under life health or accident insurance policies are similar to those connected with workmen s compensation claims and have already been discussed In recent years life insurance claims of total and permanent disability were particularly frequent when an individual suffered from angina pectoris or coronary thrombosis The economic depression and unemployment undoubtedly increased the pressure to make such claims In some instances fraudulent claims were supported by electrocardiographic abnormalities secretly induced by digitalis Fortunately this problem is becoming outdated as life insurance policies with benefit provisions for total and permanent disability have been granted rarely in recent years

Accidental Death and Double Indemnity

One of the problems arising in association with life insurance policies is the provision for double indemnity or payment of twice the face value of the policy if the insured dies of an accident A similar problem occurs in connection with accident policies which provide the payment of a lump sum in instance[illegible] accidental death We are particularly c[illegible]cerned with those instances in which [illegible] accident is claimed to have caused a card[illegible] death But in contrast with claims of wo[illegible]men s compensation it is necessary to pr[illegible] that death occurred exclusively as a result [illegible] an accident independent of any preexist[illegible] disease Under such circumstances it may [illegible] relatively easy to demonstrate a cau[illegible] relationship between death and penetrat[illegible] chest wounds severe non penetrating ches[illegible] trauma and occasional toxic agents if the onset of symptoms is immediate and death occurs promptly or as an end result of an uninterrupted progression of the immediate symptoms On the other hand it seems impossible to justify a cardiac fatality, on the basis of an extraordinary physical strain, if the heart and coronary arteries are presumed to have been previously free from disease In practice however the problem is made difficult by the claim that any preexisting disease was inactive or arrested and that the fatal cardiac disturbance must [illegible] ed en

tirely to the accidental strain which activated the "arrested" disease The physician who is required to give an opinion should adhere as far as possible to a presentation of what is known medically without becoming involved in inconsistent legalistic definitions or interpretations From the medical viewpoint, any opinion as to possible relationship between a given stimulus and a cardiac fatality should be the same whether given before a workmen s compensation referee or in a court trying an insurance claim for accidental death

PERSONAL LITIGATION

The medical problem in personal litigation (tort law) arising out of cardiac injuries is identical with that described under the above headings The physician may be askec opinion as to the presence of cardiac the degree and duration of disabili whether a given alleged injury in al ability was responsible for the disturbance In practice the prob personal litigation differs from that o men's compensation in that liability defendant must be demonstrated basis of intentional or negligent expo the claimant to the injury Furthermoi compensation as the claimant may be a for medical, hospital and nursing ex pain and suffering loss of earnings an items may depend on what percentage disability is due to the accident and preexisting disease The physician ma be confronted with the difficult task timating this percentage
